Tenth International Technical Conference on Experimental Safety Vehicles

U.S. Department of Transportation

National Highway Traffic Safety Administration

England

Tenth International Technical Conference on Experimental Safety Vehicles

Sponsored by:

U.S. Department of Transportation
National Highway Traffic Safety Administration

Hosted by:

The Department of Transportation of Her Majesty's Government

Held at:

Oxford, England, July 1-4, 1985

U.S. Department of Transportation

National Highway Traffic Safety Administration

Foreword

This report of the proceedings of the Tenth International Technical Conference on Experimental Safety Vehicles was prepared by the National Highway Traffic Safety Administration, U.S. Department of Transportation.

We wish to thank the authors and all those responsible for the excellence of the material submitted, which aided materially in the preparation of this report.

For clarity and because of some translation difficulties, a certain amount of editing was necessary. Apologies are, therefore, offered where the transcription is not exact.

Participants List

AUSTRALIA

McCaul, K.A.
NH & MRC Road Accident Research

Pound, F.R.
General Motors Holdens Ltd.

BELGIUM

Akiba, T.
JSAE Brussels

Foggini, B.F.
CCHC

Gerryn, C.
Ford of Europe Inc.

Hachiya, M.
Nissan Motor Co. Ltd.

Henssler, H.
Commission of the European Communities

Masani, M.
Toyota Motor Corporation

Meganck, A.M.
Honda Motor Co. Ltd.

Mizuno, Y.
Nissan Motor Co. Ltd.

Moritake, T.
Toyota Motor Corporation

Murao, Y.
Daihatsu Motor Co. Ltd.

Nishikawa, T.
Nissan Motor Co. Ltd.

Ono, K.
Mazda Motor Corporation

Shibagaki, Mr.
Mazda Motor Corporation

Silvestri, G.
Commission of the European Communities

Van Driessche, H.
Honda Motor Co. Ltd.

CANADA

FOREWORD iii
PARTICIPANTS v

SECTION 1: OPENING CEREMONIES
Welcoming Address
Sir Peter Lazarus
Permanent Secretary
U.K. Department of Transport 1

Keynote Address:
Diane K. Steed
Administrator
National Highway Traffic Safety Administration
U.S. Department of Transportation 2

SPECIAL SESSION: AWARDS PRESENTATIONS
Diane K. Steed, Chairman, United States 5

SECTION 2: GOVERNMENT STATUS REPORTS
John W. Furness, Chairman, United Kingdom

United States:
Michael M. Finkelstein
Associate Administrator for Research and Development
National Highway Traffic Safety Administration
U.S. Department of Transportion 11

Canada:
E. R. Welbourne
Chief, Vehicle Systems
Road Safety Directorate
Transport Canada 15

European Experimental Vehicle Committee:
Prof. Dr. Bernd Friedel
Chairman of EEVC 17

Federal Republic of Germany:
Prof. Dr. Heinrich Praxenthaler
President
Federal Highway Research Institute 19

Italy:
Dr. Franco Rossi
Direttore Centrale Motorizzazione
Direzione Generale M.C.T.C.
Ministero Dei Trasporti 22

France:
Jean Moreau de Saint-Martin
Director
Organisme National de Sécurite Routiére 23

The Netherlands:
Pieter W. Hoekstra
Deputy Head
Staff Division for Technical Affairs
Department of Road Transport 25

Sweden:
Prof. Dr. Bertil Aldman
Swedish Transport Research Delegation
Chalmers University of Technology 26

Japan:
Takashi Shimodaira
Deputy Director of the Engineering and Planning Division, Regional Transport Bureau
Ministry of Transport 27

United Kingdom:
David Lyness
Head of Vehicle Standards and Engineering Division
Department of Transport 29

SECTION 3: PROGRESS WITH AND DISCUSSION ON SAFETY DEVELOPMENTS FOR ROAD VEHICLES
Michael M. Finkelstein, Chairman, United States

A Demonstration Car with Improvements for Pedestrian Protection
C.A. Hobbs, G.J.L. Lawrence, and C.S. Clarke 31

A Motorcycle Demonstrating Improved Safety Features
P.M. Watson 39

Driver Airbag Police Fleet Demonstration Program—A 24-Month Progress Report
D. Romeo and J. Morris 45

Panel Discussion on Airbag Technology
"Optimizing Airbag Performance, Tuning to the Characteristics of Specific Vehicles, Application in Small Cars at Driver and Passenger Positions, Prospects in Vehicles with Two Seating Positions and Bench Seats, Reducing System Costs and FMVSS 208 Injury Criteria"
A.K. Breed
President, Breed Corporation, United States
(Statement) 55

Roger Maugh, Director Automotive Safety, Ford Motor Company, United States
(Statement) 59

Prof. W. Reidelbach, Director, Daimler-Benz Passenger Car Body Basic Research, Federal Republic of Germany
(Statement) 64

David Romeo, President, Romeo-Kojyo Company, United States
(Statement) 65

Panel Discussion on Safety Belt Developments
"Issues that Manufacturers Will Be Facing as They Comply with the Requirements of FMVSS 208"

C. Detloff, Engineer in Charge, General Motors Safety Belt Design Program, United States
(Statement) 66

H.G. Johannessen, Consultant, Omni Safe, Inc., United Sates
(Statement) 68

S. Sano, Research Engineer, Honda R&D, Japan

SECTION 4: TECHNICAL SESSIONS

SESSION ONE: BIOMECHANICS AND DUMMY DEVELOPMENT
Chairman: Jean Leroy, France

Biomechanics:
Biomechanics of Diffuse Brain Injuries
L.E. Thibault and
T.A. Gennarelli
University of Michigan, United States 79

Effects of Different Types of Headrests in Rear-End Collisions
A. Nygren,
H. Gustafson, and
C. Tingvall
Folksam R&D Division
Karolinska Hospital, Dept. of ENT
Stockholm, Sweden 85

Production of Injury in Blunt Frontal Impact
R. Eppinger and
J. Marcus
National Highway Traffic Safety Administration, United States 90

Thoracic Impact: A Viscous Tolerance Criterion
D. Viano and
I. Lau
Biomedical Science Department
General Motors Research Laboratories 104

Modelling the Lateral Impact of the Thorax in Car Side Impact Accidents
M. Langdon
Transport and Road Research Laboratory, United Kingdom 114

Validity of Thoracic Injury Criteria
Based on the Number of Rib Fractures
J.P. Verriest and
A. Chapon
O.N.S.E.R., France 124

Synthesis of Pelvic Fracture Criteria
for Lateral Impact Loading
M. Haffner
National Highway Traffic Safety Administration, United States 132

Dummy Development:
The Eurosid Side Impact Dummy
The EEVC Ad Hoc Group on Dummies 153

Advanced Anthropomorphic Test Device Concept Definition
J. Melvin
Dept. of Mechanical Engineering and Applied Mechanics
University of Michigan, United States 165

A New Dummy for Pedestrian Test
B. Aldman and
J. Kajzer
Department of Traffic Safety, Chalmers University of Technology, Sweden 176

Head and Neck Injuries in Human Cadavers
from Lateral Impacts
M. Walsh and
B. Kelleher
Calspan Corporation, United States 186

SESSION TWO: CRASH AVOIDANCE
Chairman: Robert M. Nicholson, United States

Discerning the State of Crash Avoidance
in the Accident Experience
A.C. Malliaris
National Highway Traffic Safety Administration, United States 199

Optimum Luminances and Areas of Rear-Position-Lamps
and Stop Lamps
H.J. Schmidt-Clausen
Technical University, Darmstadt,
Federal Republic of Germany 220

Evaluation of Headlamp Beam Patterns
Using the Ford CHESS Program
M. Perel
National Highway Traffic Safety Administration, United States 225

A Study of Laser Radar
H. Kawata,
H. Endo, and
Y. Eto
Nissan Motor Co., Ltd., Japan 230

Car Controls for Physically Handicapped Drivers
C. Haslegrave
Motor Industry Research Association, United Kingdom 235

The Prevention of Bead Dislodgement of Tyres and the
Importance of Limited Run Flat Capability on Safety
G. Tavazza
Pirelli Coordinamento Pneumatici, Italy 243

Modification of Vehicle Handling Performance by
Four-Wheel Steering System
S. Sano,
Y. Furukawa, and
S. Shiraishi
Honda Motor Co., Ltd., Japan 248

Maneuverability and New Suspension for
Four-Wheel Drive Vehicles
M. Otake,
S. Obayashi,
M. Kubota, and
Y. Nozawa
Subaru Engineering Division,
Fuji Heavy Industries, Ltd., Japan 262

Behaviour of a Vehicle During Turning
Y. Vermont
Renault, France 269

An Instrument to Measure Scattered Light
Due to Windshield Wear
A. Timmermann
Forschungsgemeinschaft Auto-Sicht-Sicherheit,
Federal Republic of Germany 276

The Development of Drowsiness Warning Devices
K. Yabuta,
H. Iizuka,
T. Yanagishima,
Y. Kataoka, and
T. Seno
Nissan Motor Co., Ltd., Japan 282

Tire Pressure Warning System
Y. Uemura,
S. Oshita,
T. Konno,
T. Kobuna, and
Y. Yoshida
Subaru Engineering Division,
Fuji Heavy Industries, Ltd. 288

Aspects of Subjective/Objective Correlation
Regarding Vehicle Tyres
L. Breindle
Technology Assessment Applied Psychology
Cranfield Intitute of Technology, United Kingdom 294

Tire Performance Measurements—Wet and Dry
L. Emery
National Highway Traffic Safety Admimistration, United States 300

Accident Avoidance—Crosswind Sensitivity of
Some Streamlined Cars
M. Jacobson, Consultant
The Automobile Association, United Kingdom 310

SESSION THREE: OCCUPANT PROTECTION FOR FRONTAL IMPACT
Chairman: Dr. Kennerly H. Digges, United States

Efficient Energy Absorption of Automobile Side Rails
S. Yamaguchi,
H. Kato, and
T. Okazaki
Toyota Motor Corporation, Japan 321

Collapse Behavior Development of Body Components
R. Brasche,
G. Giazitzis, and
H. Schmitt
Ford-Werke AG, Federal Republic of Germany 326

Advanced Concepts for Driver Air Cushion Systems
G. Kirchoff,
R. Carr,
R. Wheelwright, and
G. Adams
Morton Thiokol, Inc., United States 332

Injury Criteria for Combined Restraint Systems
L. Grösch
Daimler-Benz AG, Federal Republic of Germany 338

A Modified Steering Wheel to Reduce Facial Injuries and Associated Test Procedures
S. Petty
Transport and Road Research Laboratory
United Kingdom 342

Improved Crashworthiness Independent of Belts or Airbags
R. Wilson
Environmental Activities Staff, General Motors,
United States 347

An Impact Test Programme Using Six Models of Lower-Medium-Sized Cars
S. Penoyre
Transport and Road Research Laboratory,
United Kingdom 357

A Free-Flight Headform Impact Device for Evaluating the Energy Absorption Characteristics of Vehicle Interiors
K. Dale and
K. Clemo
Motor Industry Research Association, United Kingdom 362

New Car Assessment Program Results and the Risk of Injury in Actual Accidents
I. Jones,
R. Whitfield, and
D. Carroll
Insurance Institute for Highway Safety, United States 371

A Review of the Effects of Belt Systems, Steering Assemblies, and Structural Design on the Safety Performance of Vehicles in the New Car Assessment Program
J. Hackney
National Highway Traffic Safety Administration, United States 380

Accident Research and Frontal Testing
M. Danner
HUK-Verband, Federal Republic of Germany 413

Results of Crash Tests According to the ECE/GRCS Regulation Proposal Concerning 50km/h Frontal Impact Against the Rigid 30° Barrier

Michael M. Finkelstein, United States 1217

John Furness, United Kingdom 1217

Section 1
Opening Ceremonies

Welcoming Address:

Sir Peter Lazarus
Permanent Secretary, United Kingdom
Department of Transport

It is my very great pleasure to open this conference today and to welcome you all on behalf of the Government of the United Kingdom to this Tenth Experimental Safety Vehicle Conference and to the University and City of Oxford.

Experimental Safety Vehicle Conferences have played an important role in stimulating the development of safer vehicles, and I congratulate the Government of the United States and in particular NHTSA for being so farsighted in sponsoring these conferences since 1971.

We have here today a considerable number of the world's experts directly involved in improving the safety features of vehicles, as well as those who are influential for ensuring that the momentum of progress made in this field in recent years will continue into the future.

Your past efforts have resulted in considerable progress being made in this important area of vehicle design. However, in spite of these improvements there is much still to be done. The public expects a constant flow of improvements to make life safer for all classes of road users—motorist, cyclist, and pedestrian. For this reason I welcome particularly your discussions on reducing the adverse effect of the motor vehicle on other road users.

It is 11 years since an Experimental Safety Vehicle Conference was held in this country. In the intervening period there have been many changes in design. Cars, even though they are lighter in weight to aid better fuel economy, incorporate many more safety features for the protection of their occupants than at the time of the 1974 Conference. I congratulate industry on the inventiveness it has shown in reconciling these often conflicting demands arising from considerations of safety, economy, and the environment.

However, we cannot be complacent, and this conference will highlight several areas in which we can—indeed, must—make progress toward designs that provide even greater safety for both vehicle occupants and other road users.

I note with interest how the subject matter of these conferences has developed over the years. The early conferences dealt solely with safety features on cars. This conference extends the discussion to include safety problems associated with trucks, buses, motorcycles, and pedal cycles, which are widely used as personal transport in many parts of the world.

In this country, injuries to motorcyclists and their passengers are a matter of grave concern, and we must find ways to improve the safety of this group of road users. I am very heartened, therefore, to see the conference will be considering safety features for motorcycles and, in particular, I note that antilock braking systems for motorcycles are now being actively developed.

Even though improvement in the design of cars for safety is very important and will remain so, progress must be made with safer designs for all types of road vehicles.

I would like to remind you of one event that has taken place in this country that we consider one of the most effective measures taken in our battle to reduce injuries and fatalities arising from road accidents. I am referring, of course, to the compulsory wearing of seatbelts. In the 2 years since this requirement has become compulsory, we have seen a large reduction in deaths and serious injuries (17 percent fewer deaths, 22 percent fewer injuries), and you will be hearing more of our experience during the conference.

One of the most important benefits of this conference is that it will further encourage the free exchange of information and stimulate the cooperation necessary for the rapid development of safer vehicles. I would, therefore, like to thank the Institution of Mechanical Engineers for organising this conference on behalf of the Department

of Transport and for their efforts in preparing the Conference facilities. I am sure you will find much to interest you during the next 4 days, and I hope you will enjoy and benefit from your brief stay in this ancient university city.

Keynote Address:

Diane K. Steed
U.S. Department of Transportation, National Highway Traffic Safety Administration

It is indeed a special privilege to be here in the United Kingdom, home of the English Parliament, Buckingham Palace, and, this week especially, Wimbledon. As said earlier, I have been looking forward for quite some time to joining you at this conference.

I bring you personal greetings from U.S. Secretary of Transportation Elizabeth Dole, who very much wanted to attend this important safety conference to express personally our country's strong commitment to vehicle safety. I know it is a commitment that all of us share. As Secretary Dole has often said, safety is her highest priority. My own commitment to highway safety is no less absolute.

Over the past decade of cooperative safety research effort, we have seen many technological advances in automotive safety. Most of the safety improvements on today's vehicles were made possible through research of the governments, private industry, and individuals represented at this conference. We appreciate these contributions, and we have all benefited from them. These combined efforts have contributed substantially to the reduction of deaths and injuries resulting from motor vehicle crashes.

The critical goal of improved safety can best be realized when government and the private sector cooperate. We do not look on industry as an adversary—we consider industry a key partner in the common goal of improved motor safety.

It is government's job to regulate—and appropriately so—but it is the manufacturers who bring the experience, the resources, and the expertise necessary to design and build the safer automobiles of the future. And industry is doing just that.

Manufacturers throughout the world are working toward the development of new technologies. Germany is giving us the opportunity to look at technology in the real world by offering airbags as optional equipment in some of its automobiles. Japanese automakers have devised improvements in the comfort and performance of safety belts. Italy is studying ways to reduce vehicle weight without sacrificing vehicle safety. Major safety improvements in production design are being tested in Sweden, including advanced energy-absorbing front structures and improved safety designs for other vehicle subsystems. France has underway exciting work on designs for the 3-point safety belt. In the United Kingdom, research is producing new information on skidding and loss of control, as well as new concepts on barrier design.

These efforts—and the list could go on and on—are reducing traffic fatalities and serious injuries, and I applaud these achievements. The engineers in this room seldom make the headlines, but you are quietly and effectively laying the foundation for a better, safer tomorrow for all of us.

In the United States, we are also striving to be innovative in motor vehicle safety. One of our concerns is making certain that our limited research dollars are properly directed to a balanced safety program and the most important safety issues.

To respond to this concern—and because we know government does not have all the answers—I am working now to establish a Motor Vehicle Safety Research Advisory Committee. This will be a joint effort between government and the private sector to advise me on important safety issues of mutual concern. The committee will consist of motor vehicle safety research experts selected from the ranks of automotive manufacturers, academic institutions, trade associations, and government. It will coordinate safety research to avoid duplication and encourage innovation. Initially the committee will concentrate on occupant crash protection and heavy truck safety. These two areas, we believe, are most appropriate at present for coordinated research.

There are three other important subjects I would like to discuss with you:

1. Our increased emphasis on international harmonization
2. Secretary Dole's decision on our Standard No. 208 on occupant protection
3. Our dedication to continued international cooperation

In 1982 we announced our commitment to harmonizing our safety regulations with other countries. We recognized then that differences in test procedures, performance standards, and compliance criteria were unnecessarily complicating and increasing the costs of producing automobiles in a world market.

International harmonization is an important goal of this administration. In that regard, I am pleased to announce that I have established a new Office of International Harmonization at NHTSA. To give it appropriate visibility and increased emphasis, I have placed this new office under my direct supervision. I recognize the importance of international harmonization—and am making this a priority in our 1986 budget.

In the past 3 or 4 years, we have seen many benefits from our participation in the work of the Group of Experts on the Construction of Vehicles. Two cases in point are the common symbols on vehicle control displays and recent changes we have made in lighting standards. These are small breakthroughs, but accomplishments in minor areas such as these are the forerunners of compatibility in more complex areas—such as brake designs and side impact harmonization.

We will continue to work toward eliminating conflicting regulations that make it burdensome for manufacturers to construct cars for both domestic and foreign markets. Those differences serve as nontariff trade barriers that restrict international commerce and increase costs to consumers and industry alike.

In some cases, harmonization will promote increased production, marketing flexibility, and cost savings for vehicle manufacturers, and ultimately for consumers, without compromising safety. In fact, international harmonization can actually promote safety by upgrading standards and encouraging the sharing of safety technology by removing the differences between domestic and imported vehicles.

My pledge to you today is increased emphasis on international harmonization, and I know that through our joint efforts great accomplishments can be achieved in the future.

Now I want to discuss briefly the background and rationale behind Secretary Dole's decision on the 208 standard on occupant protection. This was one of the toughest, most complex policy decisions in which I have ever had a part. The Secretary's goal from the outset was to do what was best for the motoring public and to save as many lives as possible as quickly as possible.

Last July when Secretary Dole announced her ruling, it was one of the most significant decisions of her administration. It calls for automatic crash protection—either automatic belts, airbags, or other new technology—to be phased in beginning with 1987 model cars. The decision also encourages States to pass mandatory safety belt use laws, with a provision that if by April 1, 1989, two-thirds of the population is covered by mandatory use laws, the automatic protection requirements will be rescinded. Her decision was a major achievement in the history of occupant protection because, for the first time, the regulation is actually saving lives.

Of particular interest to those of you at this conference is the emphasis this decision gives to the development of new safety technology. For each car built with nonbelt technology, manufacturers will receive extra credit toward their percentage requirement if they use something other than automatic safety belts to protect the driver. In other words, manufacturers get extra credit for the installation of airbags, protective interiors, or other nonbelt technology that meets the test requirements of the rule.

We believe there is a definite advantage in the initial stages of compliance to encourage a variety of automatic protection technologies. This will promote the development of what may be better alternatives in the future than what might otherwise be developed.

The Secretary's decision is not an either/or decision—either automatic devices or belt use laws. It means both. We know the decision resulting in the enactment of State belt use laws already has saved many lives and prevented countless injuries. In New York, the first State to have a mandatory belt use law, fatalities are already down an impressive 27 percent. I hope to be able to report to you at our next conference that most U.S. citizens are protected by belt use laws.

Finally I want to discuss another priority of ours—to encourage continued international cooperation and technology sharing. I believe all of us agree that we can all benefit from collaboration on safety research projects. What each of us may find difficult to do alone we can and have accomplished together.

In the area of transportation, no country has a monopoly on the best ideas or most advanced technology. Therefore, we support an active international research and development program to foster data and technology sharing.

Independent, uncoordinated research and development can be wasteful and redundant. It can lead to development of safety technologies that may not always be suitable for worldwide application. International cooperation, on the other hand, can lead to the development and expanded use of improved safety equipment on a global scale.

And international cooperation does not lie exclusively with federally sponsored projects. American scientists and engineers from the private sector engage in a great many cooperative international ventures. Often they work through the universities or the industrial firms that employ them, with the Federal Government acting—at most—as a catalyst. An important goal of this administration is to encourage such private sector cooperation.

The benefits we will derive from international cooperation and from conferences such as this are crucial because they eventually filter down to improve the quality of life for all people. This research—this sharing of knowledge—is an essential investment in our future—one we must wisely and responsibly nurture.

I want to close my remarks today by extending to you a very personal invitation to my Nation's capital. In May 1987 the United States will host the Eleventh Experimental Safety Vehicle Conference in Washington, D.C. We have

already started our preliminary planning, and I know the conference will be challenging and professionally stimulating. I hope we can provide you with an equal measure of hospitality that our British colleagues have shown us this week.

Through continuing communications we will move closer to the spirit of international cooperation that is this conference's stated purpose and our sincere goal. There is mutual interest in these important areas we have discussed this week. There will be mutual benefit, and we in the United States pledge to all delegates present at this conference our mutual cooperation.

Awards Presentations

Safety Awards for Engineering Excellence

In recognition of and appreciation for extraordinary contributions in the field of motor vehicle safety engineering and for distinguished service to the motoring public.

Italy

Dott. Ing. Lamberto Maestripieri
Manager of the Alfa Romeo Safety Laboratory

Dr. Maestripieri has been working actively for improved passive and active safety since joining Alfa Romeo in 1967. He was directly involved in the development of the Safety Laboratory established by Alfa Romeo at its Experimental Center and in 1970 was appointed head of the laboratory. Dr. Maestripieri has conducted both theoretical and experimental research on improved vehicle structural performance in frontal and side impacts, weight reduction without sacrificing safety, and reductions in noise and air pollution. He was responsible for the design, development, and testing of the Alfa Romeo Synthesis Vehicle (S.V.A.R.), which was presented at the Ninth ESV Conference in Kyoto. By these many efforts, Dr. Maestripieri has made a major contribution to vehicle safety.

Federal Republic of Germany

Professor Dr.-Ing. Klaus Rompe
Director of the Institute for Traffic Safety, TUV Rheinland

Professor Rompe has made significant research contributions in the areas of active safety. First he analyzed passenger car handling characteristics by comprehensive computer programs. Then he initiated the development and application of objective test procedures for these characteristics. In comprehensive comparative test programs for passenger cars, cars and trailers, trucks, and truck combinations, he developed the necessary evaluation criteria and test procedures needed for a better understanding of the driver-vehicle-environment system, for investigations of the causes of accidents. Professor Rompe also investigated the view conditions of the drivers, especially for night driving, the interaction phenomena in a car crash with two and more passengers, and improved passenger protection in bus crashes. For these many safety accomplishments, Professor Rompe is deserving of special recognition.

France

Francois Hartemann
Head of Section on Accident Research Investigation, Laboratory of Physiology and Biomechanics, Peugeot-Renault

In 1970 Mr. Hartemann was appointed head of the Research Unit created by Peugeot and Renault to conduct detailed analyses of accident data. In this position Mr. Hartemann has made major contributions to vehicle safety by his work on the relationship between driver fatigue and accidents, the effects of collision force in frontal and side impacts, the definition and validation of test procedures, and improvements in the efficiency of the 3-point seat belt. Many of the results of these research efforts have been incorporated in production vehicles, resulting in a reduction in deaths and injuries. Through his research work, Mr. Hartemann has made a significant contribution to improved vehicle safety.

Jean Leroy
Manager, Laboratoire des Chocs et de Biomecaniquee, Organisme National de Securite Routiere

Mr. Leroy has had a long and distinguished career in furthering vehicle safety. His work with Renault involved accident analysis, improved restraint systems, deformable vehicle structures, and improved interior padding. His work with ONSER addressed improved protection for motor car users as well as research to improve the road environment. Mr. Leroy is well recognized both nationally and internationally for his expert participation in international working groups and scientific and technical societies. His contributions have resulted in major improvements in the safety performance of vehicles. Therefore, he is especially deserving of this award.

Sweden

Hans A. Norin
Senior Safety Engineer
Volvo Car Corporation

Through lectures, technical papers, and presentations, Mr. Norin has taken part in and deepened the international traffic safety debate with special emphasis on child safety and side collisions. The work of the Volvo Car Accident Research Group for which Mr. Norin is responsible has led to major safety improvements in production car design. Some examples are improved steering column systems, advanced energy-absorbing front structures, improved gas tank design and location, improved safety belt systems, and improved safety designs for doors, seats, suspension systems, and other vehicle subsystems. For these many impressive safety accomplishments, Mr. Norin is deserving of the special recognition.

Dr. Bertil Aldman
Professor, Department of Traffic Safety, Chalmers University of Technology

Dr. Aldman has been instrumental in the design of protective devices of various types. His research has influenced the development of 3-point seat belt systems, automatically locking retractors, and crash helmets and protective clothing for motorcyclists. He designed the first rear-facing child seat and presented it at the Stapp Conference in 1964 and participated in the development of booster cushions for children. Together with a team in France, he is currently involved in the design of a new type of pedestrian dummy, which will be presented during the Tenth ESV Conference. Dr. Aldman has published over 200 technical papers covering subjects

from first-aid and hospital care, the biomechanics of trauma, the design of protection devices, to definitions and theories as a basis for road safety research. For these many safety contributions, Dr. Aldman is especially deserving of receiving the award for engineering excellence.

United Kingdom

Gwilym Jones

Manager, Vehicle Legislation and Safety Research, Austin Rover Group
Product Engineering

Mr. Jones began his career working in car development and then specialized in vehicle testing, particularly braking and handling. As a result of this work, he was appointed Chief Experimental Engineer and then assumed responsibility, for the Vehicle Safety Engineering Department. In conjunction with this responsibility he is also managing the vehicle legislation aspects of car design and development. His major contributions to vehicle safety include research work on the skidding behavior of vehicles, vehicle handling, loss of control, and future trends in improved protection in frontal impact. Mr. Jones has been chairman of the SMM&T Car Safety Technical Committee for the past 4 years. Because of Mr. Jones's significant contributions to vehicle safety, he is recognized for his accomplishments by this award for engineering excellence.

Gunter Persicke

Ing., F.I. Plant E., Quinton Hazell Ltd.

For the past 20 years, Mr. Persicke has been particularly interested in the development of hydraulic shock absorbers and their application to a wide range of safety problems. Mr. Persicke has developed a versatile and inexpensive design for use in the design of barriers and bridge parapets, truck bumpers, and truck front and rear underride protection. Many of these applications are now in production and in use. Mr. Persicke currently leads a development team at Quinton Hazell developing suspension energy absorbers to provide controlled but variable rates of damping to improve handling and ride for road vehicles. For his significant contribution to vehicle safety, Mr. Persicke is deserving of special recognition.

G.D. Suthurst

Ford Motor Company Limited, Research and Engineering Centre

Mr. Suthurst joined Ford in 1963 in its Passenger Vehicle Research Department. He has been involved with vehicle safety since 1968 and has managed Body and Safety Research for the past 8 years. During this time he has been associated with initial development of a collapsible steering column used in the Cortina; design, development, and fabrication of the Ford demonstration car of 1974 to show the protection possible without restraints and the resulting loss of interior space; initial development of adjustable B-pillar seatbelt mountings; and development of computer optimization programs for simulating side impacts and pedestrian impacts. His research group is the focus for developments within Ford for improving the safety of cars and bridges the gap between outside research and production design. For his major contributions to vehicle safety, Mr. Suthurst is deserving of special recognition.

Japan

Kenichiro Nomura
Project Manager, Toyota Motor Corporation

Mr. Nomura has been manager of Toyota vehicle safety research and development since 1979. The results of much of this research can be found in Toyota production vehicles. Mr. Nomura was the project manager of Toyota ESV-III, which was introduced and exhibited during the Ninth ESV Conference in Kyoto. The ESV-III incorporated advanced accident prevention electronic developments such as the supermonitoring display, the radar-autodrive system, and the back sonar and antiglare mirrors. These latter two systems now appear in production vehicles. Because of his dedication to automotive safety, Mr. Nomura is selected to receive this award for engineering excellence.

Tomokazu Tokuda
General Manager, Research Department No. 1, Vehicle Research Laboratory Central Engineering Laboratories Nissan Motor Company, Ltd.

Mr. Tokuda has had a distinguished career with the Nissan Motor Company since 1958. As general manager of the Research Department, Vehicle Research Laboratory, Mr. Tokuda has conducted research in all areas of vehicle technology including safety, fuel economy, and weight reductions. As a part of his work, he developed the NRV II (Nissan Research Vehicle II), which was introduced and exhibited during the Ninth ESV Conference in Kyoto. The NRV II featured advanced technologies to lighten the driver's tasks as well as improved accident avoidance and occupant protection, energy and resource savings, and significant vehicle weight reductions. Mr. Tokuda is certainly deserving of the award for engineering excellence.

Shoichi Sano
Staff Engineer and Manager for Research Section Tochigi R&D Center, Wako R&D Institute Honda R&D Co., Ltd.

Mr. Sano, as the chief engineer for development of the Honda ESV project, contributed immeasurably to the completion of the compact 1,500-pound advanced technology ESV. Since completion of the ESV project in 1974, Mr. Sano has actively participated in the development of an airbag system for Honda small cars. His current effort to advance the accident avoidance capabilities of production cars has centered on the development of a four-wheel steering system. Mr. Sano is now leading a major effort to develop this new four-wheel steering system for commercial production cars. Because of these major safety research efforts, Mr. Sano is most deserving of special recognition.

The Netherlands

Dr. Johan G. Kuiperbak (Retired)

Director, Department of Road Transport
Ministry of Transport and Public Works
The Netherlands

Upon Dr. Kuiperbak's retirement from the Netherlands Ministry of Transport and Public Works, it is appropriate that we recognize his many years of effort to improve vehicle safety on the world's highways. Dr. Kuiperbak has been an active supporter of the ESV Program through his participation in the European Experimental Vehicles Committee and through his support and participation in the International Technical Conferences on Experimental Safety Vehicles. Dr. Kuiperbak's major contributions to road and vehicle safety are recognized by this special award.

Sweden

Nils Bohlin (Retired)

Senior Engineer for Automobile Safety
AB Volvo

Mr. Bohlin received the NHTSA Award for Engineering Excellence in 1979 for his many contributions to automotive safety. Now on his retirement, we are especially pleased to again recognize his outstanding research work over the years. Mr. Bohlin has been instrumental in advancing the state of the art in safety engineering and development. His contributions have indeed been impressive and have directly affected the safety performance of production vehicles.

United Kingdom

J.W. Furness (Retired)

Chief Mechanical Engineer
Department of Transport

Mr. Furness has had a long and distinguished career in furthering the cause of vehicle and road safety. His efforts in the harmonization of vehicle safety regulations are worthy of special recognition. As Chief Mechanical Engineer for the United Kingdom Department of Transport during the past 10 years, Mr. Furness has brought a keen insight to all the environmental aspects of motor vehicle safety, emissions, noise, weight, and fuel consumption. Because of Mr. Furness's major contribution to improved vehicle and road safety, he is most deserving of this special recognition.

Federal Republic of Germany

Professor Dr.-Ing. Willi Reidelbach (Retired)
Director, Passenger Car Body Basic Research,
Daimler-Benz A.G.

Professor Reidelbach initiated the Daimler-Benz accident analysis effort resulting in mathematical models that permitted evaluation of occupant behavior in all accident modes. The results were incorporated in vehicle design to improve structural integrity and controlled stiffness of the passenger compartment while reducing the weight of the car bodies. Professor Reidelbach's work in the area of car-to-car compatibility and driver/vehicle interaction in both real life as well as mathematical models is a yardstick for the designers today. As the Daimler-Benz safety officer for the Body Division, he was most influential in the design, testing, and final installations of the Daimler-Benz SRS System. For his many years of productive safety engineering, Professor Reidelbach is especially deserving of special recognition.

Italy

Dott. Ing. Giacomo Pocci (Retired)
Head of Studies and Research
General Administrative Department
Department of Civil Motorization
and Licensed Transports Ministry of Transport

Dr. Pocci has been an active and productive participant in vehicle safety improvement since 1955. His contributions include not only his impressive work for the Italian Ministry of Transport but also his performance as chairman of Working Party 29 of the ECE, his chairmanship of Working Group 6 of the EEVC, and other impressive research contributions to international groups and committees. Dr. Pocci has published many significant technical papers covering all aspects of vehicle safety. It is appropriate that he receive this special recognition.

Section 2
Government Status Reports

John W. Furness, Chairman, United Kingdom

Status Report of the United States

Michael M. Finkelstein
Associate Administrator for Research and Development, U.S. Department of Transportation, National Highway Traffic Safety Administration

Introduction

It is my pleasure to present the U.S. Government Status Report on our progress in automotive safety.

Since the Kyoto conference in November 1982, the National Highway Traffic Safety Administration's (NHTSA) automotive safety program has undergone several significant changes with encouraging results.

Of most importance has been Secretary Dole's decision of July 1984 on FMVSS 208, with the resulting efforts in many States to require the mandatory use of safety belts. In the near term, these laws will have a greater impact on highway safety than anything else we can do. However, we are also excited by the prospects offered by passive protection—both airbags and automatic safety belts.

Major efforts are also progressing throughout the United States to get drinking drivers off our highways. The decade of the 1980's has witnessed impressive reductions in the proportion of intoxicated drivers involved in fatal crashes.

Taken together, these steps have resulted in changes in vehicles and driving habits. The combination has been paying off. Last year witnessed the lowest fatal accident rate ever measured in the United States, and highway fatalities have declined by more than 11 percent from the levels we reported in Kyoto only 3 years ago.

The Accident Environment

Since 1980 the fatality rate per 100 million vehicle kilometers of travel in the United States has declined from 2.1 to 1.6 in 1984, the lowest rate ever recorded in the United States. The total number of traffic fatalities decreased from 51,091 in 1980 to an estimated 44,250 in 1984, while travel increased by approximately 3 percent per year.

A major goal in NHTSA's continuous effort to reduce the number of traffic fatalities and injuries has been to increase the use of occupant restraints in passenger vehicles. Within the past few years, almost all States have adopted mandatory child restraint laws with very encouraging results. In 1979 only 11 percent of young children in car accidents were restrained; by 1983 the proportion had increased to 48 percent.

Following on this achievement, mandatory safety belt use laws are being enacted throughout the United States. As of June 15, 1985, mandatory safety belt use laws for front seat passenger car occupants have been enacted in 13 States and legislation is pending in many others. The first law took effect in January 1985 in New York.

Another NHTSA priority is the reduction of drunk driving on the Nation's highways. Since 1980 the number of drivers who were involved in fatal accidents and had a BAC of .10 or above has been decreasing steadily. In addition, although traffic fatalities decreased during all periods of the day between 1980 and 1984, the reduction during nighttime hours, 6 p.m. to 6 a.m., was 19.2 percent, as compared to 3.4 percent during daytime hours.

Accident Data Collection and Analysis

The accident data cited throughout this report are derived from the Fatal Accident Reporting System (FARS) and the National Accident Sampling System (NASS). Both of these accident data collection systems are operated by NHTSA's National Center for Statistics and Analysis.

FARS is a computerized data base containing information on all fatal motor vehicle accidents occurring in the United States. The system became operational in 1975 and currently has records on almost 500,000 fatalities. FARS data are acquired directly from each State's operational records. The FARS file provides the most comprehensive, detailed, and accurate data available on the U.S. national motor vehicle fatality toll.

NASS is a network of 50 experienced, highly trained accident investigation teams that collect data on a nationally representative sample of police-reported accidents. Data are compiled and evaluated from detailed accident site inspections, measurements and assessments of damaged vehicles, driver interviews, medical records, autopsy data, and other pertinent State records. The NASS system collects information in significantly greater detail, both in number of variables and precision of observations, than existing records or systems. NASS presently has more than 40,000 accidents in the file from 1979 through 1984.

Crashworthiness Research

Since Kyoto, crashworthiness research at NHTSA has concentrated principally on the reduction of harm resulting from lateral crashes. We have completed most of our research on chest injuries resulting from contact with the vehicle interior. We are now attempting to increase our understanding of side crash protection, addressing other types of injuries, particularly head contacts with interior objects and ejections. Our other major project initiated since Kyoto has been a frontal protection project. Initially it was addressing unrestrained occupants, but the changing environment with respect to mandatory belt use laws has us expanding this project to cover restrained occupants as well. The foundation for much of our crashworthiness research is our biomechanics program, which is now completing work on the Side Impact Dummy (SID) and exploring the possibility of expanding the capabilities of the Hybrid III. Finally we have been exploring the feasibility of aftermarket airbag systems as well as encouraging the introduction of airbags from vehicle manufacturers.

Side Protection

Since Kyoto, the research reported on the Moving Deformable Barrier (MDB) was completed. A detailed test procedure for conducting perpendicular side impact tests using the MDB has been made available.

In addition to full system tests, a component test procedure was developed to simulate the interaction of the human thorax with the side door interior.

In a joint effort by NHTSA and Motor Vehicle Manufacturers Association (MVMA), a coordinated study of side impact accident data was completed and the predominant side impact injury categories were defined. Analyses of the accident data provided insight into the sources of injury and the injury-causing mechanisms in side impacts.

Frontal Protection

The major activity in our frontal crashworthiness research program is the accurate assessment of the safety problems associated with both restrained and unrestrained occupants of passenger cars involved in frontal impacts. The current effort focuses on the analytical characterization of the in-use vehicle fleet to identify present injury mechanisms, alternative countermeasures, and to predict the effectiveness of these countermeasures.

In addition to these efforts, a study of the safety performance parameters of production vehicles for restrained occupants is continuing. Belt systems, steering assemblies, and frontal structural energy management designs are being carefully examined from the New Car Assessment Program test results.

With an increasing number of mandatory safety belt use laws in the States and the effect of FMVSS 208, it is expected that a much larger percentage of U.S. vehicle occupants will be restrained. The different problems faced by unrestrained and restrained occupants will be closely examined in the course of our research.

Biomechanics

In biomechanics we have initiated several efforts to investigate injury production in frontal impacts for both the driver and passenger.

Trauma assessment technology efforts have also been very active. The design, development, testing, evaluation, and documentation efforts on the SID have been completed. This has been complemented by the recent publication of the Thoracic Trauma Index (TTI), which links the SID's impact response measures to the probability of producing various levels of thoracic injury.

Airbag Fleet Demonstration Programs

NHTSA, in cooperation with State police agencies, is conducting two demonstration projects to support research, manufacturing, and testing of retrofit airbags. The first project uses conventional airbag technology in retrofit kits developed by the Romeo-Kojyo Company of Tempe, Arizona.

Our second retrofit project began in March 1984 with the Breed Corporation. This project requires the production of retrofit driver airbag systems using a mechanical rather than an electrical signal to initiate inflation.

The Department of Transportation is also interested in gaining more experience with original equipment airbag systems. To this end, in March 1983 DOT signed an interagency agreement with the General Services Administration (GSA) to purchase 5,000 model-year 1985 Ford Tempos equipped with driver-side airbags, virtually all of which have been delivered and are currently on the road.

Crash Avoidance Research

Crash avoidance research continues to receive considerable attention at NHTSA. Several of our research programs have reached the point where we have been able to quantify safety benefits in terms of predicting actual accident reductions. In other areas we are focusing our efforts on the development of the technical framework and data bases necessary to insure that our activities are addressing well-defined safety problems and that they will yield useful results.

Work continues on the development and refinement of the data bases that will be used for problem identification and establishing research priorities. We are concentrating on developing large-scale crash data files that focus on the precrash events leading up to the accidents. We are particularly interested in identifying vehicle maneuvers and driver actions in the 3- to 5-s time period immediately prior to the crash.

Lighting and Visibility

In the report at the Kyoto conference, earlier research on rear-lighting systems was described where we established the effectiveness of a high-mounted brake lamp in reducing rear-end collisions. Since then a regulation has been promulgated that will require all passenger cars manufactured on or after September 1, 1985, to be equipped with a single center high-mounted brake lamp.

In current research, we are assessing the photometric requirements contained in Federal Motor Vehicle Safety Standard 108 that deals with the intensity of presence and brake lamps. During the past 2 years NHTSA's headlight research has been directed toward improving the light distribution pattern of low beam headlights. In a recently completed experimental study, a new low beam was found to offer potentially better lighting in comparison with typical U.S. and European beam patterns. Comparison of the results of the experiment and an analytical evaluation of the same beam patterns using the Comprehensive Headlamp Environment Systems Simulation model indicated the need for a more comprehensive approach to headlamp evaluation. At the present time, a program is underway to examine improved measures and procedures for evaluating headlamp performance in the context of the driver-vehicle-roadway system.

Research to examine approaches for reducing crashes by increasing vehicle conspicuity is continuing. Preliminary results from a fleet study involving nearly 4,000 tractor-trailer units indicate that reflectorization of trailers may be an effective means of reducing the number of crashes of other vehicles into trailers. In another fleet study, the use of daytime running lights will be evaluated to determine if the benefits of this countermeasure in reducing multiple-car crashes apply to U.S. roadway and environmental conditions.

Handling and Stability

In handling and stability, we have just concluded extensive research on the influence of brake balance on vehicle yaw instability. Several new computer simulations have been developed to predict lateral position and yaw deviation as a result of rear axle lock. Open loop experiments with an instrumented variable brake balance vehicle have been conducted to confirm the simulations. In addition, human factors testing has been performed to investigate the effects of brake balance on the driver's ability to maintain vehicle brake control during braking with rear axle lock.

Finally, under our crash avoidance research program, a joint project has been initiated between NHTSA and the National Aeronautics and Space Administration for the development of an advanced radar crash warning system. The program is being conducted at the Johnson Space Flight Center in Houston, Texas, and is expected to be completed 18 months from now. A prototype system suitable for vehicle test and evaluation will be available at the completion of the project.

Heavy Duty Vehicle Safety Research

The goal of the heavy duty vehicle safety program is to improve the accident avoidance capabilities and crashworthiness of vehicles with gross vehicle weight ratings in excess of 10,000 lb through improvements in vehicle performance and driver/vehicle interaction. Even though they comprise only 3 to 4 percent of the motor vehicle fleet, heavy trucks continue to be involved in more than 10 percent of the fatal accidents.

Current heavy truck research focuses primarily on high priority crash avoidance programs aimed at improving

the dynamic performance of heavy vehicles in braking and steering maneuvers. A core level brake research program continues to seek ways to improve the safety performance of both air and hydraulically braked trucks in accident avoidance maneuvers involving braking, i.e., improved stopping capability without compromising directional stability.

Driver and Pedestrian Safety Research

While most of the activity we are focusing attention on at this conference deals with motor vehicle safety research, NHTSA has an active program addressing the behavioral components of traffic safety. Our major efforts these past few years have continued to concentrate on impaired driving problems and on safety belt and child restraint use.

Alcohol Safety Research

The goal of the alcohol safety program is to develop procedures that effectively reduce alcohol-impaired driving and related accidents.

Alcohol safety is focused on the following four areas:

- General Deterrence—Development of combined enforcement, public information, adjudication, and licensing programs designed to increase public perception of DWI detection risk among the general population
- Specific Deterrence—Development of programs directed at identified drunk drivers and designed to prevent future DWI offenses
- Prevention—Development of education, public information, and local community training programs designed to instill responsible attitudes toward drinking and driving and promote cooperative action for avoiding DWI
- Intervention—Development of programs designed to identify techniques that will enable and motivate third parties (e.g., bartenders, hosts/hostesses, drinking companions) to take action in a drinking situation that will deter potential DWI incidents

We are also beginning to initiate more work on drug-impaired driving, a potentially significant problem in the United States and many European countries.

Safety Belt Use Research

The enactment of mandatory belt use laws by State governments has brought about a revamping of the agency's program to foster increased safety belt use. Rather than relying almost exclusively on educational and persuasive efforts to motivate drivers and passengers to buckle up voluntarily, attention is now focused on providing educational information for States considering belt use laws and assisting those States that have such laws to develop programs to implement them in the most effective manner. Research concentrates mainly on: (1) assessing the impact of these laws through the analyses of crash data and tracking use rates; (2) exploring the situational and demographic variables associated with nonuse of belts; and (3) field testing and evaluating both traditional and innovative techniques to achieve higher belt use rates.

Vehicle Safety Standards

Since the Ninth ESV Conference in Japan, some significant changes have occurred in our Federal Motor Vehicle Safety Standards (FMVSS).

In the crashworthiness area, in July 1984 we reinstated the FMVSS 208 requirements for automatic occupant crash protection. Automatic crash protection will be required in 10 percent of new 1987 models, 25 percent of new 1988 models, 40 percent of new 1989 models, and in all new cars starting with 1990 models.

However, if mandatory safety belt usage laws meeting specified conditions are passed by a sufficient number of States, effective not later than September 1, 1989, the automatic crash protection requirements will be rescinded.

FMVSS 205 was amended to permit antilacerative glass/plastic windshields and other windows in U.S. cars. Some U.S. car models are already being sold with glass/plastic windshields as an option or as standard equipment.

In the near future, NHTSA is considering crashworthiness improvements in the side impact area. Every attempt will be made to include full consideration of the worldwide efforts underway in side impact protection research.

Finally, we have recently issued a proposal to permit the use of the Hybrid III anthropomorphic test dummy, and to ultimately have it replace the dummy currently used in U.S. crash tests.

In the crash avoidance area, we have issued a proposal for a new hydraulic brake systems standard for passenger cars. This new FMVSS is the culmination of several years of our work with the GRRF, and represents a significant attempt by the United States to harmonize European and U.S. brake system regulations.

We have issued several amendments to the FMVSS 108 to harmonize rear lamp photometrics and headlamp height with the European requirements. Additionally, we now permit replaceable bulb headlamps in the United States, a major step toward international harmonization; and we have proposed adoption of a U.S. version of the H-4 headlamp bulb.

The United States has just proposed that devices be installed on heavy trucks and trailers to reduce the splash and spray from the tires when driving on wet roads. Included in the proposal are spray suppressant flaps behind the wheels, and side skirts on both sides of the vehicle wheels.

International Harmonization

NHTSA is committed to fostering international harmonization of motor vehicle safety standards. This policy is, of course, tempered by legal and procedural requirements that the agency must follow and by concern that motor vehicle safety in the United States not be compromised.

Our efforts are directed toward controls and displays, lighting, and brakes. The agency has issued amendments to the controls and displays standard and the lighting standard and recently proposed a new harmonized standard for passenger car brakes.

FMVSS 101, Controls and Displays, was amended on July 27, 1984, by changing several identification requirements to agree with the symbols recommended by the International Standards Organization (ISO).

On November 26, 1984, FMVSS 108, Lamps, Reflective Devices, and Associated Equipment, was amended to bring the requirements into closer harmony with those of ECE.

The agency recently published, on May 10, 1985, a notice of proposed rulemaking that proposes a new standard, FMVSS 135, Passenger Car Brake Standards, which would replace FMVSS 105, Hydraulic Brake Systems for passenger cars. The new standard would differ from the existing one primarily in that it contains a revised and shortened test procedure based on a draft harmonized international procedure developed by ECE.

With regard to future endeavors, the agency has under serious consideration the question of establishing a new standard for side impact protection of occupants of passenger cars.

ECE/WP29, through its Group of Rapporteurs on Crashworthiness (GRCS), is also studying the problem. The United States, as a participating member, has offered to test both the anthropomorphic device and movable deformable barrier that are decided on by the GRCS in the interest of furthering harmonized requirements for both devices.

Status Report of Canada

Eric R. Welbourne
Chief, Vehicle Systems, Road Safety and Motor Vehicle Regulation Directorate,
Transport Canada

Introduction

As many of you are aware, Canada has been an interested observer of the ESV and RSV programs almost from their beginnings. We have participated in most of the conferences, which continue to provide unequalled opportunities for the exchange of research information relating directly to the development of safer motor vehicles. I am pleased to have this opportunity to contribute to that exchange by telling you something of recent work in Canada.

The design, construction, and performance of motor vehicles manufactured in or imported to Canada are regulated by the Federal Government under the authority of the Motor Vehicle Safety Act of 1970. The associated Canada Motor Vehicle Safety Standards (CMVSS) are, for the most part, either identical or compatible with the corresponding U.S. Federal Motor Vehicle Safety Standards. In a few instances, compliance with the relevant ECE regulation is an acceptable alternative to compliance with the North American standard.

The high level of harmonization of standards between the United States and Canada is a logical consequence of the integration of vehicle manufacturing in the two countries, which followed the conclusion in 1965 of the Canada-U.S. Automotive Products Agreement. This high level of harmonization offers certain evident advantages to Canada but does not relieve the Federal Government of two important obligations arising from its regulatory role. The first is to determine whether the net social and economic benefits of adopting a specific U.S. standard are likely to be positive in Canada. A second obligation is to determine whether current and proposed U.S. standards are sufficient for Canadian needs. Such considerations have, in the past, led to significant differences in the specific requirements of Canadian and U.S. standards in such areas as occupant protection, lighting, heavy truck braking, and exhaust emissions. They have also resulted in the development of several standards having no equivalents in the United States.

Perhaps more importantly in the present context, these obligations have continued to provide the principal motivation for a modest research and development

program in support of the Canada Motor Vehicle Safety Standards. The resources now available are such that we can usually consider only one major topic in crash avoidance and one in crashworthiness at any given time. I would therefore like to describe briefly the work we have been doing; first, on daytime running lights and, second, on the improvement of occupant protection.

Daytime Running Lights (DRL)

The Directorate first became interested in the potential of daytime running lights as a crash avoidance countermeasure in 1973. Following a review of the existing literature, our first thoughts concerned the feasibility of conducting a properly controlled field experiment to measure effectiveness and obtain associated cost data. In fact, we began a series of studies, addressing many of the specific questions relating to the costs and effectiveness of DRL, that was completed in 1984.

From these studies and the results that had been obtained from DRL use in Finland and Sweden, we concluded the general use of daytime running lights in Canada would lead to important reductions in the number of accidents involving two or more vehicles or a single vehicle and another road user. In our view, the favorable results obtained in Scandinavia had little to do with the lower levels of ambient illumination in the more northerly latitudes of those countries; it had much to do with the high proportion of collisions that are associated with perceptual errors on the part of drivers and other road users under all lighting conditions. It was further apparent that these accident reductions (equivalent to a 3 to 6 percent reduction in all accidents) could be obtained at a very modest cost, provided that the measure was not implemented simply by the use of existing lighting systems with low beam headlights on.

A comprehensive discussion paper that deals with several options for the implementation of general DRL use in Canada is substantially complete and will be published shortly. Following a review of its contents with various interest groups, it is hoped that a decision will be made quickly on implementation.

Improvement of Occupant Protection

Following the introduction of the first provincial laws requiring the use of seatbelts, a study was undertaken of the injury experience of passenger vehicle occupants restrained by 3-point belt systems. The results of this study, and a review of the literature on the performance of 3-point belt systems, suggested that the effectiveness of current systems could be improved significantly with little increase in either their cost or their complexity. The principal areas for improvement were the incidence of head and facial impacts with the vehicle interior, the thoracic loading induced by the upper torso belt, and the internal abdominal injuries induced by the lapbelt.

It did not appear there was any particular difficulty in designing a belt system to give the desired performance (some existing systems were evidently very good). The problem was simply that the current design-based standards for seatbelts permitted the use of a wide range of designs, many having obviously unsatisfactory features from a biomechanical viewpoint. It was also evident the use of the existing set of three performance criteria (HIC, maximum chest acceleration, and maximum femur load), specified in CMVSS and FMVSS 208 for passive restraint systems, offered no panacea. From some tests of our own and from an analysis of data from other sources, we determined that those criteria can be met readily by the use of belt systems that provide very poor control of occupant motion during a collision yet impose very high restraining forces on the occupant. Indeed, it became clear that under some circumstances the criteria could be met with a completely unrestrained test dummy.

The general problem then was to develop a set of performance criteria that addressed the actual injury experience of restrained occupants. That is what we set out to do, accepting as a practical constraint that those criteria would be applied in the context of the standard 48km/h frontal barrier crash. We then turned to the specific problems of defining performance criteria and developing the means of determining compliance with them. Within the scope of the present short report, it is not feasible to describe the development work in any detail. Much of it has been described elsewhere. For present purposes I shall, therefore, simply summarize the current status of the work.

Using a modified General Motors Hybrid III dummy, we are presently proposing performance criteria to address closed head injuries, facial bone fractures, and thoracic injuries in the standard barrier test collision. The basic Hybrid III head has been substantially modified to incorporate a frangible facial insert of methyl methacrylate and a compliant chin of silicon rubber. The original covering of the head has been replaced by a featureless skin of nominally uniform thickness. The Hybrid III chest has been replaced with a new structure that more closely approaches the shape of the human thorax. Its compliance distribution is based on the results of human volunteer tests and cadaver data. The deflection response to blunt mid-sternal impacts is essentially the same as that of the original Hybrid III chest.

An interim criterion for the prevention of closed head injuries has been proposed. It is based on a linear combination of the instantaneous value of the resultant translational acceleration of the head and the rotational acceleration of the head in the sagittal plane. Facial bone fractures are controlled by the frangible insert, which

fails at an impact energy level based on available cadaver data. Thoracic injury is presently controlled by specifying a maximum chest compression at mid-sternum.

No dynamic criterion has been proposed to control loading of the soft tissue of the abdomen. Instead, a separate static test procedure has been developed that provides a quantitative measure of the fit of the lapbelt in relation to the anterior/superior iliac spines. The procedure uses the standard H-point machine, modified to accept pelvic and thoracic forms. A small number of these accessory sets has been produced and the participation of interested agencies in evaluating the proposed procedures and hardware will be sought shortly.

We believe the U.S. administration's recent acceptance of the Hybrid III dummy as a compliance test device is a significant step toward the specification of more relevant and comprehensive criteria for the performance of occupant protection systems. As we approach a first series of crash tests to evaluate the developments I have described, we are optimistic the results will contribute to some long overdue progress in that direction.

Other Activities

Although I do not wish to take any more time than is necessary, it would be remiss of me not to mention at least a major cooperative research project presently in progress in Canada. The project, which is funded jointly by the Federal and provincial governments and industry, seeks to provide objective data on the implications of more uniform weight and dimensional regulations for commercial vehicles in Canada. The research addresses the effects of vehicle weight and dimensional variations on the stability and control characteristics of the vehicles themselves and their effects on the strain and deflection response of pavements. The availability of a common base of objective information should facilitate the more uniform acceptance of vehicle configurations offering improved safety and operational efficiency. I would be glad to provide additional information to anyone who would like to know more about the work.

Status Report of the European Experimental Vehicles Committee (EEVC)

Prof. Dr. Bernd Friedel
Chairman, European Experimental Vehicles Committee (EEVC)

When we met in Kyoto in November 1982, we stated in the Status Report of the European Experimental Vehicles Committee (EEVC) that the considerations in Europe with respect to occupant protection are based on the compulsory use of the seatbelt. In this respect, a number of changes have been successfully introduced since 1982. In some European countries, it has been possible to achieve drastic increases in seatbelt usage rates on the front seats: up to 90 percent and even more. These high rates, apart from various other factors, certainly contributed to injury mitigations and further reductions in the number of traffic deaths in particular.

Apart from these positive developments with regard to the number of accident-involved injured and killed persons, a series of problems had to be dealt with since the Ninth ESV Conference. We will have to take care that, under the pressure of other urgent problems, the safety of our cars does not lose in importance. Environmental problems and their discussion doubtless are growing in importance. We all know that extensive and serious attempts at improving the quality of the air have to be made—still, we should not give up and cease developing, making demands for, and introducing automotive engineering solutions to improve road safety.

As you know, the European Communities (EEC) have declared 1986 as the year of road safety in Europe. For several international bodies, the subject of occupant protection has remained under discussion, i.e., the work for a global test in a frontal collision has continued along with priority discussion on side impact and pedestrian protection at the Economic Commission for Europe (ECE).

For passenger protection in frontal collisions, it has been proved that a big step forward had been taken. It now seems necessary to implement the available scientific knowledge into political decisions to improve also the protection of passengers in side collisions and the safety of pedestrians and two-wheelers. It is our conviction that differences of existing opinions cannot be harmonized by further research alone. It needs a stern resolve and firm will, with its reflection in policies, to achieve solutions for all parties concerned.

Upon an extensive inquiry of NHTSA, EEVC proposed after the last ESV conference cooperation in the field of research between Europe and the United States. It was

our opinion the following tasks were to be dealt with by cooperative efforts:

- NHTSA participation in the EEVC ad hoc group on side impact dummies
- Participation in the EEVC ad hoc group on pedestrian safety
- Clarification of national viewpoints and interests with regard to the compatibility of cars
- NHTSA establishment of bilateral contacts with partners in different European countries to deal with special studies by joint efforts, e.g., Advanced Motorcycle Brake System, Driver Performance Measurement Systems, and Heavy Truck Control and Dynamic Stability

Efforts initiated to improve cooperation have just started. Despite our good intentions, however, it must be admitted that cooperation was more difficult than we expected, partly due to the traveling costs involved.

As mentioned before, special efforts were invested in the development of a side impact dummy for a study and evaluation of occupant protection in side impacts. A set of specifications and requirements for the EUROSID, as the dummy is called, was drawn up by an EEVC ad hoc group under the chairmanship of Mr. Neilson (TRRL) and published in 1984. The Commission of the European Communities (EEC) has sponsored in their large biomechanics programme intensive research concerning the comparison of different side impact dummies. Those studies formed the basis of the common attempt to develop a special European side impact dummy. Various institutions were engaged to produce specific parts of this dummy (e.g., pelvis, neck, and shoulder). We are pleased to demonstrate a prototype of the EUROSID at this conference. A validation program concerning the EUROSID is set up, in particular to investigate whether this dummy would meet the abovementioned EEVC specifications. The involvement of EEC will still be continued and the validation work will probably be undertaken with the contribution by EEC. After finishing this task, the dummy will be available for a wider use in side impact testing. NHTSA, the car industry, and other interested bodies are then invited to collaborate and participate. It is hoped that arrangements can be made for production of the EUROSID.

Efforts were made by several European research institutions to advance the work on the mobile barrier with a deformable front face, which had been proposed by a working group of EEVC. The barrier is built with a polyurethane hard foam block and will be exhibited during this conference. It seems the test device performs according to EEVC specifications for the perpendicular crash mode mentioned by our Working Group 6. For 2 years the ECE group of rapporteurs of vehicle structures (ECE/GRCS) have based the draft regulations for side impact tests on this EEVC barrier.

As stated at the Kyoto conference, EEVC dealt with the subject of "Cycle and Light-powered Two-wheeler Accidents" within new Working Group 8. An extensive report was published in 1984 that outlined the following:

- Detailed presentation of numbers of accidents involving cyclists and riders of light-powered two-wheelers
- Description of injury-influencing parameters
- Current knowledge on human tolerances (with special relevance for two-wheelers)
- Injury prevention measures and related consequences for other road users

Among the results one will find proposed improvements of two-wheelers and other vehicles (e.g., lighting equipment, braking performance of bicycles, energy-absorbing materials in front structures of cars, and underrun-guards on heavy goods vehicles). In general there seem to be no big discrepancies in measures to protect pedestrians and two-wheelers. General recommendations and recommendations for future research are outlined. We hope the EEVC report will be included in the proceedings of this conference.

Suggestions and proposals with respect to pedestrian protection are reviewed and discussed within an EEVC ad hoc group under the chairmanship of Mr. Moreau de Saint-Martin (ONSER). Thus the state of the art of pedestrian safety continues to be kept up to date despite the completion of the work of EEVC Working Group 7 (the report was published and disseminated at the ESV conference in Kyoto, 1982). The ad hoc group concentrated on the following factors in particular: accident analysis, injury mechanism, human tolerances, and possible methods to test and evaluate the effectiveness of pedestrian protection measures.

It was further attempted to draft guidelines for the design of cars related to stiffness and shape and to list priorities for further research. With respect to the guidelines, the idea was that although they should be introduced soon, the points to be considered in the long run should also be taken into account. There will be a report about this presented at the conference.

We have come to this year's ESV conference to present and discuss the results and suggestions arrived at by EEVC since the last conference. We have also come to exchange new research findings and information obtained at other places, e.g., in the United States and Japan. We trust this exchange will deepen our understanding and insight and also our acceptance of the need for further car safety improvements. The possibilities of cooperative efforts should be studied thoroughly and coordinated so as to fully concentrate our resources on priority problems—the protection of passengers in lateral collisions and the protection of pedestrians and two-wheelers.

Status Report of the Federal Republic of Germany

Prof. Dr. Heinrich Praxenthaler
President, Federal Highway Research Institute

When the Ninth ESV Conference was held in 1982 in Japan, we stressed the necessity of continuing our efforts to improve motor vehicle safety, to save energy and raw materials, and to reduce further the impacts on our environment in close collaboration with the car industry. Since that conference, efforts to improve environmental conditions by vehicle measures have gained prominence.

Since 1982 the trend of road traffic accidents in the Federal Republic of Germany is marked by an increase in accidents of about 9.3 percent, with injury accidents remaining more or less unchanged. A noticeable decline in fatal accidents took place in 1984, amounting to about 12 percent compared with 1982. Based on the mileage figures, which have risen by about 5 percent since 1982, these figures gain special importance. Concerning car occupants from 1982 to 1983, there was an alarming increase in fatalities, but an encouraging decrease took place from 1983 to 1984 resulting in an overall drop in the number of car occupant fatalities by about 8.6 percent since 1982.

Of special importance in this connection is that from the summer of 1984, noncompliance with the seatbelt usage law by front seat occupants incurs a fine of DM40. Because of this measure, belt usage rates changed between March and September 1984: on motorways from 81 percent to 97 percent and on rural roads from 62 percent to 94 percent. In urban areas the rates rose spectacularly, from 47 percent to 88 percent. There has been no decline in these figures so far; they even continued to increase slightly up to March 1985.

In 1984 the Federal Government presented a comprehensive program for improving road safety. It strongly appeals for road users to be more circumspect in traffic, drive more relaxed, and be regardful of others. Federal states and communities, associations and industry, and companies and societies are asked to support road safety to an even greater extent than before. Higher financial commitments are also needed because road safety efforts cannot be the sole responsibility of the state. One does not rely so much on more rules and regulations but on strengthening road users' individual and joint responsibilities for human life and health. That is why traffic education measures and safety campaigns are priority concerns of the Federal Government. Still, additional regulations are considered to be indispensable. Young car drivers and young two-wheel riders are marked by above-average learner risks. The introduction of a probationary driving license and a graduated driving permit for motorcycles is to effect more caution by learners during their first years of driving practice. The pleasure enjoyed in taking risks must be controlled and more relaxed attitudes displayed with respect to traffic.

Among other things, motorcyclists will have to comply with the mandated use of low lights during daylight hours, and mofa riders will be required to wear safety helmets. The seatbelt usage law has now been made compulsory for occupants in rear seating positions, but they are not fined for the time being. A model test will demonstrate whether it is possible to reduce the number of traffic signs on roads. The introduction of antilock braking systems for heavy-duty trucks and coaches has been set as an aim; the same applies to in-car displays that visually or acoustically remind drivers of buckling up and to the further standardization of seatbelt locking systems.

On the road sector, accident black spots, the construction of bypasses and cycle lanes, and influencing drivers by means of variable message signs are in the foreground. Further improvements to the emergency medical services system are also being undertaken.

In the field of accident research, activities of the Federal Government, car industry, and motor vehicle insurers can again be mentioned at this ESV conference. Further improvements to occupant protection continue to be an issue of general concern, especially in side collisions, from the viewpoint of the compatibility of cars and the protection of other road users, i.e., pedestrians and two-wheel riders. We are confronted here with the problem of designing front and side structures, based on detailed accident analyses, to optimize deformation values, bearing in mind the other road users.

The accident research efforts of the German motor vehicle insurers (HUK Association) are continued in the field of interior safety. In addition, studies on active safety, driver training, and the rating of the safety of driver groups and car categories are becoming increasingly important.

The HUK Association's accident research data base, revised in 1980, has been extended and presently comprises about 11,000 accidents occurring since 1980. Roughly 2,000 car accidents in which belts had been used, 3,000 single car crashes, 4,000 two-wheeler accidents, and 2,000 truck and bus accidents are available for accident research. These retrospective studies are increasingly undertaken in direct collaboration with the police and accident clinics. A study of 200 car frontal collisions in which occupants had been belted again confirmed the high protective effect of this restraint system; this effect may, however, be bettered by additional measures, such as preloaders and the use of airbags or steering column and wheel design alterations. Another study revealed that belt usage in rear seating positions could protect about 350 car occupants in Germany per year against fatal injuries and about 4,000 against major injuries.

Work on the sector of active safety concentrates on describing the accident characteristics in relation to the interactive driver-car behavior and particularly on the possible benefits of an antilock system. Based on the outcome of these initial studies, the motor vehicle insurers have been granting a premium rebate of 10 percent in the case of complete vehicle insurance policies for antilock braking system-equipped cars, trucks, and buses. Concrete studies into the effectiveness of such vehicles are envisaged for 1985-86.

It is also an objective of the HUK Association's accident research to use accident research findings for the benefit of driver training. In collaboration with other institutions, it has been possible to derive knowledge from studies on actual accidents, such as, for instance, the distribution of accidents with respect to categories of motorcycles, and consider them in the proposed revision of the regulations applying to the operating permit for motorized two-wheelers and the probationary driving license.

An analysis of 1,100 truck accidents with respect to exterior safety and partner protection has been completed by collaboration with the Research Association Motor Vehicle Techniques (FAT); work on the truck front structures is being continued by means of a second series of 14 crash tests and shows that practicable solutions are possible. An analogous study on truck occupant safety was started early in 1985.

Further research efforts of the HUK Association will aim at reducing injuries despite buckling up and at obtaining improved biomechanical safety criteria. Improved starting points for an approach to the safety rating of different car models in a crash can be expected to emerge from new methods of evaluation. A project extending over several years is expected to lead to information about accident frequency characteristics for particular car models and the accident consequences therefrom; it is also expected to provide tips, particularly for automotive engineers, as to necessary remedial measures.

The accident research efforts of the state have primarily been concentrated on continuing the numerous projects started since the last ESV conference. At-the-scene accident investigations undertaken since 1973 have been continued. These include special evaluations with respect to truck accidents, pedestrian accidents, and accidents involving motorized two-wheelers.

Roughly 30,000 rear-end collisions, each involving two cars, respectively, were analyzed to study the effects of two additional high-mounted stoplights. This analysis revealed no noticeable effects on accidents, either in terms of frequency or severity. A fact that attracted attention is the disproportionately high percentage of rear-end accidents in which both cars involved were equipped with additional high-mounted stoplights. An analysis of about 8,000 rear-end accidents involving between three and five cars also did not provide a confirmation of the effect of these lights.

A pilot study on the definition of critical situations with respect to driver-car behavior has been completed. Furthermore, reconstructions of accidents have been started to determine characteristic driving maneuvers in the phase preceding a crash and in the direct precrash phase.

The effects of safety helmets for motorized two-wheel riders were analyzed in laboratory tests and at-the-scene accident investigations. The main questions concerned the impact points and the resulting head injuries. On the whole, the studies clearly confirmed the helmet's positive effects on safety, which mitigates considerably the severity of injuries. The benefits of a safety helmet for riders of light-powered two-wheelers were also confirmed. A study of protective clothing demonstrated its positive effects; these mainly consist of mitigating open wounds and the danger of infection whereby otherwise protracted healing processes are shortened.

An extensive research project, "Design of Cars Affording Optimum Occupant Protection from the Viewpoint of the Economy," sponsored by the Federal Ministry for Research and Technology, was undertaken to study the optimization of the safety-related design aspects of cars, taking economic viewpoints into account. A mathematical simulation program was developed for this purpose. Occupant injuries were studied and evaluated in addition to the cost of design and production and changes in operating costs. Among other things, the results demonstrate that by optimizing requirements, considerable safety gains are still attainable without an increase in costs.

All efforts toward optimization presuppose belt usage by occupants. It is clearly important that car structures be adjusted to the restraint system employed. If that is not the case, a part of the restraint system's benefit is wasted.

It was further recognized that occupant protection in side collisions can be even partially achieved by designing car front structures accordingly, i.e., attenuating the aggressiveness of the impacting car. Based on experience acquired by car manufacturers, such improvements appear to be possible.

It must be the objective of future efforts to develop test methods taking the protection of both the occupants of the impacting car and those of the impacted car into consideration, thus simulating car behavior in an actual accident more realistically than is possible by means of head-on collisions against a rigid barrier.

In another side collision project, a deformable element of a movable barrier was developed in accordance with EEVC specifications. The barrier is currently being tested in collaboration with institutes in France and Great Britain.

In a new series of tests, the studies on the interaction of car occupants were continued. With respect to the frontal

collision, it has been possible to demonstrate that an interaction load can be totally avoided if occupants in rear seating positions are belted. To avoid such loads in the rear-end collision, the stiffening and additional upholstering of the backs of front seats should be required.

Furthermore, the variations of data measured on the car and dummy in collisions against a rigid barrier at a speed of 50km/h were determined. The scatter for the vehicle loading remained clearly below 10 percent and that for the protection criteria HIC and SI between 22 and 33 percent. It still must be clarified how the scatter should be taken into account in the legal regulations applying to full-scale tests.

Accident analyses revealed that it appears appropriate to incorporate clear evidence of the elimination of submarining into the corresponding regulation on frontal collisions.

Since no method is known at present by which the aggressiveness of vehicles with respect to pedestrians can be adequately described, a proposal for a standardized pedestrian test was worked out in collaboration with other European research institutions. Based on accident statistics, dummy positions and collision speeds were determined in particular and their applicability studied in a global test. In cooperation with experts from Switzerland, recommendations with respect to vehicle design considerations for the protection of the pedestrian were developed for the responsible ECE group.

A number of the projects mentioned were undertaken in close cooperation between state authorities and the car industry. The wide range of the car industry's own activities is the topic of numerous contributions to this conference.

The objective of safety was enlarged years ago by including in a farsighted manner the three well-known E-factors—energy, environment, and economy.

The last conferences paid special tribute to the achievements of the car industry in the field of more economical vehicles. We are accustomed to their existence and often forget how difficult the path toward fuel economy has been and that the favorable energy situation today is also due to fuel savings in motor vehicle traffic.

Environmental problems regarding the car are characterized above all by noise pollution and exhaust emissions. In EEC countries, the noise emission limits for motor vehicles were reduced in the past years, based on ISO measurements. The noise emission limits for motor vehicles should be lowered still further. In the past years, the car industry, with the decisive support of the Federal Government, developed commercial vehicles to the production stage with a noise emission level comparable to that of cars. An important condition of mass production and the corresponding demand for these vehicles was the establishment of binding criteria in respect to a noise-controlled commercial vehicle. It is important for the Federal Government to increase the proportion of such noise-controlled trucks in the total number of registered vehicles.

The extent to which measures of traffic restraint can contribute to mitigating the noise exposure of the residential population is currently being studied.

In the Federal Republic of Germany, particularly because of exhaust emissions, environmental impacts caused by cars have become an issue of symbolic character. "Waldsterben" is spreading and has become an alarming concern. This is not the place to talk about the stony path to an emission-controlled car. Facts have compelled us to act and emotions have aggravated the situation, but nobody should believe it is primarily the domestic policy conflict that has determined our outlook. All responsible forces of the Federal Republic want resolute efforts to be undertaken to reduce the levels of air pollution and want automotive engineering to contribute its share. We are also convinced that this recognition will soon spread to countries that are not yet alarmed by damage to their forests. What matters is not only the protection of our forests but the protection of human beings.

Although activities aim mainly at the new environmentally acceptable car, the roughly 25 million cars with internal combustion engines on our roads are also the objective of our efforts. No efforts should be spared to obtain noticeable emission reductions by means of subsequent alterations to the combustion system of cars.

Furthermore, the annual emission control introduced in January 1985, in association with optimal engine adjustment, will reduce emission levels. The customary interval between two emission controls has thus been reduced by half. This control concept also applies to cars with catalytic converters until a suitable test method becomes available.

The emission behavior of diesel engines with respect to gaseous emissions is essentially superior to internal combustion engines without an exhaust gas cleaning system. However, the Federal Government is presently working on a concept of reducing the gaseous pollutants, and especially the noxious particles, emitted by diesel vehicles.

Economy also stands for the moderate price of a car. We still regard a car as a means affording freedom that should be owned by many citizens. The production of emission-controlled cars has its price just as safety does. So that those who contribute to environmental protection are not put at a disadvantage, the state provides support and assistance. This is the approach we chose; it is in no way unusual since state incentives and state subsidies are given in many areas, not only in our country.

Concepts and activities today largely concentrate on environmental and competitive objectives. These matters should not, however, push the issue of safety out of the limelight, which was the problem of original concern at

ESV conferences. Each time we face conflicting aims, there is the danger that the permanent objectives, pursued for so long, are inadmissibly pushed aside by current issues. For that reason, the ESV conferences continue to be meaningful and significant.

Status Report of Italy

Dr. Franco Rossi
Direttore Centrale Motorizzazione, Direzione Generale M.C.T.C., Ministero dei Trasporti

Analysis of Accidents

In the past few years, the Italian domestic statistics have shown a slight decrease in casualties due to road accidents and a practically stable situation with regard to injuries. This notwithstanding, it appears further improvement is still possible.

In this connection, it should be pointed out that accident distribution according to type varies from one country to another. It is, therefore, necessary that an international accident data bank be established so the international regulatory bodies can determine priorities of intervention and evaluate the effectiveness of provisions adopted. Lack of such a data bank is a gap in the legislative procedure that both the EEC (European Economic Community) and ECE (Economic Commission for Europe) must fill. EEC has already stated that a road accident and safety data bank should be established at the community level.

General Provisions

Road Infrastructures

Our country has been developing a General Transport Plan that also takes road safety into account.

The Italian political authority will, therefore, have some guidelines available for the priority actions aimed at improving the infrastructures and reducing road fatalities.

Statistics show that whereas the Italian motorway network is more than adequate, the secondary road network perhaps does not compare with that of some other nations when related to traffic density. This is an area in which considerable effort will have to be made in the future.

Motor Vehicle Regulations

With regard to technical provisions concerning motor vehicles, Italy has adopted as many as 55 ECE regulations and 46 corresponding Community Directives. These are practically all the legislative documents issued by the international intergovernmental bodies. As a result of the experience gained from such instruments, we think careful consideration should be given to future amendments.

The criteria that have formed the present regulatory policy, based on geometric protection concepts, are no longer adequate in view of the evolution of accident investigation and vehicle test techniques.

We think it is necessary to evaluate the means—for example, biomechanics, dummies, and mathematical models—now available. Development of integrated test methods to evaluate overall vehicle behavior is, in our opinion, a more adequate response to the need to improve the motor vehicle fleet.

The Italian Government thinks, however, that efforts made so far to improve vehicles have already yielded considerable results and that further progress will require extensive investigation.

It is necessary to point out here the need to improve use of the vehicle through more shrewd traffic management to reach the main goal of reducing accidents and their effects.

The Human Factor

Finally, as far as the last and most important safety factor—MAN—is concerned, it should be noted that in our country a great many initiatives are underway to raise the public consciousness about traffic safety and to educate road users.

The Ministero dei Lavori Pubblici has declared 1985 the "Year of Road Safety," thus anticipating of one year the initiative of the European community. This means that throughout 1985 and 1986 the efforts of many of our national bodies will be focused on traffic problems.

In particular, the Ministero dei Trasporti has set up a permanent Commission on Road Safety, chaired by the Minister of Transport, whose tasks are—

- To examine the Italian road safety situation
- To propose a Road Safety Plan that will take into account the most recent technical progress in the areas of standardization and information

- To express opinions on provisions and initiatives concerning road safety and environment protection

Investigation committees will be established within this Commission to examine and discuss specific problems.

Active Safety

With regard to active safety, consideration has been given at the international level to braking regulations.

To extend antilock systems even to medium/small class vehicles, the possibility of approving simplified antilock systems was advocated during appropriate meetings.

In addition to the braking performance of a vehicle obtained with traditional means, these devices permit excellent stability on low-adhesion courses even though their cost is within acceptable limits.

In the past few years, Italy has conducted extensive investigations of braking, which have resulted in concrete proposals about replacement linings. Since vehicle safety shall be insured over many years of use, a test method has been devised for spare linings to assess braking performance and to insure they are fully interchangeable with original linings.

This is particularly important because the average life of in-use vehicles is increasing. The Italian Government also favors the addition, where possible or necessary, of conformity standards and in-use vehicle inspection standards to the existing approval regulations.

It is also necessary to investigate whether spare parts must be original equipment and, if so, which ones, or if they must at least have the same characteristics as the original parts.

Passive Safety

In the period from the Ninth ESV Conference to this conference, research activity was directed mainly to exposed road users and to assessing and setting up test instruments for occupant protection in side collisions.

In the session devoted to pedestrians, Alfa Romeo will, in fact, present a paper on the results of overall tests conducted with suitably instrumented dummies. Italy also participated in the three EEVC Working Groups (Pedestrian Protection, Bicyclists and Moped-Riders Protection, and European Side Impact Dummy). The evaluation of the results obtained by these groups is included in the schedule of the Congress.

Mention should also be made of the significant contribution to the solution of safety problems given by the GRCS, GRDP, and WP29, chaired by representatives of the Italian administration.

Exhaust Emissions and Noise

Italy is providing an active contribution to international work on new emission limits and test methods.

For applicability at the national level, community decisions are awaited to harmonize the Italian regulations with European legislation.

Regarding the technology to be adopted to reduce emission limits, legislation should be enacted to permit the use of techniques already tried in the United States, and other solutions should be adopted during research that will yield excellent results in terms of exhaust emissions and represent valid alternatives.

When investigating new motor vehicle regulations, an analysis should always be made of the cost/benefit of possible solutions to take account of the user's requirements and industrial impact.

As far as noise pollution is concerned, Italy has adopted promptly the latest EEC tightened requirements, thus showing its consciousness and availability.

Generally speaking, the Italian Government is of the opinion that to further protect the environment from motor vehicle pollution and noise, action should be taken in regard to traffic density and organization.

Status Report of France

Jean Moreau de Saint-Martin
Director, Organisme National de Sécurite Routiére

Road safety remains an overriding preoccupation of the French government, which is sustaining and developing its effort in this direction and achieving positive results in consequence. In 1983 some 11,946 people were killed in road accidents, the first time the figure had dropped below the 12,000 mark since 1964. This trend continued in 1984, when 11,685 people were killed and 284,907 injured (73,314 of them seriously) in 202,637 accidents. The level of risk has decreased correspondingly, since the number of vehicles on the road continues to increase slightly. It is difficult to give an exact measure for the level of risk, however, since recent research shows the volume of traffic using secondary roads has been considerably underestimated in past

assessments. Once this has been rectified, the level of risk will certainly work out to less than four deaths per 100 million vehicle-kilometers.

French road safety policy is largely devoted to measures aimed at influencing the behavior of road users and at encouraging local authority officials and opinion leaders to take action in support of road safety. This policy does not rule out other possibilities for taking steps of a more general nature, such as measures for improving vehicle safety. The main elements in the government's policy are—

(1) The "Réagir" (React) campaign provides for all serious accidents to be investigated administratively and technically to identify all the factors that might have played a role in the accident, as well as to propose preventive measures and to counteract the tendency of public opinion to treat road accidents as events of no importance. This program aims to have 10,000 accidents analyzed per year.

(2) The "Objectif Moins 10 percent" (Objective 10 percent Less) program is an incentive scheme aimed at local authorities (at both departmental and big city levels) that links the level of subsidies allocated to each local community taking part to their success in reducing the number of road accidents causing personal injury by 10 percent. Since the scheme was launched in 1983, some 80 departments and as many urban authorities of over 50,000 inhabitants have committed themselves to this objective, and several have already succeeded in reducing the number of accidents by 10 percent.

(3) A new drinking and driving law passed in 1983 will make it easier to carry out breathalyzer tests and render penalties more effective.

(4) Following extensive consultations with motorcyclists, changes were introduced on January 1, 1985, in the administrative classification of motorcycles and the corresponding driving licenses. Motorized two-wheelers are now divided into three categories:
- Mopeds: under 50cc, designed to give a maximum speed of 45km/h, minimum age 14
- Small motor bikes: less than 125cc and 13hp, minimum age 17 for an AL license (16 for bikes of under 80cc with a maximum speed of 75km/h)
- Motor bikes: over 125cc, maximum power 100hp, open to 18-year-olds with an A license

In addition, new regulations were laid down concerning two-wheelers' lights and indicators (officially approved headlights, lateral reflectors at rear).

(5) Additional regulations were introduced for heavy goods vehicles:
- Rules concerning rear bumpers were harmonized with the EEC directive.
- Lorries of 10 t and over must be equipped with speed limitation devices corresponding to the permitted maximum.
- Lateral bars are mandatory to prevent pedestrians and cyclists from being run down.
- For the same reason, additional rear-view mirrors are now mandatory to comply with the new EEC directive.

Furthermore, the "lorries for the future" project (which forms part of the "Virages" program) is going ahead and its effect on road safety will be evaluated shortly.

(6) The following measures have been taken in respect to motor cars:
- Safety laminated windscreens have been made compulsory.
- Mandatory roadworthiness tests are to be introduced shortly for all cars that have been involved in accidents, as well as for all secondhand cars over 5 years old each time they change hands.
- An agreement has been reached with motor manufacturers and importers to refrain from advertisements stressing maximum speeds that exceed legal limits.
- All motorists are now subject to stiffer speed restrictions when it is raining.

In addition, with a view to taking advantage of the latest technical developments for making driving easier, a tender has been launched inviting manufacturers to bid for the supply of six types of driving aid. They are concerned with information about road conditions, drivers' lack of attentiveness, avoiding obstacles, additional devices for near rear-view vision, limits on visibility and speed in fog, danger of skidding, and loss of tire pressure.

To improve the protection of car occupants in head-on collisions, France and West Germany have proposed a joint program of experiments aimed at a more accurate and realistic assessment of protection when new official standards are laid down in the future. As far as side-on collisions are concerned, France is participating in the studies and consultations that are taking place at a European level, such as those being conducted by the European Experimental Vehicles Committee. The results of some of this research will be presented at this conference, along with those of other research work dealing with all aspects of the fight against road accidents.

To complete this summary of current developments and initiatives, I should point out that ONSER (the National Road Safety Agency) and IRT (the Transport

Research Institute) have been merged into a new public research establishment, with a view to giving greater scope for developing transport research in general and road safety research in particular.

Status Report of the Netherlands

Pieter W. Hoekstra
Ministry of Transport and Public Works,
The Netherlands

For the first time representing our Government at an ESV conference in many years, it is my pleasure to present here a short statement on Dutch policy and activities regarding safety of road vehicles. After many years of following at some distance the experimental work on safer vehicles, the Netherlands has become more involved in the past few years; both as far as research work by private institutions is concerned, such as governmental activities in planning and sponsoring such work and other measures, and through contribution to and preparation of international requirements.

One of the reasons for this involvement is the remaining number of traffic casualties. As in most countries, the total number of both killed and injured in traffic has gone down from an absolute maximum of 3,264 killed in 1972 and 72,167 injured in 1971 to 1,710 killed and 52,212 injured in 1982, both lowest figures since 1966. (For 1984, 1,610 casualties are indicated, but a recent study says that the development is less positive; the registration rate seems to have diminished.)

Nevertheless these figures represent an enormous amount of harm and misery, and, of course, material or financial damage (recently a figure of 7 milliard guilders, or some 1.5 milliard pound sterling has been calculated for 1984).

Among these remaining casualties in our country in 1982, 260 pedestrians were killed and 5,117 were injured by road vehicles (15.2 and 9.8 percent). Figures for bicyclists are especially high in our country: 372 (21.7 percent) resp. 12,897 (24.7 percent); for mopeds: 143 (8.4 percent) killed and 12,380 (23.7 percent) injured. These categories amount to 45.3 percent killed and 58.2 percent injured; a large part of them crashed with cars (50 percent if private cars are considered, 80 percent if HGV's and vans are included). EEVC produced reports on these problem areas during the Ninth ESV Conference in Kyoto 1982 (pedestrians) and at IRCOBI, Delft 1984, and this ESV Conference 1985, regarding bicyclists and moped riders.

Consequently, the Dutch Government gives high value to the vulnerable road users: children, elderly, handicapped, pedestrians, cyclists, moped riders, and drivers of motorcycles. For pedestrians and cyclists, we work on the outside/front construction of cars; for handicapped, on easier and safer transportation in road vehicles through fixation of better constructed wheelchairs. At the same time, we think that by changing car designs, much can be gained for people in cars. These road users also deserve our special attention because roughly one out of every two road traffic casualties was seated in a car.

Some of the measures under consideration, after the introduction in recent years of a front seatbelt use obligation, helmet use for mopeds and motorcycles, and safety seats and systems for children, are the following:

1. Extra mirror for the off-side of HGV-cabs
2. Slow-moving vehicle warning plate
3. Side reflection for bicycles (January 1, 1987)
4. Improved side protection on HGV's for pedestrians and two-wheelers
5. Making cars less aggressive toward pedestrians and two-wheelers
6. Draft ECE regulation on side protection in passenger cars
7. Installation of seatbelts in the rear of cars (1987 or 1988)

Of course such proposals form only part of our traffic safety policy. Many other activities aim at preventing accidents:

- Physical planning (towns, roads)
- New types of restricted areas (like "woonerf"), the so-called 30km/h zones
- Antialcohol campaigns and measures
- Education
- Emergency services
- Improved organization of and communication within the Administration at all levels

For 1984 and 1985 a National Traffic Safety Scheme was published, listing among others some 125 measures, problems, and research areas. This scheme will be updated yearly to provide a continuous guideline and program of work. (A summary was published in 1984 by UNO/ECE in Doc. TRANS/SCI/GE.20/R.223.)

We look forward to a fruitful conference, where once more information may be brought forward that will help us, motor vehicle manufacturers as well as governments, to make decisions that will benefit the road users in traveling more safely than today. We count on international cooperation in research as well as in drawing up new legal requirements, preferably on the basis of internationally harmonized and recognized requirements as set up in ECE WP29 and/or EEC.

Status Report of Sweden

Professor Dr. Bertil Aldman
Swedish Transport Research Delegation,
Chalmers University of Technology

The positive trend in Sweden, indicated by decreasing numbers of police-reported road accidents since 1970, was unfortunately broken 2 years ago. In 1983 the number of injury-producing accidents increased by 3.7 percent from the previous year. An additional increase of 4 percent was reported in 1984. The accidents of last year resulted in 717 fatalities, 4,882 severely and 10,792 slightly injured people. The number of accidents was highest in built-up areas where an increase by 6 percent was reported. One explanation for this unfortunate development may be that the number of vehicles on the roads is increasing again after some years with almost constant numbers.

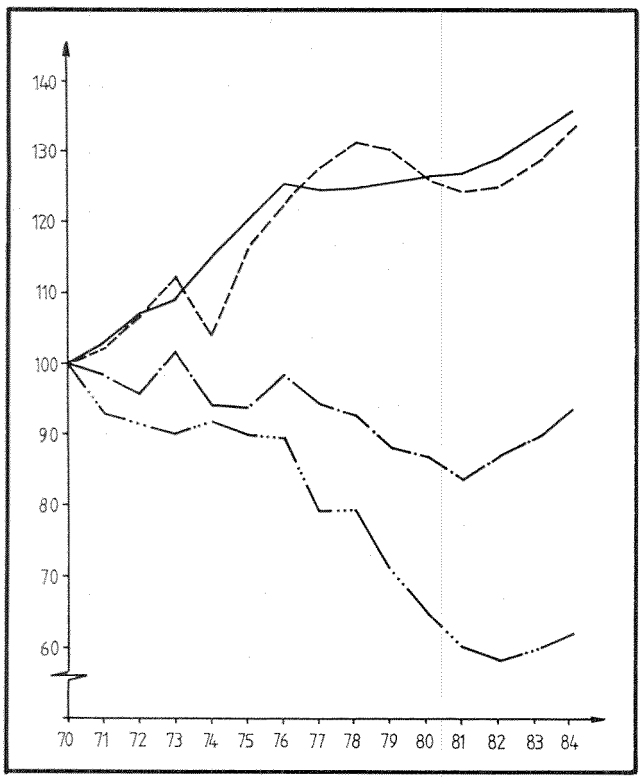

Figure 1. The development of vehicle registration, fuel consumption and casualties 1970-1984.

The negative trend for two-wheelers was particularly disturbing, and in December 1983 the Swedish Government appointed a special group of experts to deal with this problem. Its task was to initiate coordinated efforts toward better safety for pedal- and motorcyclists. The actual work was carried out by three subgroups, and some of their proposals have already been implemented.

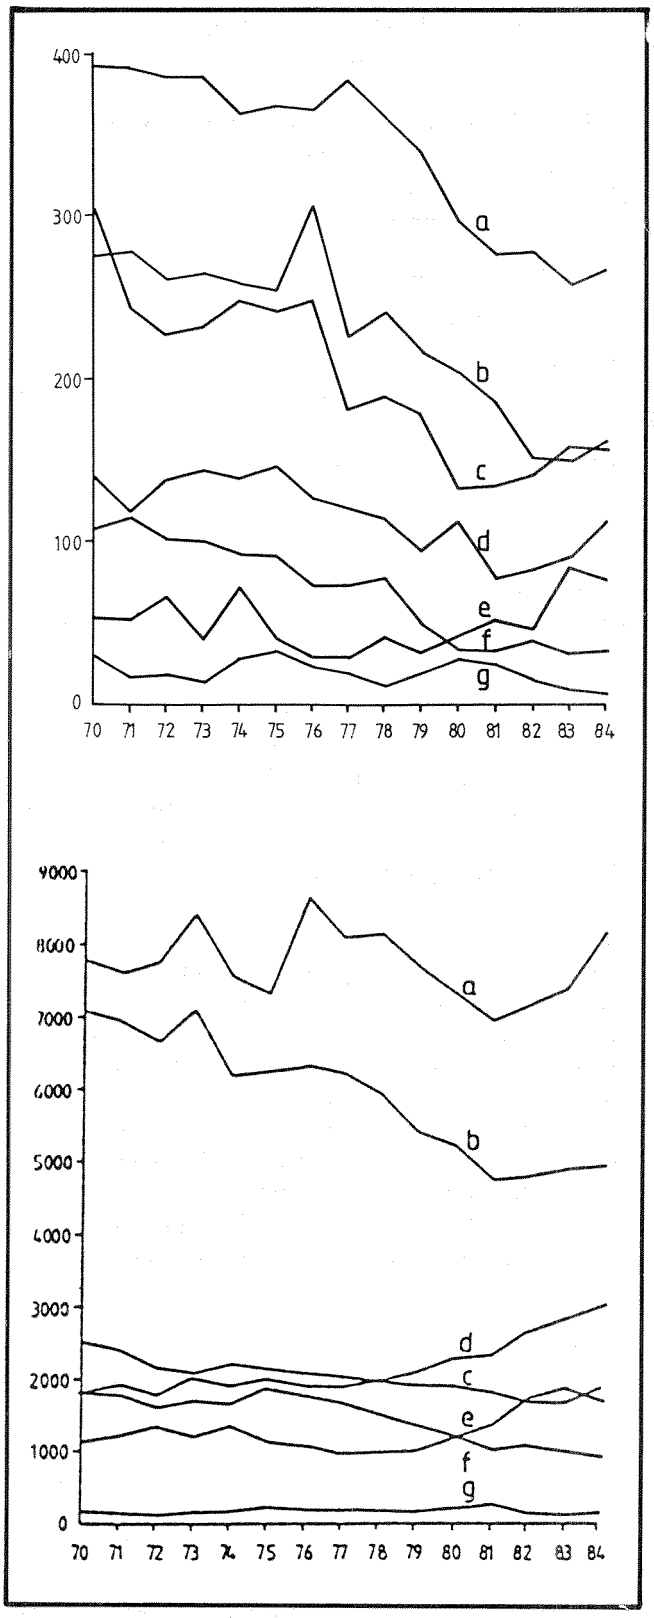

Figure 2. Number of people killed (top) and injured (bottom) in road accidents 1970-1984.

The recommendations regarding motorcyclists include the following items:

- Improved training for driving instructors and additional training for the staff carrying out driving tests will be instituted.
- Motoryclists will be taught how to drive with a pillion passenger and will have more driving hours on rural roads before they get their license.
- They will be trained in estimating their vehicle's turning capacity and be taught the technique and hazards involved in turning, particularly with a pillion passenger.
- They will also be trained in using the vehicle's full braking capacity both when going straight and during evasive maneuvers. Driving tests will include braking from 50, 70, and 90km/h.
- Condensed, 1-day courses will be available for continued training of those holding a driver's license for motorcyclists.
- A standard will be prepared for type approval of protective clothing for motorcyclists.
- Measures will be taken to improve the visibility of motorcycles.

Status Report of Japan

Takashi Shimodaira
Deputy Director of the Engineering and Planning Division, Land Transport Engineering Department, Regional Transport Bureau, Ministry of Transport

It is a pleasure to know that a series of ESV international conferences have produced many fruitful results since the first ESV international conference was held in Paris in 1971. Also, it is a pleasure to see that the ESV conferences have been playing a significant role in enhancing the safety of motor vehicles.

Nevertheless, in view of the current situation in which a great number of persons are killed or injured due to road traffic accidents, we believe the furtherance and strengthening of traffic safety measures are indispensable to insure the healthy and cultural living of people.

As for the trend of road traffic accidents in Japan, the number of annual casualties was on the decrease after 1970 when a peak number was reported. This trend was reversed in 1980. Since then the number of annual casualties has been on the increase. The government-conducted forecast survey of traffic accidents in the future reveals this increase trend will continue. It estimates the number of casualties will reach about 10,600 in 1990, while the number of accidents will reach about 576,000 in the same year. According to statistics of road traffic accidents in 1984, the death toll was 9,262, representing 7.7 persons per a population of 100,000. Furthermore the number of persons injured reached 644,000, representing 536 per a population of 100,000. When the accident cases were broken down according to the category of accidents, motor-vehicle to motor-vehicle accidents accounted for about 80 percent. Also, the majority of these accidents were head-on accidents and rear-end accidents. In regard to other kinds of accidents, motor-vehicle accidents involving pedestrians accounted for about 15 percent, whereas those accidents involving motor vehicles accounted only for about 5 percent.

The foregoing statistics of road traffic accidents classified by the category of accidents show that motor-vehicle to motor-vehicle accidents far outnumber other kinds of accidents. However, as far as motor vehicle fatalities are concerned, the combined number of the killed pedestrians and bicycle riders accounts for 40 percent. This fact behooves Japan to exert more efforts on safety measures for pedestrians and so forth than other countries.

With a view to preventing road traffic accidents and tackling its countermeasures with efforts of the whole Nation, the Fundamental Law Related to Traffic Safety Measures was enacted in 1970. Based on this law, the traffic safety basic planning has been made at intervals of 5 years. Moreover, wide-ranging safety measures, including keeping the traffic safety facilities in good condition, have been promoted totally and powerfully. At present, the Third Planning, which covers a period of fiscal years 1981 through 1985, is underway. A wide variety of measures have been promoted with emphasis placed on realizing a safe, comfortable traffic society—one that makes it possible for people and motor vehicles to co-exist and that is benefiting the motor vehicle society.

As a concrete road traffic safety measure achieved recently, the use of seatbelts by drivers and passengers of motor vehicles becomes a statutory obligation effective September 1985. It is expected that the rate of wearing seatbelts will increase sharply and fatalities owing to road traffic accidents will decrease significantly with this statutory provision.

On the other hand, as for the safety measures from the viewpoint of motor vehicle construction, they have been progressing steadily toward a stage of practical use, based

on the technical development accomplished through ESV and RSV vehicles. Concretely, we can cite the following accident preventive measures:

(1) Measures where the drivers' ability to prevent accidents is assisted from the side of motor vehicles, the reduction in drivers' burdens, the use of abnormality warning devices for systems, and so forth

(2) Measures to enhance accident preventive performance inherent in motor vehicles themselves, improvements of controllability, stability and braking performance, the use of fail-safe mechanisms, the installation of impact-absorbing-type bumpers, and so forth

Furthermore, for safety measures in the event of accidents we can cite the following:

(1) Occupant protective measures, the use of devices that take into consideration insuring a safe space for occupants, the restraint of occupants and impact reduction, and so forth

(2) Preventive measures for motor vehicle fires, the prevention of fuel leakage in the event of collisions, etc., the adoption of flame-resisting materials of interior appointments, and so forth

From now on, it is expected the number of various systems incorporating electronic control equipment will increase rapidly. Hence we believe it is urgently needed to make these systems safer and more reliable.

Regarding the motor vehicle safety standards in Japan, they are to be stipulated progressively in accordance with the Second Enlargement and Strengthening Targets of motor vehicle safety standards set forth in October 1980. We have been exerting efforts to further the research activities necessary for achieving these targets.

As an example of revisions of the safety standards, the maximum permissible luminous intensity of headlamps was raised in October 1983. Also, the performance requirements of other lamps were harmonized with international standards.

In addition, draft standards were completed as to the following subjects in June 1985, while taking into consideration the harmonization with those standards of other nations:

(1) Enlargement of categories of motor vehicles where the installation of seatbelts is compulsory and enlargement of applicable seats

(2) Installation of front windshields made of penetration-resistant, laminated glass, as has been the case with European countries and the United States

(3) Strengthening of fuel leakage preventive requirements in the event of rear-end collisions

With respect to these draft standards, in accordance with the GATT Agreement, we have already notified those persons concerned in the relevant nations so we may hear their comments.

With a view to promoting the importation of foreign-made motor vehicles, the government of Japan has been endeavoring to further the rationalization and internationalization of our standards and certification systems.

Concretely, as for the certification procedures, we have stipulated the following measures for the sake of convenience for overseas motor vehicle manufacturers:

(1) Dispatch of examining officials abroad

(2) Acceptance of results of tests conducted by foreign official testing institutes

(3) Handling system of small quantity motor vehicles

Since August 1983 the type designation system has been drastically simplified.

With regard to implementation of motor vehicle standards, the government of Japan has been paying thorough consideration to various aspects, such as insuring of safety, harmonization with the standards of foreign countries, and hearing opinions from those in foreign countries concerned with the process of preparing the standards.

In October 1983 as many as 12 items of the Safety Regulations for Road Vehicles were revised to attain harmonization with the counterpart standards in European nations and the United States.

Besides the aforesaid measures, we have been taking all possible measures, including positive participation in the WP29 as the international uniform standards planning activities.

With respect to the drafting activities for international uniform standards for motor vehicles, we intend to participate positively in their activities in the future through meetings of the ECE WP29. Thus, we are determined to make our utmost efforts to fulfill an international role as the second largest motor-vehicle-producing nation.

Status Report of the United Kingdom

David Lyness
Head of Vehicle Standards and
Engineering Division, United Kingdom
Department of Transport

I have pleasure in reporting that since the 1982 Experimental Safety Vehicle Conference in Kyoto, there has been progress both through the introduction of new regulations and the fruition of research work toward improving the safety of vehicle occupants, pedestrians, motorcyclists, and other road users in the United Kingdom.

Compulsory Seatbelt Wearing

At the Kyoto conference, it was announced the United Kingdom intended to introduce compulsory wearing of seatbelts for front seat occupants in cars and similar vehicles with effect from 31 January 1983. In our view, this has been a very successful measure. Since the implementation of this law, we have observed a consistently high wearing rate (well in excess of 90 percent) among those required to do so. This in itself is a very impressive result when compared with the wearing rate of around 35 percent in 1982, the year before the new regulation went into effect, and compares very favourably with the wearing rates reported by most other countries.

Our regulations have been introduced for 3 years, ending January 1986, after which they will lapse unless renewed by Parliament. Parliamentary debate on whether compulsion should continue will take place toward the end of the year. Already the pros and cons of the existing requirements are a matter of public controversy, and much has been written about certain side effects. The facts remain, however, that in the first 23 months of compulsion, February 1983 to December 1984, there were 690 (17 percent) fewer deaths and 12,153 (22 percent) fewer injuries to front seat occupants of cars and light vans compared with the corresponding period before the regulations.

These results were achieved with the seatbelts on the current car fleet and show that the current designs of seatbelts perform well. However, there is room for improvement in seatbelt design. For example, TRRL is investigating methods of reducing the forward movement of a seatbelt wearer without causing injury. There is reason to believe that quite small changes in the detailed design of seatbelts could bring substantial additional benefits in future years.

Rear Seatbelts

The restraining of rear seat passengers provides further scope for reducing casualties. At present we are considering making mandatory the fitting of rear seatbelts, with child restraints or disabled persons' belts as permissible alternatives.

Improved Design of Steering Wheels

Information from accident studies and other research work has shown that drivers wearing seatbelts can be subject to injuries of up to AIS 2 due to the face hitting the steering wheel. Later in the week, TRRL will report on the work they have carried out aimed at reducing this type of injury. A modified test procedure has been developed using the standard pendulum procedure but with an aluminum honeycomb-faced head form. We believe tests have shown that the modifications suggested by TRRL can be readily incorporated into vehicle design and that such changes will produce worthwhile benefits.

Accident Studies

For well over 10 years, the United Kingdom has had programmes running, almost continuously, to collect and analyse data relating to car accidents. Although such exercises are costly and difficult to finance, we are at present in the process of planning to extend this work until about 1989. The current studies are carried out for the Department of Transport and other sponsors by the Universities of Birmingham and Loughborough, using data collected by the universities and by the Department's Vehicle Inspection Division. This work will be described to you in more detail during the course of the conference.

Current Levels of Car Occupant Protection

TRRL has carried out a series of tests on six models of recent design by leading manufacturers around the world. The tests included front and side impacts and checked much of the interior for resistance to head form impact. When compared with earlier and similar tests on designs of 10 years ago, I am pleased to report there has been a distinct improvement in occupant safety, particularly from frontal impacts, even if not from side impacts. It is encouraging to report that a number of manufacturers

are designing well in advance of the current mandatory requirements. The test programme and the results will be presented in a TRRL paper later.

Side Impact Protection

At the Kyoto conference, we expressed concern that it had not been practicable to establish minimum mandatory standards for side impact performance. Sadly that is still the case. The work on a manikin and deformable barrier essential for a mandatory requirement continues, but there is still some way to go before we have a practical test. As an alternative to the full-scale test, we in Britain consider that more attention should be given to subsystem requirements—at least as an interim measure. For example, it would be feasible to legislate against unnecessarily stiff armrests, which can be tne cause of internal injuries. We have put this idea to ECE with the proposal it should become a common European requirement. We believe such a measure will constitute a worthwhile, albeit a small, step in reducing injuries from side impact. We intend to continue searching for similar areas where worthwhile improvements can be made.

Pedestrian Protection

It is now possible to put forward a set of design guidelines for the frontal area and bonnet (hood) tops of cars. Designs following these guidelines should much reduce the severity of leg injuries and soften the impact at many places likely to be struck by the heads of both children and adults. In the outdoor exhibition, you can see how these guidelines can be applied, for example, to an Austin metro. TRRL will present a detailed description of this work. There are several papers later in the conference dealing with pedestrian protection, and I draw attention in particular to that from EEVC. I urge all manufacturers to take note of this important exhibit and of the guidelines, which indicate a potential saving of some 33-1/3 percent of serious injuries and 10 percent of fatalities.

Motorcycles

Motorcyclists and pillion passengers in the United Kingdom comprise about 30 percent of the total number of motor vehicle users killed, this despite the fact that motorcycles amount to less than 3 percent of motor vehicle traffic. In the United Kingdom, we have been working on several ideas to improve the safety of motorcycles. In particular I would draw your attention to the antilock braking system that is now undergoing service trials with several police forces in this country. The leg guard shown is an advanced design that has performed well under test and is a design we believe with a little more work could be incorporated in production machines. These developments give the prospect of major improvements in motorcycle safety in the long term. More immediately we intend to introduce the newly agreed ECE standard for wet braking into our national regulations.

Buses and Coaches

In general, buses and coaches have a very good accident record, but there are some areas that need attention. One such area is a standard for the structural strength of coaches to mitigate the results of rollover accidents. There has been a very recent agreement in ECE to a suitable specification for structural strength, and we intend to introduce this specification into our national rules for the construction of coaches.

Goods Vehicles

A great deal of progress has been made to improve the safety of heavy lorries. At Kyoto it was reported we were investigating a basis for U.K. requirements for underrun guards and sideguards for lorries and trailers. We now have mandatory requirements for sideguards to be fitted to all new lorries and trailers and to existing heavy trailers. Rear underrun protection is also required on all new lorries and trailers. We are also investigating the practical application of front underrun devices to commercial vehicles. On display is an example of a device developed by TRRL and industry that has proved satisfactory under test. We continue to encourage the fitting of antilock braking systems to heavy goods vehicles, and over 80 percent of trailers are now being fitted with antilocks as standard equipment.

Finally, we have made mandatory antispray devices on all new trailers, and these requirements will be progressively extended to new motor vehicles (October 1985) and existing trailers in 1986/87.

Progress With and Discussion on Safety Developments for Road Vehicles

Michael M. Finkelstein, Chairman, United States

PSC1—A Demonstration Car with Improvements for Pedestrian Protection

C.A. Hobbs,
G.J.L. Lawrence, and
C.S. Clarke
Transport and Road Research Laboratory, Department of Transport, Crowthorne, Berkshire, United Kingdom

Abstract

A demonstration pedestrian safety car has been produced based on the Austin Metro car. The modifications did not require the use of materials not already familiar to the motor industry, and changes to the car's styling were limited. The modifications have been shown to give substantial improvements in the level of protection offered to adult and child pedestrians up to impact speeds of 40km/h. In particular, the most frequently injured body region, the lower limbs, was afforded much increased protection. Tests on the head impact area indicated that worthwhile reductions in child head injuries could be expected. It should be possible for modifications of the type made to this car to be incorporated in other production cars, in which case significant reductions in pedestrian injuries could be expected.

Introduction

Following a cooperative project carried out by TRRL and Austin Rover(1), it was decided to produce a demonstration pedestrian safety car (PSC1) designed to give improved protection to adult and child pedestrians in impacts up to 40km/h (25mph) (Figure 1). The car was based on the Austin Metro, this being the car chosen for much of the earlier work. The modifications were carried out without using new materials or manufacturing techniques—the aim being to demonstrate that worthwhile improvements in pedestrian protection could be achieved without radically altering a current car. No attempt has been made to incorporate any safety features for car occupants. It is recognised that pedestrian safety requirements would need to be integrated with those of other road users. The effectiveness of the modifications was tested by impacting the car into adult and child pedestrian dummies. Additional headform impact tests were carried out to check those parts of the head impact area not hit by the dummy heads.

This project was carried out by TRRL in cooperation with Austin Rover Group Ltd. and DA & PR Simpson Ltd.

Pedestrian Accidents

Of the 60,000 U.K. pedestrian casualties each year, about three-quarters are hit by cars, most of them hit by the front. About 35 percent of the casualties are children under the age of 15, and 20 percent are under 10(2).

Figure 1. PSC1—pedestrian safety car

Accidents with impact speeds below 30km/h (19mph) have been shown to result in predominantly minor (AIS 1)(3) injuries, with those above 30km/h being predominantly more severe than minor(4). The transition from predominantly survivable to predominantly fatal injury is between 50 and 60km/h. Further analysis predicted that a car front that eliminated serious injuries induced by vehicle contact, at speeds up to 40km/h, would result in a 30 to 40 percent reduction in the number of seriously injured pedestrians(5).

The most frequently injured parts of the body are the lower limbs and head, with fatal injuries being predominantly to the head. In general, injuries to the lower legs and knees result from impact with the bumper. The upper legs and pelvis are injured by the leading edge of the bonnet, and the head from contact with the windscreen, its surround, the scuttle, bonnet, or wing tops. The stiff areas, which are of particular concern, are the windscreen surround, joints between bonnet and scuttle or bonnet and wing, and the bonnet where it is supported by a stiff frame or where there are stiff structures close to its underside. On the scuttle, the wiper spindles present the additional risk of penetrating injury.

Because of the Metro's short bonnet length, most adult heads would impact the windscreen. Head contact with the bonnet top and scuttle should be restricted to children and short adults. The stiffest part of the bonnet is at the hinge mounts. Immediately below the bonnet are the carburettor, the rocker cover with its oil filter, the brake master cylinder, and the battery. These could each be contacted if the head hit the bonnet above them.

Modifications To Improve Pedestrian Safety

Bumper Area

Because of the high initial force necessary to displace a complete bumper assembly, a locally compliant bumper was required. Adoption of a tall bumper-air dam assembly should give a large leg contact area, and if the lower edge were contacted first, then this should overcome foot to ground friction early in the impact. Early tests showed that the most uniform bending moment in the adult's lower leg was obtained if the bumper to air dam force was split in the ratio 60:40.

The high cost of manufacturing a mould prevented the production of a new bumper skin; therefore, standard mouldings were used. Tests on a range of plastic bumpers in current use showed that without their inner steel reinforcements, most could be adapted to give good leg impact characteristics. The Metro bumper was found to be slightly stronger than desirable, but by removing internal flanges and returns it could be weakened sufficiently. To make the bumper assembly taller, it was combined with an air dam taken from the Metro Turbo, which was positioned immediately below the leading edge of the bumper. As an energy-absorbing medium to go behind the bumper-air dam skin, it was found the best characteristics were obtained using a low-density, rigid polyurethane foam, cored to reduce its stiffness. A maximum crush depth of 150mm was provided. As the polyurethane foam was produced using the bumper-air dam as a mould, it was possible to use it to support the assembly along its length. Additional sliding clips were fitted between the bumper ends and the front wings. Although this construction performed satisfactorily, the use of a weaker outer skin and stiffer foam would be preferable.

Even though a bumper of this type has local compliance when hit by the almost line contact of a leg, much larger forces would be generated when hit by a wide object. Such a bumper could be satisfactory for other types of impact. However, additional strengthening may be needed behind the crushable bumper.

Bonnet Leading Edge

Although the leading edge of the Metro's bonnet is not itself sufficiently strong to pose a problem for pedestrians, it is supported by the bonnet lock platform, which is supported by the radiator that sits on the lower front cross member. To reduce the effect of this support, the bonnet was extended 75mm forward. The bonnet lock platform and radiator were left where they were though it was necessary to extend the platform forward to support the grille. An advantage of extending the bonnet was the ability to accommodate the extra bumper crush depth without the need for it to protrude unduly.

Headlight and Grille Area

The headlights, grille, and front wings were extended forward to correspond with the bonnet leading edge but were softened to reduce their potential to cause injury. Metro headlights are mounted in enclosed units with internal beam adjustment. The mounting arrangement was changed to allow the headlight units to collapse rearward if impacted. The mountings for the grille were arranged so it would not form a strut supporting the bonnet leading edge. To remove the hazard of their stiff leading edges, the front wings were made with separate leading edge sections that could break away on impact. Though these leading edges are steel on the demonstration car, in production they could be made in plastic.

Bonnet

With the bonnet area, the most difficult problem is posed by the closeness of under-bonnet structures. As a crush depth of up to 100mm is required to achieve satisfactory decelerations for an adult head, adequate clearance over stiff structures is essential. Clearance can be achieved in three ways: the components could be lowered, the bonnet could be raised, or a mechanism could be incorporated that would detect the initial impact and elevate the bonnet in anticipation of head contact.

With the Metro, lowering the under-bonnet structures is not feasible. Although the carburettor and oil filter could be moved, moving the rocker cover would involve lowering or tilting the engine. Lowering would result in insufficient ground clearance, and both would be technically difficult. The brake master cylinder is mounted vertically above the servo on the bulkhead. Space limitations make moving them difficult. On the other hand, lowering the battery would not be difficult.

The third option, that of elevating the bonnet at the time of an accident, has been considered and work is in hand to develop such a system. If a satisfactory method could be developed, other measures such as improving the scuttle and windscreen lower edge may prove unnecessary.

In the demonstration car, the second option has been adopted. The rear of the bonnet has been raised by 50mm. This has provided adequate clearance at the bonnet's rear for an adult head impact. Toward the centre of the bonnet, where a child's head would impact, clearance is also increased. As there was little increase in clearance toward the front of the bonnet, the battery was lowered, even though the likelihood of head contact in this area is small.

To eliminate the stiff joint between the bonnet and wing, the joint was taken over the side of the car. The line of the new bonnet joint was dictated by the inner wing panel and styling considerations. With a new design, it would be desirable to have the joint a little lower.

The bonnet strengthening frame on the Metro is essentially V-shaped with two top hat sections going between the centrally mounted bonnet lock at the front and the two hinges at the rear corners. An additional strengthening plate spans the V about halfway up the bonnet (Figure 2). For head impact considerations, an ideal bonnet would have almost uniform stiffness. To achieve this, a considerable amount of work would be needed on the development of a strengthening frame. In the time available, it was necessary to modify the existing frame in an attempt to achieve satisfactory performance. This was done by drilling holes along the edge of the top hat sections adjacent to the bonnet skin. The cross plate was weakened by slitting it lengthwise and shortened so that it did not reinforce the top hat sections. At the front, the bonnet lock and antirattle pads were mounted on collapsible pillars (Figure 3).

Windscreen Surround and Scuttle Area

The windscreen surround is stiff and presents a narrow contact area. Any major improvement in the crush characteristic of the windscreen pillar would almost certainly result in a reduction in driver visibility and possibly in roof strength. Although improvements to the leading edge of the roof should be possible, there has been insufficient time for this area to be considered.

The lower windscreen edge forms part of the scuttle where there is more potential for improvement. On the Metro, the scuttle is cantilevered out from the lower windscreen edge and is relatively soft, other than at the windscreen edge. However, mounted on the scuttle are exposed windscreen wiper spindles. As the bonnet could not be extended rearward over the scuttle area without a redesign of the hinging arrangement, a new scuttle panel

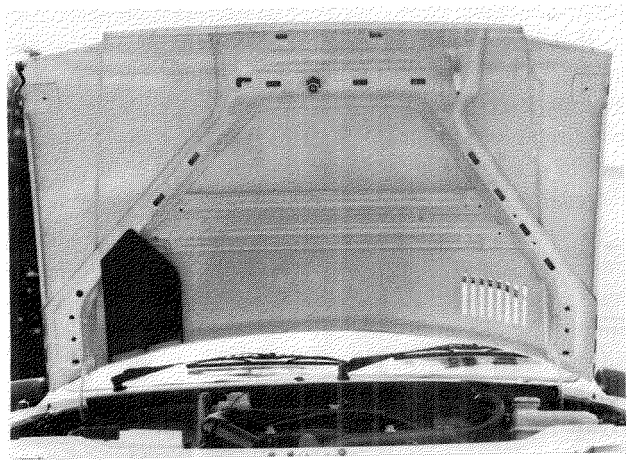

Figure 2. Metro bonnet frame

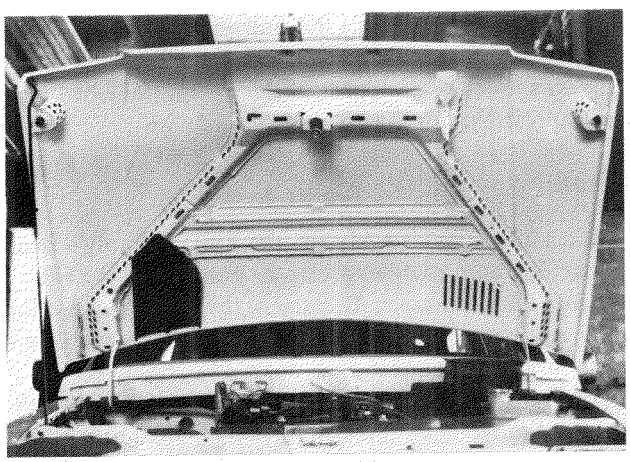

Figure 3. PSC1 bonnet frame

was fitted above the original. The original scuttle panel was angled downward and the wiper spindles repositioned to increase their clearance beneath the new scuttle. The panel was then used to support the new scuttle panel above it. This arrangement provided for collapse of both panels, as a sandwich, as well as collapse of the top panel. In this way, the scuttle was prevented from bottoming out on the spindles. The windscreen edge itself was weakened by slotting the return in which the windscreen rubber locates.

Safety Performance Evaluation—Dummy Tests

A prototype of PSC1 was tested by being impacted at 40km/h (25mph) into a 50th percentile adult pedestrian dummy(6) and a 50th percentile 6-year-old child dummy. These tests were each carried out on the centreline of the car and offset toward the side, virtually in line with the centre of the car's headlight. For comparison, the same tests were carried out on a standard Metro.

The child and adult dummies were instrumented to measure accelerations of the head, thorax, and pelvis and to measure the bending moment in the middle of the upper and lower leg first hit by the car. On the adult dummy, additional measurements were made of the bending moments at the hip and the top of the lower leg, and of acceleration at the knee.

Because of the way the car was modified, the original tests were carried out with the bonnet leading edge mounted about 40mm too low. Subsequent centreline tests were performed with the bonnet leading edge at the correct height and with the bumper weakened by additional coring of the foam.

The target limits for the head have been taken as a Head Injury Criterion (HIC)(7) of 1,000 or agreement with the Wayne State criteria(8). Preferably the head should not sustain an acceleration of over 80g for a period exceeding 3ms. For the thorax and pelvis, a Severity Index (SI)(9) of 1,000 and an acceleration of 60g for 3ms have been taken. For the knee, a limit of 60g for 3ms was used with the rest of the lower limbs having a limit of 200Nm for 3ms(6).

Head

With the standard Metro, the child dummy's head impacted about halfway along the bonnet and the adult's head on the windscreen. Because of the forward extension of the bonnet on the modified car, the impacts were a little further forward.

With the child dummy and the modified car, while the forward movement of the body had resulted in the head moving vertically downward, the head had not started moving in the direction of travel of the car by the time it hit the bonnet. By this time, the pelvis was travelling at about the speed of the car. As the body became horizontal, forces transmitted up the spine caused the head to accelerate suddenly toward the pelvis. Because of the inelastic nature of the dummy's spine, this resulted in high vertical accelerations on the head at precisely the same time the head hit the bonnet. This is a phenomenon not seen before and is probably not a realistic representation of a human, where the spine is slightly elastic. Because of the short duration of this vertical acceleration, about 2ms, only a small time difference is required to reduce substantially the effect on the head's resultant acceleration.

With the child impacted on the standard Metro's centreline, the head hit the bonnet above the central plate of the bonnet frame. This gave an HIC value of nearly 1,300 and a 3ms exceedence level of about 140 (Table 1). When the child was impacted toward the side of the car, the head hit the bonnet near to, but not over, part of the V frame. In this case, the HIC was about 1,000 and the 3ms level about 100. In neither case was any contact made with any structure below the bonnet. With the modified car, the head accelerations were a little lower but were affected, as previously stated, by the timing of the force transmitted up the spine.

With the adult, the centreline test on the standard car gave an HIC of about 600 and the side test gave one of nearly 700. The 3ms exceedences were about 80 and 100, respectively (Table 2). With the modified car, the head accelerations were slightly higher, though still acceptable.

When tested, the bonnet frame on the modified car was unaltered in the child's head impact area. Modifications carried out later should reduce the child dummy's head acceleration, but their effectiveness has not yet been checked with the dummy.

Thorax

In general, the thorax was not found to be a problem area and indeed accident data support this assertion. However, with the standard Metro, the 3ms exceedence level on the child was slightly high at around 70g. The initial modifications brought these levels down. However, they appeared to be closely related to what happened to the legs, and subsequent alterations to the bumper increased the accelerations to this level again.

Pelvis and Hip

On the adult dummy, pelvic accelerations and hip bending moments with both the standard and modified cars were low and did not give cause for concern. With the child, however, the standard car gave very high pelvic accelerations with 3ms exceedence levels of around 130 and 150 for the centreline and offset impacts, respectively. In both cases, the SI was above 2,000.

Table 1. Results of car to child dummy tests at 40km/h (25mph)

* Following correction to ride height and weakening of bumper

The modified car gave much lower values, with a 3ms exceedence level of about 80g and SI's of under 1,000. Later modifications to reduce leg accelerations increased the 3ms exceedence level to nearly 90g. Post-impact examination of the bonnet revealed that the frontal extention of the bonnet frame had resulted in a locally stiff area, at the point where the extension was joined to the original frame. In the impact, a plastic hinge was formed at this point, and it is thought this allowed the pelvis to partly interlock with the bonnet. This could have given rise to higher than necessary accelerations. On the demonstration car, the bonnet frame has been modified in an attempt to avoid this hinge, and tests will be carried out to see whether these modifications have improved the situation.

Legs

With the standard car, the leg accelerations and bending moments were all very high. In impacts at this speed, it is clear that very serious damage would be done to a pedestrian's legs. For the child, upper leg bending moments of around 600Nm were measured. The lower leg bending moments were also high at between 260 and 340Nm. With the adult, the highest bending moments occurred at the top of the lower leg. Here the 3ms exceedence levels were about 500Nm.

The modified car gave a greatly improved performance. With the child, initial tests gave 3ms exceedences for the upper leg of under 200Nm and for the lower leg of just over 200Nm. Subsequent centreline tests with the bumper weakened slightly more gave even better results, with a 3ms exceedence level of around 135Nm for the upper leg and 160Nm for the lower leg. Although improvements were made for the adult, particularly to the top of the lower leg, it was not possible to get the levels as low as would have been desirable. Nevertheless, the leg injuries that would be sustained in a severe impact such as this would have been substantially reduced in severity.

Safety Performance Evaluation—Headform Tests

To check those parts of the head impact area not hit by the dummy, headform impact tests at 11m/s were carried out. This impact velocity is toward the top of the range of expected head impact velocities. The only headform presently available for use with the air gun was adult size.

The headform impacts were carried out on both the standard Metro and the modified car at the following locations:

- Scuttle midway between the nearside wiper spindle and the windscreen lower corner
- Scuttle over the offside wiper spindle
- Scuttle at the base of the windscreen pillar
- Scuttle at the windscreen lower edge

Scuttle Midway Between the Nearside Wiper Spindle and the Windscreen Lower Corner

On the standard Metro, an HIC of just under 800 was recorded with a 3ms exceedence level of almost 100g (Table 3). With the modified car, although the impact velocity of the headform was a little higher, the HIC was reduced to nearly 700 and the 3ms exceedence level to below 80g.

Scuttle Over the Offside Wiper Spindle

The main purpose in testing at the wiper spindle was to check whether the scuttle panel bottomed out on the spindle top. Although the standard Metro gave an HIC of about 900 and a 3ms exceedence level of 100g, this is not representative of what would happen to a human head. With a real head, the wiper spindle would penetrate causing very serious injury. With the modified car, the acceleration levels were higher, partly because of the greater inertia of moving two panels and partly because the lower panel had been unintentionally stiffened when the test car was modified. A correctly made scuttle should be somewhat softer, though this has not yet been tested. More importantly, the upper panel did not contact the spindle and, as expected, both panels collapsed together with some extra collapse of the top panel. In an impact

10ms exceed.	(g)	51	69	64	68	52	79	74	79

with a human head, there would not be a penetrating injury, though accelerations would be higher than desirable.

Scuttle at the Base of the Windscreen Pillar

No attempt has been made to improve this area. On the Metro, the main box section from the front of the car joins the A-pillar just below this point. A major redesign of the car would be required to make improvements, in the absence of a bonnet elevating mechanism. On both the standard and modified cars, HIC values of between 4,500 and 5,000 were recorded with 3ms exceedence levels over 200g. In the few head contacts that might occur in this area, serious injury should be expected.

Scuttle at the Windscreen Lower Edge

Tests on the standard Metro gave an HIC value of around 800 and a 3ms exceedence of about 90g. However, this area gives a concentrated line loading so that localised forces could cause serious damage to the human head. The weakening of the windscreen edge should reduce this effect. Unfortunately, as stated previously, this area on the test prototype was unintentionally stiffened during modification and so was not suitable for testing.

Bonnet Over the V Frame Midway Between the Hinge and the Bonnet Lock

On the standard car, an HIC of about 1,800 and a 3ms exceedence of about 150g was measured. With the modified car, the HIC was reduced to about 950 and the 3ms exceedence to about 100g. A more radical redesign of the bonnet frame would probably be needed to improve on these figures.

Bonnet Over the Midpoint of the Centre Plate

By slitting the centre plate along its length combined with the weaker V frame, the HIC was reduced from about 1,250 to 900 with the 3ms exceedence level from

135g to 105g. Further reductions may be possible by increasing the separation between the half plates.

Bonnet Over the Hinge Mount

Where the hinge mounts onto the bonnet, the frame is necessarily stiff to resist hinge forces. On the standard Metro, an HIC of over 2,000 and a 3ms exceedence of 150g were recorded. The modified car gave an HIC of about 1,100 and a 3ms exceedence of about 100g. This was thought to be due to the reduced support given by the bonnet to wing joint, because of its greater distance from the hinge. Following the weakening of the V frame, which was extended around the hinge area, head accelerations at the hinge should be reduced even further. To date, it has not been possible to retest this area.

Bonnet Over the Original Bonnet to Wing Joint, Halfway Along the Bonnet

When impacted by the adult headform, the standard and modified cars gave similar HIC values of just under 1,100. Although the 3ms exceedence level was lower on the modified car, it was still over 100g. However, examination of the acceleration traces showed that for the modified car, the acceleration remained at about 35g for the first 6ms, which corresponded to a deflection of 60mm. The amount of kinetic energy absorbed in this period was more than that required to decelerate a child's head from 11m/s to rest. So it would appear that moving the bonnet joint over the side of the wing has been of benefit to the child. If protection were to be adequately provided for the adult, the joint would have to be lower on the wing, and structures under the bonnet at this point would also have to be lower.

Conclusion

The production of this demonstration pedestrian safety car has shown that substantial reductions can be readily made to the pedestrian injury-producing potential of a small car, at impact speeds up to 40km/h (25mph).

Modifications to the front of the car resulted in substantially reduced loads on the lower limbs and pelvis, particularly for the child. Although protection of the head impact areas is not complete, again worthwhile improvements were made. The problem of the head contacting stiff structures below the bonnet skin was eliminated, except in the unlikely event of an adult head hitting the bonnet at its edge. With a little further work, it should be possible to arrange for the bonnet stiffness to be even more uniform. The modifications to the scuttle were seen to prevent penetrating injuries to the head, but improvements in the areas of the roof leading edge, the windscreen pillars, and the scuttle at the base of the pillars were not attempted at this stage.

The modifications incorporated in this car have not required the use of new materials or technologies and have not radically altered the car's styling. Any additional cost in manufacturing the car would probably be small. If cars in production were built with the characteristics of this car, significant reductions in pedestrian injuries could be expected.

ESM2—A Motorcycle Demonstrating Improved Safety Features

P.M. Watson
Transport and Road Research Laboratory, Department of Transport, Crowthorne, Berkshire, United Kingdom

Abstract

This paper gives details of safety features that have been incorporated in the second United Kingdom Safety Motorcycle (ESM2). Progress on research and adoption of those features fitted to ESM1 exhibited at the Seventh International Technical Conference on Experimental Safety Vehicles in 1979 is outlined.

An assessment is made of the benefits of four of these features in relation to the saving of casualties.

Introduction

At the Seventh International Technical Conference on Experimental Safety Vehicles in Paris, June 1979, the United Kingdom exhibited their first Experimental Safety Motorcycle (ESM1)(1). This vehicle incorporated six features that were in the prototype development stage to provide solutions to the problems of motorcycle safety derived from a number of studies since 1974.

On the occasion of the Tenth International Technical Conference on Experimental Safety Vehicles, the United Kingdom now exhibits their second Experimental Safety Motorcycle (ESM2). This vehicle is based on a BMW 800cc twin-cylinder motorcycle, which is in service with a number of police forces. ESM2 has seven safety features and shows the progress made on those originally fitted to ESM1. The features are—

- Improvements in braking
- Daytime conspicuity aids
- Forward impact restraint system
- Safety fairing with leg protection
- Nonspill fuel system
- Interlocked parking stands
- Digital speedo and instruments

Brakes

ESM1 was fitted with an antilock brake system to both wheels using a system (developed by TRRL) that had originally been designed for cars. The control system was electronic. The motorcycles fitted with this system gave excellent results when tested but the device was very much in the experimental stage at that time. ESM2 is fitted with an antilock brake system to both wheels that has been developed by Lucas/Girling. This is a fully productionised, developed system. The control is mechanical and contained within each separate unit. Motorcycles are now being fitted with these units for use by police forces, and a number are already in service. This exercise is part of a field trial to assess the performance of motorcycle antilock from the point of view of effectiveness, reliability, and rider reaction.

A paper, Aspects of Motorcycle Braking(2), by Donne and Watson is being presented at this conference and gives details of some experiments with antilock brakes. The Transport and Road Research Laboratory has been promoting their use on motorcycles for 20 years.

ESM1 was also fitted with sintered metal brake pads to the calipers of the disc brakes. The problem of having inconsistent braking(3) when the discs were wet could be prevented by replacing the standard pads of that time with the sintered metal alternative. Today the problem has largely been overcome by developments in industry in response to regulations that will require new motorcycles to be tested with the brake system both dry and wet. Unfortunately there is no such requirement for replacement pad linings, whose users may have problems with inconsistent brake performance if they fit replacements of a lower standard.

In the exhibition associated with this conference, the United Kingdom is showing an experimental version of a mechanical brake incorporating a simple antilock system still under development. Promising results from experiments have been obtained on good dry surfaces and wet slippery surfaces without wheel-locking. We consider this system is best exploited on light machines with low performance. Simple antilock systems have not yet been developed for these vehicles.

Conspicuity

Studies by the Transport and Road Research Laboratory conclude that in many accidents between motorcycles and other vehicles, the other-vehicle driver did not see the motorcycle in time to avoid a collision. The subject of motorcycle conspicuity has been widely studied in many countries by researchers during the past decade, and it is generally agreed that other road users not seeing motorcycles is a major problem.

It is not possible to identify another single motorcycle safety problem that is a contributory cause in over 30 percent of casualty accidents. Particular attention has been paid to this topic to find solutions to improve the situation. Details of the joint study by The Institute of

Consumer Ergonomics and TRRL are given in the paper, "Motorcycle Conspicuity in Daylight,"(4) by Donne, Fulton, and Stroud, which is in the proceedings of this conference.

The two main options for conspicuity aids are rider-based and machine-based features. Of the rider-based options, a fluorescent jacket or waistcoat has been found to be the most effective. However, fluorescence decays with exposure to light, and garments must be stored away from light to prolong their effectiveness. Because of this decay, they need to be replaced fairly frequently. A further disadvantage with all rider-based options is that for each journey, the rider has a choice whether or not to wear the conspicuity aid. For this reason, machine-based options are to be preferred because they provide the conspicuity aid as a permanent feature. The use of headlamps has considerable appeal because they are machine-based and are generally fitted as standard. Research has shown that the use of large, powerful headlamps is beneficial but small headlamps provide no benefit. In Great Britain, over half the motorcycle population has a capacity of 150cm^3 or less and is neither likely nor required to have headlamps of adequate dimensions to provide effective conspicuity. Consequently, a requirement to use headlamps in daytime is unlikely to be of overall benefit because small machines may be put to increased risks. One solution would be to require better headlamps for small machines. One problem with headlamps is that they can be switched to full beam and cause glare in daylight. Results show the most effective machine-based option assessed was a pair of daytime running lamps, and the combined wattage required can be as low as 16 watts. ESM2 is equipped with a pair of these lamps, which has been shown to be effective for all machines. Some 80 percent of new police service machines are now supplied with this equipment. The situation for nighttime conspicuity continues to be a problem where, despite considerable effort, no adequate solution is apparent. Between one-third and one-half of motorcycle casualties occur at night because the risk per mile at night is twice as high as during the day, although the accident sites are similar. The possible introduction of two level lighting systems (Dim/Dip) for new vehicles in Great Britain may now provide an opportunity for motorcycles to be identified more easily in traffic because of the variations in light output between them and other vehicles. Future research on nighttime conspicuity will study this new system, which at present appears to be the only available option that may provide a solution.

Frontal Impacts

A frontal impact on a standard unmodified motorcycle at 30mph causes a rider to be ejected horizontally headfirst at 28mph. Fatal accidents often occur when a hard obstacle is in the path of the rider's head.

A solution to this problem is to provide a restraint system that operates for this type of impact, to reduce the rider's kinetic energy and control his trajectory. A total restraint system would not be acceptable because, in some accident situations, it is preferable for the rider to part from his machine.

ESM1 was fitted with an experimental chest pad restraint system that produced excellent results in tests for frontal impacts. It required fairly major design changes to the frame and fuel tank to assemble the unit, and it also detracted from the general appearance of the motorcycle. The paper supporting ESM1 particularly examined the problems associated with the initiation device for airbags for motorcycle applications and concluded these problems should be solved before further work could be justified on a system that otherwise had much to offer.

Further research into bag initiation by sensing vehicle deceleration concluded this could not be engineered to provide a reliable restraint system that would fire when required without inadvertent activation. Of other methods studied, it was decided to proceed using the forward movement of the seated rider as the sensor. From studies of rider trajectories in frontal impact, it became clear that a significant force was generated on the saddle by the rider moving forward at impact. This force is used to move the saddle forward a short distance against an energy absorber; this movement operates a mechanical switch that provides current to fire the cartridge, which inflates the bag in the centre of the handlebar mounting.

This system has been tested successfully on a full-scale impact rig and on a complete motorcycle with dummy rider at 50km/h into the side of a car at 90°.

With this airbag frontal impact protection system, the rider's forward velocity was significantly reduced when compared with that in a similar test on an unmodified machine.

The airbag provides the restraint system for the rider relative to his motorcycle, but other work shows that some features need attention if the best use is to be made of the airbag as a restraint. First, the stiffness of the front end components has a marked effect on the pitch of the motorcycle during impact. Cast wheels are stiffer than spoked wheels, and it has been found that because of this the pitch of the motorcycle on impact is greater when it has a cast wheel. This could detract from the effectiveness of the restraint system. Second, it is preferable for the motorcyclist to ride down in the restraint system during the soft crush of the vehicle. Third, the interaction between the knees of the rider and the padding of the safety fairing also helps to reduce the kinetic energy of the rider and is part of his trajectory control. Fourth, as pitch of the motorcycle is undesirable, a second load path has been introduced high on the motorcycle that takes the form of a tubular structure in the fairing headlamp surround, and this transmits some of the load to the main frame.

These features, together with the airbag and rider-movement initiation system, form the basis of a viable frontal impact protection system that would not require drastic redesign of the motorcycle, particularly if a fairing is fitted. It is not claimed that this system has yet been optimised. Although there is no problem with fully inflating the bag prior to the rider reaching it, consideration must be given to using a bag larger than the 70 l-devices used in these tests. Inflation of the bag was by firing a cartridge, but a system using high-pressure stored gas should be evaluated in terms of bag inflation rate, cost, and serviceability. The fairing screen forms part of the bag reaction system and could be designed as a yielding structure to assist rider deceleration. This may permit the inflation time to be increased, which could reduce the effect of a secondary impact.

ESM2 is fitted with the forward impact restraint system described. A machine that is fitted with the system and has been impacted into the side of a car is also on display.

A paper by Chinn, Donne, and Hopes, "Motorcycle Rider Protection in Frontal Impact,"(5) is in the proceedings of this conference.

Leg Protection

The high incidence of serious injuries to the legs directed attention to possible methods for reducing the severity of these injuries. ESM1 was fitted with a safety fairing to provide a survival space for the legs on impact and a progressive crush to prevent the rider being ejected unnecessarily violently into the obstacle struck. Work on leg protection devices has since been carried out on light, medium, and heavy motorcycles. This work is summarised in the paper, "Leg Protection for Riders of Motorcycles,"(6) by Chinn, Macaulay, and Hopes, which is presented at this conference. Results are given for damage to the dummy leg and of changes in head velocity after the motorcycle impact. These are for different designs of a leg protection device and are compared with results for unmodified motorcycles. The results show clearly that for the tests conducted, a worthwhile reduction in injury severity and head velocity is to be expected when motorcycles are fitted with such leg protectors. While at this point it is not claimed that the required characteristics for leg protection have been optimised, the importance must be stressed of the design of the device in absorbing some of the kinetic energy of the rider and motorcycle during the impact.

ESM2 is fitted with a BMW RT fairing that has been modified to contain the leg protection device on both sides within the outer skin panels of the fairing. It is felt that this demonstrates leg protection can be adopted within a fairing without detracting from the appearance of the vehicle.

Safety Fairing

ESM2 is fitted with a safety fairing. The top part is a standard BMW RT fairing modified to receive the new instrument pack. The lower part has been restyled so the leg protection devices can be contained within the inner and outer skin panels. The forward impact test motorcycle incorporates the leg protection cones, which can be seen inside the fairing together with the tubular framework that provides the second load path for frontal impact. The inner skin panels of ESM2 cover these features and also supply the crush zone for the riders' knees in forward impacts. On the outside, the fairing is painted white as an aid to conspicuity, and the twin daytime running lamps are positioned on either side of the headlamp. The smooth line of the fairing with no external projections provides the best available solution for primary impact with a pedestrian.

Further work on the fairing is needed to provide controlled yield of the windscreen for part of the occupant ride-down with the airbag restraint system. Further research will show if the airbag stowage position is more effective if it is contained within the fairing rather than in its present position.

It is considered that this safety fairing offers significant protection in impacts without detracting from the visual image of what is acceptable for a motorcycle.

Other Features

Digital Speedo and Instruments

ESM1 was fitted with a speedometer with a 1-in-high digital display. Experiments had shown that a significant difference exists in the time riders take to read their speedometers and this depends on the type of instrument fitted. The time taken to read a large-dial instrument was reduced by 0.58s when a digital display was used. During this time saved, a distance of 8m is covered at 48km/h, which allows the rider to concentrate more fully on the road scene.

ESM2 is also fitted with a digital display speedometer, adapted from a unit produced for a car, supplied by Lucas. This also provides a tachometer and fuel gauge display together with warning lights. A warning light is lit on the panel if a system failure develops in either of the antilock brake units to alert the rider the machine is back to standard brakes. At this stage, the speedometer is also switched off as a further warning of a failure. This failure warning system is now being developed so the speedometer is a constant on-vehicle monitor that the antilock brakes are functioning. A separate failure warning lamp will also be provided. This section of the instrument display is considered to be a part of the antilock brake system.

Fuel System

Reports on accidents show that in the case of motorcycles, 30 percent involve spillage of fuel from the machine; in one-third of these, spillage is reported to be excessive. The incidence of fire in motorcycle accidents is higher than for cars, and spillage of fuel is an unnecessary hazard if it can be avoided easily. The Transport and Road Research Laboratory has developed a simple system using two fixed tubes inside the petrol tank that shut off the fuel supply to the fuel lines if the machine falls over on either side (Figure 1). Designs are available using this principle for both gravity feed systems and pumped feed systems. ESM2 is fitted with a gravity-fed system. The petrol tap positions have also been resited to forward takeoff points to overcome the external protrusions provided by the original taps. A single tap is now provided in the centre position of the fuel tank. This fuel tap is operated by a solenoid valve that turns the fuel on when the ignition is switched on. Similarly, the fuel is turned off when the ignition is switched off.

A habit with some riders is not to refuel their motorcycle until they have gone on to the reserve fuel position. This can be a hazard in some instances as the engine loses power until the fuel supply is resumed, which can lead to accidents. No manually operated reserve fuel supply is available on ESM2 because a fuel gauge is fitted.

Interlocked Stands

Accidents have been caused by drivers riding off from rest with the side stand down, so requirements are in hand for the vehicle to be constructed to prevent this. The side stand on ESM2 is automatically returned when the clutch is operated and is additionally provided with an interlock with the ignition circuit. The centre stand is also fitted with an ignition interlock, but a manual override is provided that locks the stand down so the engine can be run for servicing while the machine is raised on its centre stand. A better solution would be to have the centre stand also hand-operated so the rider could use it while still astride the motorcycle. More effective use of the main stand could result on heavy motorcycles where frequently only the side stands are used for convenience. This was not found to be possible on ESM2 because of the cylinder layout.

Assessment

Accident and casualty data in Great Britain have shown that motorcycles are 10 times more likely to be involved in a casualty accident per mile travelled than are cars (not allowing for rider and driver age differences). In 1983, there was a total of 64,494 casualties among their

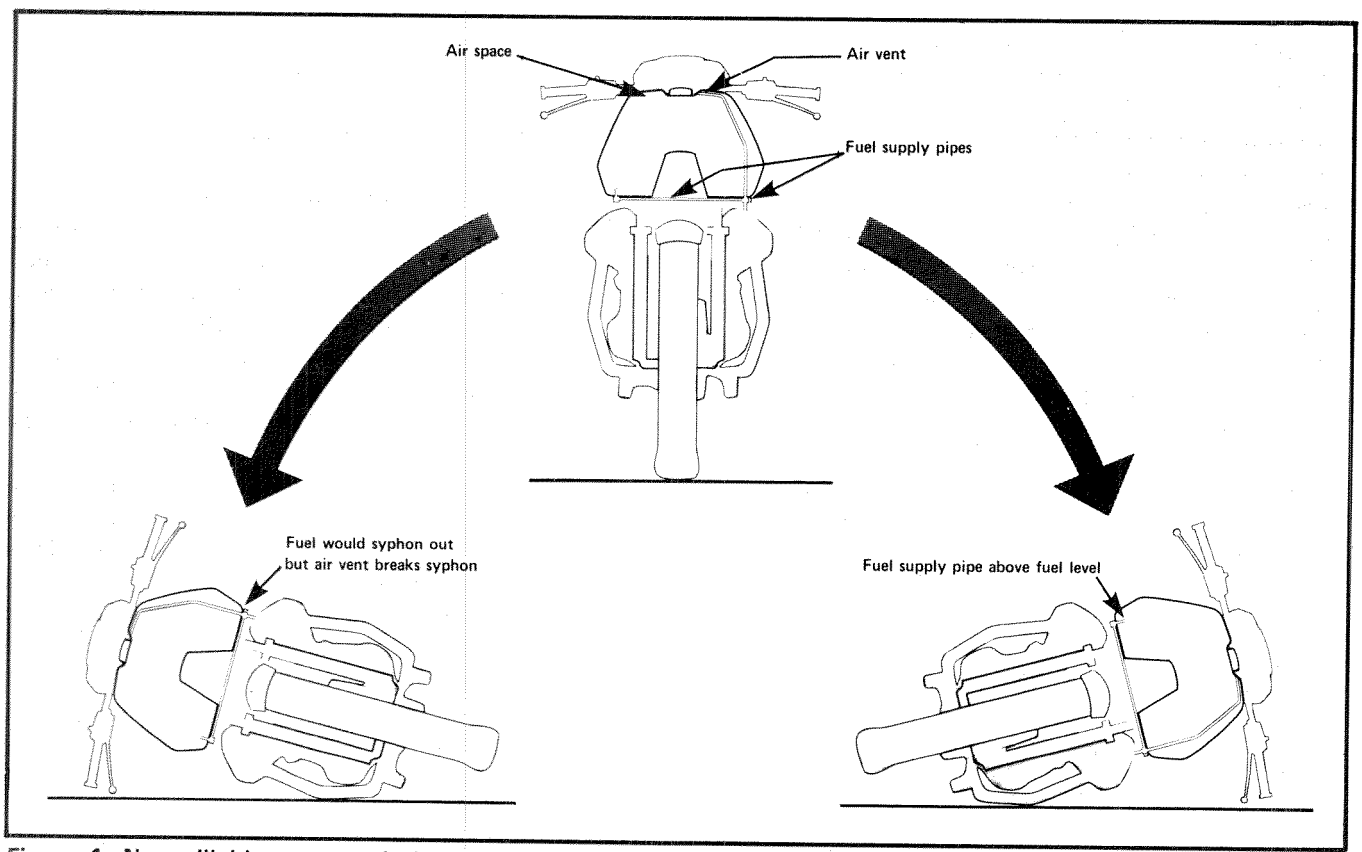

Figure 1. Nonspillable motorcycle fuel tank

riders and passengers, of which 963 were fatal. In this year, the casualty rate was slightly up on previous years but the total number of casualties was lower. The trend of reducing motorcycle mileage continued in 1983, and the casualty savings for the year appear to be due mainly to this reduction. The reasons for the decline in motorcycling in recent years are not clear, but the recession could be one of the variables producing this trend. If in subsequent years the motorcycle mileage increases, as has occurred previously, the increase would contain a larger portion of inexperienced riders, which would tend to increase the accident rate, thus producing a disproportionate rise in casualties.

There are certain safety features that can be incorporated in a motorcycle to provide part solutions to problems that exist, and estimates of effectiveness can be made from the data available. Of the accident avoidance and rider protection systems on ESM2, it is worth speculating on four features and the value of each of them independently. This is done in terms of casualty savings using 1983 data and assumes that all motorcycles would be fitted with these systems (Table 1).

Although the features are considered independently in the analysis, the effect of applying one treatment to the vehicle would reduce the number of available accidents that the other features could benefit from. Improved daytime conspicuity, which has the best cost-benefit, would reduce the present quantifiable accidents that would benefit from the other three features. Conversely, other benefits exist that cannot be quantified by the data. The introduction of antilock brakes would contribute to reducing the 6,000 accidents involving skidding in adverse conditions. It is not possible to quantify the potential savings on dry roads arising from skidding or from underbraking due to the fear of a skid. Work at the Laboratory toward reducing leg injuries has shown in the tests carried out to simulate leg injury accidents that with correctly designed leg protectors, the rider's head velocity is reduced compared with results from a similar test on an unmodified motorcycle. In some of these accidents, a reduction in head injury severity would also be expected.

Frontal impact research has considered the motorcycle hitting an object normal to its direction of travel. The research work on leg protection has shown that on an unmodified motorcycle if the object struck is inclined at 30° either side of normal, the trajectory of the rider is virtually the same as a frontal impact. The frontal impact accounts for 60 percent of motorcycle collisions, and for these the restraint system could assist in reducing the rider's kinetic energy.

The work on motorcycle safety at the Transport and Road Research Laboratory is aimed at providing viable solutions to problems identified by research without departing from the image of a motorcycle. Although this task is far from complete, there has been some notable progress made since the first safety motorcycle exhibit ESM1 in 1979. A preliminary consideration of possible costs and savings for antilocking brakes, by protection, forward trajectory control, and daytime conspicuity suggests that all are likely to be worthwhile and deserve further development for general use.

Acknowledgments

The work described in this paper forms part of the programme of the Transport and Road Research Laboratory and is published by permission of the Director.

Driver Airbag Police Fleet Demonstration Program— A 24-Month Progress Report

David J. Romeo
Romeo Kojyo Company Inc.

John B. Morris
U.S. Department of Transportation, National Highway Traffic Safety Administration

Abstract

The objective of this program is to design, test, evaluate, manufacture, and install in 500 state highway patrol vehicles a driver airbag retrofit system.

Airbag system benefits are universally accepted. However, the costs, complexities, and availabilities of these systems are widely misunderstood. This program takes much of the mystery out of the airbag and demonstrates to fleet operators and the public at large that airbag technology, components, and systems do presently exist and can be acquired at a reasonable cost.

Detailed information on system design, selection of vehicles and states to participate, as well as sled testing and full-scale crash testing are presented as SAE Paper 841216, "Driver Airbag Police Fleet Demonstration Program—A 15-Month Progress Report" by the same authors. The present paper reviews very briefly those aspects of the program and places emphasis on the field experience of the 500-car fleet, which to this point has experienced 18 actual airbag deployment crashes (16 of which have occurred in the past 9 months).

Program Discussion

The primary goals of this program were to design, test, and evaluate a driver airbag retrofit system, and using production hardware to manufacture sufficient kits for demonstration purposes, and to install these kits into police vehicles in a number of State Highway Patrols.

Retrofitting the driver's side with an airbag system was not overly difficult; the essential production components already existed. It was accomplished by replacing the existing steering wheel with an airbag wheel, installing crash sensors, providing a proper electrical circuit, and adding a knee restraint to the instrument panel. The retrofitted vehicle appears little different from the original vehicle.

To make retrofit kits available for this program, engineering effort was required to finalize design of airbag components (airbag, module, steering wheel, crash sensors, and knee restraint). These components, with the addition of minor brackets and cosmetic components peculiar to each type vehicle, complete the retrofit kit. Once design was finalized, these components needed some additional minor tooling for limited production, and parts needed to be produced in sufficient quantities to enable evaluation testing and retrofit of selected demonstration vehicles.

The system consists of sensor(s), wiring, diagnostics, connectors, steering wheel, gas generator, airbag and all module components including the cosmetic cover, and a knee restraint. The system design consists (to the extent possible) of commercially available production components. The gas generator, airbag, and sensor are production designs and heretofore have been subjected to acceptable automobile manufacturer's qualification tests and specifications.

The project was initiated April 15, 1983. A review of the program through April 1985 is presented here. Topics to be discussed include—

- Selection of States
- Selection of Vehicles
- System Design
- Sled Testing
- Crash Testing
- Installation of the Retrofit System
- Field Experience to Date

Selection of States

When funding for the program was committed, NHTSA sent letters to each of the States regarding their interest in participation. Approximately 20 States responded positively and the selection of six States was made, based on earlier commitments, earnestness expressed, and geographical location (there was an effort to represent as wide a range of locations, e.g., west, southwest, midwest, etc., as possible).

Vehicle availability, type, and scheduling were considered. The States originally participating in the program were Arizona, California, Ohio, Maryland, Mississippi, and Wisconsin. Later in the program, the system was modified to include improved installation procedures and a new diagnostic. At that time, the New York State, New York City, and River Vale, N.J., police fleets were added.

Selection of Vehicles

Two basic car types were included—the Ford Panther and the Chrysler M-body. Both represented Ford's and Chrysler's V-8 engine, rear-wheel drive, full-size cars. Ford versions of this vehicle include the Ford LTD up to

1982, Ford LTD Crown Victoria, Mercury Gran Marquis, and, with some front end change, the Lincoln Town Car. This vehicle has been manufactured without change from 1979 to the present. The Chrysler M-body has been sold since 1982 as the Plymouth Gran Fury and at least since 1981 as the Dodge Diplomat. It was formerly sold as the Chrysler Le Baron and presently is the Chrysler 5th Avenue.

System Design

The latest system (see Figure 1) consists of the following items: two front sensors, a safing sensor, and wiring with protective shielding in the engine compartment that passes through the firewall and plugs into a diagnostic unit mounted in the occupant compartment. From the diagnostic unit, wiring leads go to (1) power and ground, (2) a readiness indicator light, and (3) up the steering column through a special coiled connector to a four-spoke airbag steering wheel. The wheel, which mounts using a hub fabricated to fit the column shaft, has two horn buttons mounted on the upper spokes. The airbag module is attached to the special wheel using four allen-head cap screws and consists of the gas generator, the nylon airbag, metal mounting components, and a highly developed reinforced cover assembly.

The knee restraint is mounted over the lower part of the instrument panel on the driver's side and consists of a sheet metal frame, energy-absorbing foam, and a vinyl cover colored to match the vehicle interior.

A photograph of the system mounted in a police cruiser is shown as Figure 2.

The sensors and diagnostic system were supplied by the Technar Corporation of Arcadia, California. The steering wheel and airbag module were supplied by Takata Corporation of Tokyo, Japan, and the gas generator was supplied by Bayern Chemie GmbH of Ottobrunn, West Germany.

Sled Testing

A total of 31 sled tests were run using the HYGE facility at the Transportation Research Center, TRC, in Marysville, Ohio. Twenty-two tests were run with the

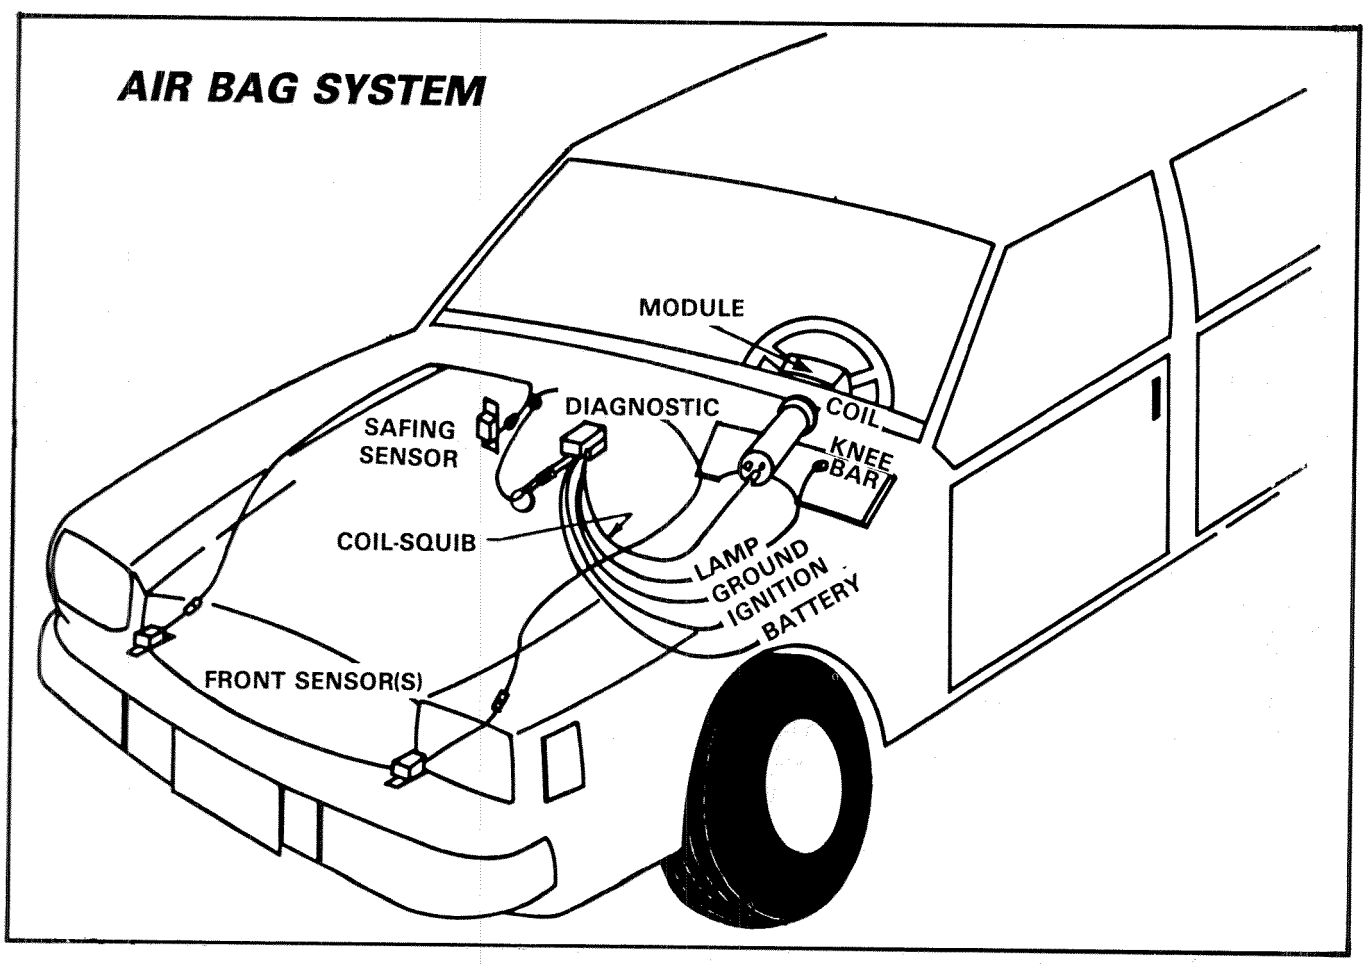

Figure 1. Airbag system

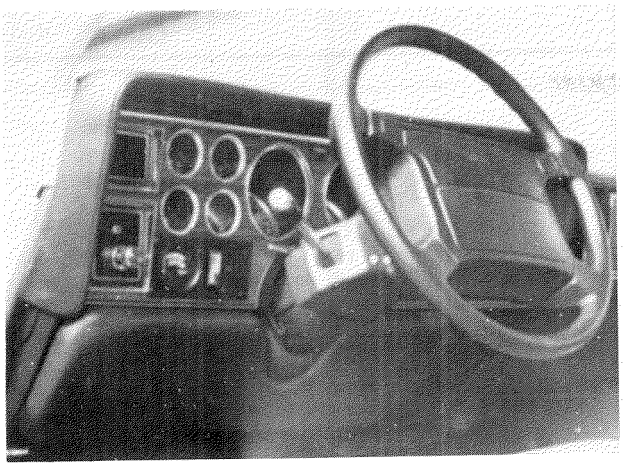

Figure 2. Typical Romeo Kojyo airbag system installation

Ford body buck and crash pulse and nine with the Dodge. A detailed discussion of these tests is beyond the scope of this paper, but is available through NHTSA. Only a brief summary of results is presented here.

The tests on the Ford body were run first to finalize system design. Once this was accomplished, the remaining tests were run to study effects of test dummy size and to simulate crash speed, crash angle, and a range of restraint configurations.

The airbag system, that is, the steering wheel, airbag module, and knee restraint, were tested alone and in combination with lapbelt only, and with lapbelt plus shoulder belt. The belt restraint configurations were also tested without the airbag. Two other comparisons were made. The 50th percentile dummy was tested with no restraint system, and finally the airbag was tested without the knee restraint.

These results are summarized below for the 50th percentile head, chest, and femur load results.

Sled test results, Ford LTD, 32.5mph

	HIC	C_R	Femur*
Unrestrained	2,401	59g's	2,754lb
Lapbelt	2,584	44	410
Lapbelt/Airbag	468	43	702
Lap/Shoulder Belt	865	36	433
Lap/Shoulder/Airbag	510	35	427
Airbag	209	38	1,690
Airbag, w/o Knee Bar	263	40	3,002

*max value, left or right leg

It is clear that results for the unrestrained case are very poor (the reader's knowledge of injury criteria, i.e., HIC, C_R, and femur loads is assumed). As can be seen further, the lapbelt controls leg loads and improves chest results but plays no role in controlling injury to the head. The airbag and lapbelt work well in combination and provide superior protection to the head than does the lap and shoulder belt.

Crash Testing

Seven full-scale tests were conducted between September 1983 and January 1984 to evaluate the performance of the driver airbag system. The results of these tests are summarized in Table 1. A description of each of these tests is presented in the previously mentioned SAE paper.

Results of crash tests with the 1982 Ford LTD were better than anticipated, while results with the Dodge Diplomat were satisfactory but not as good. To a lesser degree, these results were seen in the sled tests, which used nearly the same crash pulse.

Regarding overall system performance and design in the two vehicles, the following remarks can be made:

- Sensor closure time was sufficiently early in both vehicles.
- The bag position was excellent. Therefore, although some improvement in chest ride down, that is $-C_R$, would result from removal of the bag straps, there is strong reluctance to do so since it is believed that the bag straps are important in locating the bag.

Installation of the Retrofit System

When police cruisers are purchased and received from the automobile dealers, they are cars that have been assembled with special police package options such as heavy-duty springs, shocks, radiator, and a large engine. However, before the vehicles are put into service, they are prepared by police technicians at special facilities and receive radio equipment, sirens, light bars, bumper bars, decals, and various other equipment. The point is, each highway patrol agency has its own skilled mechanics, technicians, radio men, and garage facilities. These men and facilities were used for installation of the airbag retrofit systems.

For each vehicle type, a detailed set of installation instructions was written and supplied to the police agencies. In addition to these instructions, a few days were spent at each State facility demonstrating installation of the first half-dozen systems. After installation in the first one or two cars was completed, the technicians took over installation responsibility with Romeo Kojyo and NHTSA representatives in attendance to answer specific questions. This methodology worked very well in every State, and comments or feedback from the installers were used to improve on the installation method.

Field Experience

Maintenance

No major problems associated with any of the system components have occurred. A few minor problems arose that required changes to the system itself or to its installation procedure. These were discussed in the earlier paper.

Accidents Involving Airbag-Equipped Vehicles

Appendix A presents a synopsis of the airbag deployment crashes as of April 15, 1985. Photographs of some of these crashes are shown in Figures 3-5. Attempts have been made to analyze and categorize the 18 deployments using several different approaches (see Table 2). Two methods were selected. The first was by crash type, frontal or frontal offset, versus undercarriage or suspension impacts. The second method was whether a higher sensor threshold could have been used.

The second method of comparison is clearly subjective and necessarily includes such important factors as whether or not the belt was worn, and whether or not police cruisers should be considered as a separate group because of the hard use to which they are subjected.

With regard to belt use, it was a condition of each State participating in the program to have a strict belt use policy. However, 100 percent belt use was not an allowable assumption, and a goal of the design was to provide adequate protection for both belted and unbelted officers.

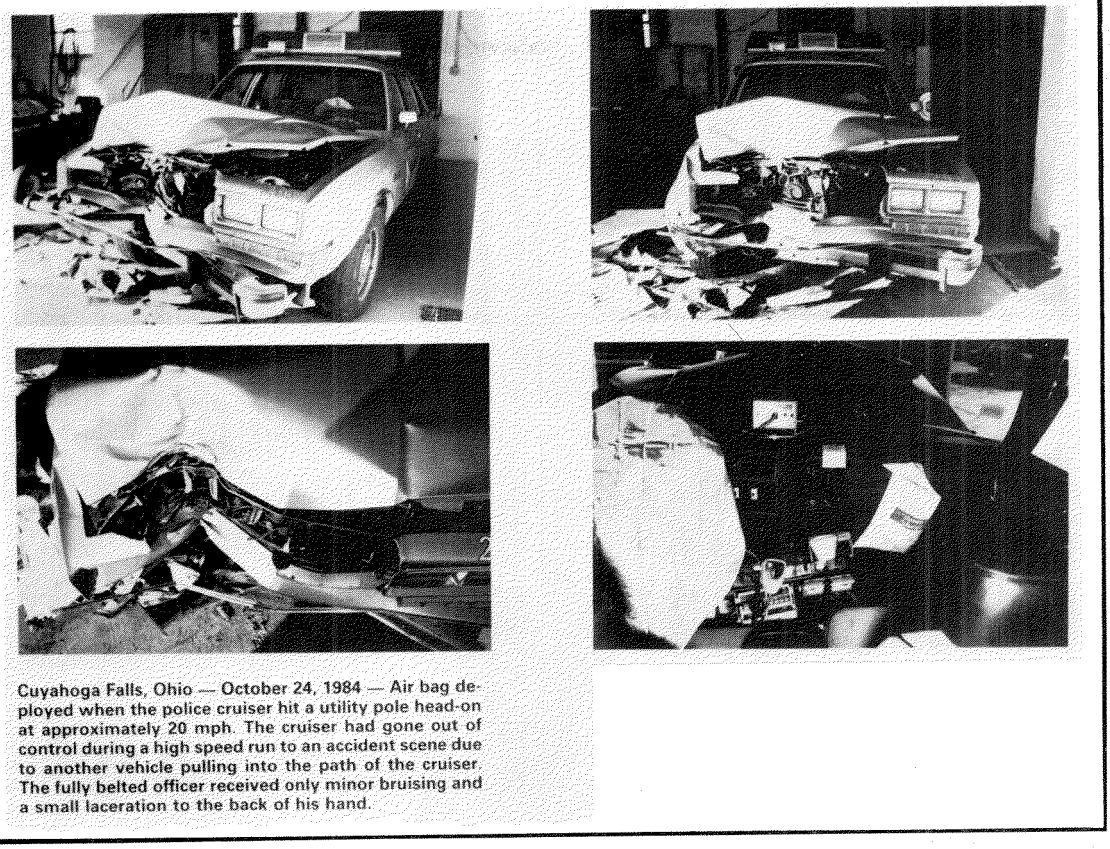
From Table 2, it is seen that by counting all undercarriage accidents and the two impacts with deer, it might be argued that in nine of the deployments supplemental airbag protection may not have been needed. It is interesting to note, however, that with the exception of the initiation threshold level of the first deployment, there were positive reactions from the officers who were driving the vehicles.

The deployment threshold of the crash sensors used in this program was established to accommodate the general driving public. Following the first airbag deployment, the question arose as to whether the threshold level should be raised for police vehicles, which, as previously mentioned, are subjected to harder than normal use. To further complicate matters, two police fleets, California and Arizona, use pusher bars attached to the front of the vehicle. Test data indicate that pusher bars lower the deployment threshold 2 to 3mph compared to cars without pusher bars.

From an engineering standpoint, it was concluded that an increase in the threshold level of the crash sensors could be accepted. Accordingly, the higher level threshold sensors were incorporated into the California Highway Patrol vehicles and into the newer systems provided to the State Police of New York and to the New York City Police.

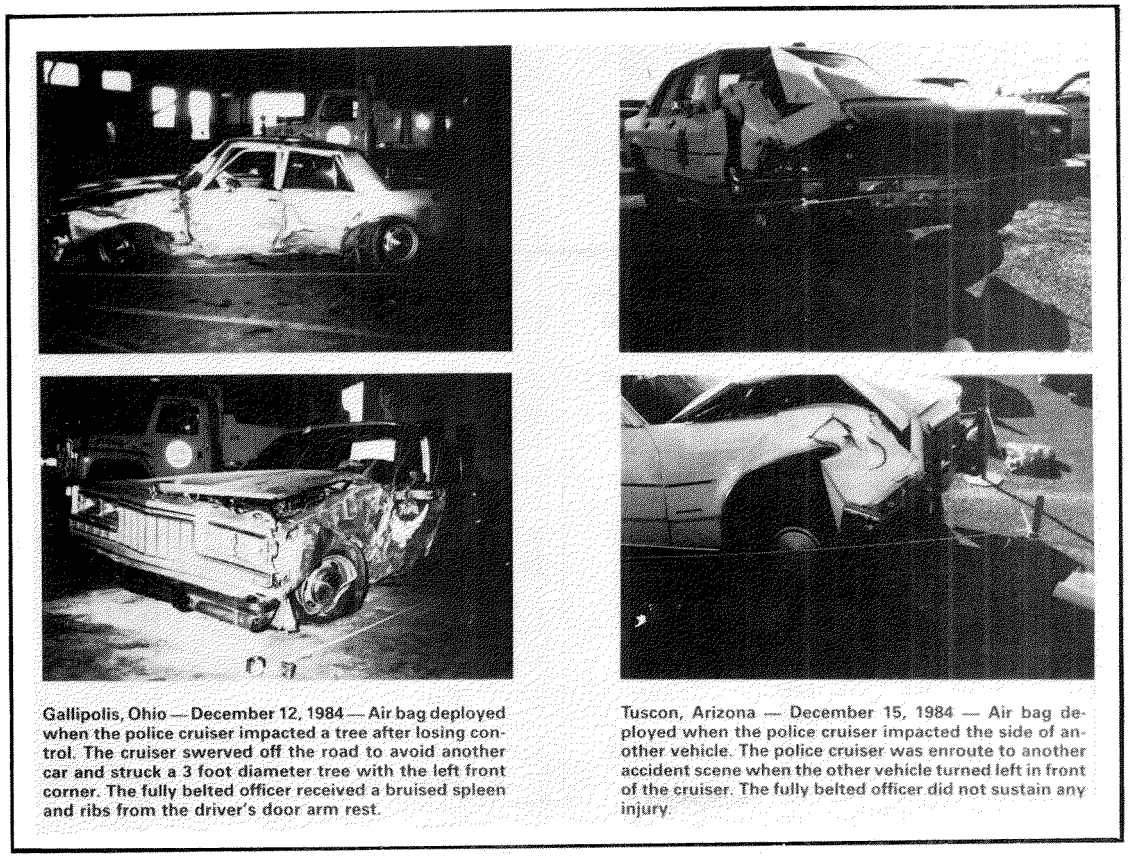
Currently, two airbag deployment strategies are being used in the study: a deployment threshold intended for the general driving public and a higher deployment threshold possibly more suitable for police use. During the remainder of the program, the two deployment strategies will be evaluated.

The program will continue for at least 1 more year. During this time, we expect to gather valuable information on the types of accidents in which the airbag deploys, the injury prevention capability of the system, and the appropriate sensor threshold for vehicles depending on the use to which they are put.



Cuyahoga Falls, Ohio — October 24, 1984 — Air bag deployed when the police cruiser hit a utility pole head-on at approximately 20 mph. The cruiser had gone out of control during a high speed run to an accident scene due to another vehicle pulling into the path of the cruiser. The fully belted officer received only minor bruising and a small laceration to the back of his hand.

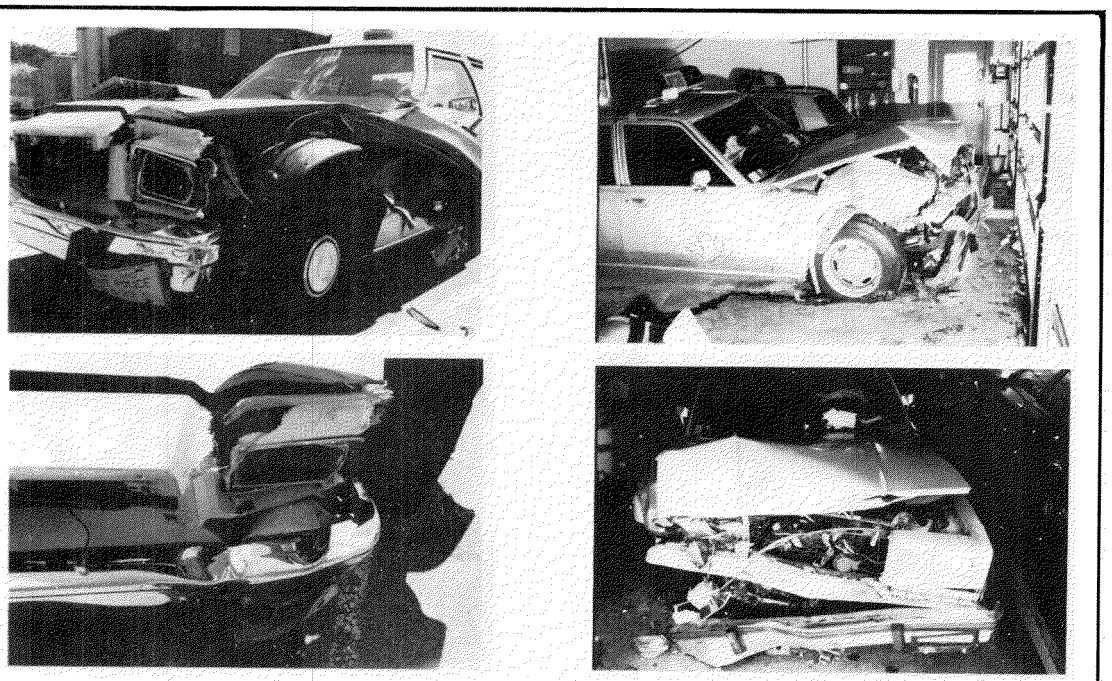
Figure 3. Police fleet airbag deployments



Gallipolis, Ohio — December 12, 1984 — Air bag deployed when the police cruiser impacted a tree after losing control. The cruiser swerved off the road to avoid another car and struck a 3 foot diameter tree with the left front corner. The fully belted officer received a bruised spleen and ribs from the driver's door arm rest.

Tuscon, Arizona — December 15, 1984 — Air bag deployed when the police cruiser impacted the side of another vehicle. The police cruiser was enroute to another accident scene when the other vehicle turned left in front of the cruiser. The fully belted officer did not sustain any injury.

Figure 4. Police fleet airbag deployments



Elkridge, Maryland — September 4, 1984 — Air bag deployed when the police cruiser impacted a car stopped in a travel lane on the expressway as a result of a previous accident. Another car had swerved in front of the police cruiser leaving the cruiser without an avoidance path. Impact speed was estimated at 45 mph. The two officers in the front seat of the cruiser were both fully belted and neither received appreciable injury.

Marion, Ohio — January 22, 1984 — The police cruiser was parked heading south. Its occupants were attending another accident. A northbound vehicle, whose driver was distracted by the first accident and lost control of the car, struck the police cruiser head-on. The air bag deployed. The two police officers were belted and uninjured.

Figure 5. Police fleet airbag deployments

18	4/9/85	MD	Ford	Deer	8

Conclusion

1. In 450 police vehicles, approximately 20 million vehicle-miles, there has been no occurrence of airbag deployment without a reportable accident.
2. There have been approximately 25 to 30 accidents, of varying intensity, involving the airbag-equipped police vehicles, resulting in 18 deployments.
3. There have been no significant injuries of consequence in any of the accidents.
4. In no case has an accident occurred in which the airbag should have deployed and did not.
5. Evaluation of the system will continue at least through July 1986.

Appendix A

Police Airbag Retrofit Experience

4-11-84 Sacramento, California—Airbag deployed while in hot pursuit on a dirt roadway. The driver was wearing a lapbelt and received bruises on inner wrist and upper right inner arm. The car was driven from the scene by the police officer. The vehicle was a 1983 Dodge Diplomat. The airbag was deployed after running through a ditch and striking large stones in the roadway. The pusher bar on the police car bumper was found to reduce the deployment threshold speed for this type of accident. These pusher bars are unique to the California police cars, and the airbag sensors of all California cars have been adjusted for this difference. The investigation is by Dynamic Science.

6-29-84 Cordes Jct., Arizona—Airbag deployed when an unoccupied 1983 Ford Crown Victoria police cruiser was pushed into the rear of a 1980 Cadillac Eldorado as a result of the airbag car being rear-ended by a 1979 Dodge van. The airbag police vehicle had stopped the Cadillac for a traffic violation. The ignition was on and the engine was running in the unoccupied police car at the time of impact; therefore, the airbag system was ready for activation. Only minor injuries occurred to the driver of the van and both occupants of the Cadillac. The police officer was not injured. The investigation is by Dynamic Science.

7-25-84 Reedsburg, Wisconsin—Airbag deployed when the undercarriage of the 1984 Plymouth Gran Fury impacted an embankment while chasing a motorcyclist across a golf course. The fully belted officer received abrasions and contusions to the inner wrists/forearms and biceps that did not require treatment. The car bottomed out with such force that the officer driving was thankful for the airbag deployment. The officer drove the car away after apprehending the cyclist. The investigation is by Calspan, Buffalo, NY.

8-25-84 Ironton, Ohio—Airbag deployed when the torsion bar bracket (undercarriage) of the 1984 Plymouth Gran Fury dug into the entrance ramp of an asphalt church driveway. The police cruiser had slowed from an 80+mph pursuit down to an estimated 35mph when the impact occurred. The impact produced an estimated 15mph delta-V and left a gouge in the pavement approximately 30in in length and 2-½in deep. The cruiser did not sustain any deformation in the impact; the crash energy was dissipated by the stiff torsion bar bracket trenching the pavement. The fully belted officer sustained an abrasion to his inner left forearm but was otherwise uninjured. He braked the cruiser to a controlled stop after the impact and apprehended the suspect, who tried to hide behind the church. The cruiser was driven from the scene. The officer, when asked if he would spend $500 for an airbag in his personal car, replied, "Yes." The investigation is by University of Tennessee.

9-4-84 Elkridge, Maryland—Airbag deployed when the 1982 Ford police cruiser impacted a car stopped in a travel lane on the expressway as a result of a previous accident. Another car had swerved in front of the police cruiser, leaving the cruiser without an avoidance path. The left front corner of the cruiser impacted the right front corner of the stopped car (perpendicular impact) at an estimated 45mph. The left front fender of the cruiser was peeled away from the car structure, the driver door was distorted and sprung, and roof buckling occurred over the B-pillar. The two officers in the front seat of the cruiser were both fully belted and neither received appreciable injury. The driver incurred a minor lower back strain and a contusion to the left arm and left knee. The Maryland State Police associated with this incident were favorably impressed with the airbag performance. The investigation is by Calspan, Washington, DC.

9-12-84 Magee, Mississippi—Airbag deployed when the 1984 LTD Crown Victoria Ford police

cruiser impacted the left front corner of a 1980 Chevrolet Caprice as it pulled from a parking lot into the path of the cruiser. The impact speed was about 15mph and inflicted about 8in of crush to the right front of the cruiser. The police officer was unbelted at the time of the impact and received an abrasion to the inner left arm and chest. The police officer was leaning to his right over the console with his left arm on the steering wheel when the deployment occurred. The driver of the Chevrolet left the scene of the accident prior to questioning and apparently was not appreciably injured. The investigation is by Dynamic Science.

10-10-84 Ashland, Ohio—Airbag deployed when the 1983 Plymouth Gran Fury impacted a 120 lb deer (four-point buck) with the right front corner of the cruiser at an estimated 50mph. The maintenance man driving the cruiser was not injured. The cruiser sustained 3in of buckling to the hood and fender, and the grille and right front headlight assembly were shattered. The damage to the cruiser is estimated at over $1,000. The investigation is by University of Michigan.

10-24-84 Cuyahoga Falls, Ohio—Airbag deployed when the 1983 Plymouth Gran Fury hit a utility pole head-on at approximately 20mph. The cruiser had gone out of control during a high-speed run to an accident scene due to another vehicle pulling into the path of the cruiser. The police cruiser sustained 23in of crush in the right front. The fully belted officer received only minor bruising and a small laceration to the back of his hands as a result of their contact with internally mounted radar equipment. The damage to the police cruiser is estimated at $3,700. The investigation is by University of Michigan.

11-10-84 Lucedale, Mississippi—Airbag deployed when the 1984 Ford LTD police cruiser left the roadway, grazed a pole, right front wheel dug into the dirt (which appears to have initiated the deployment), and then hit a tree. The cruiser had lost control enroute to an accident scene when another vehicle pulled into the path of the cruiser. The fully belted driver received a swollen lip and scratch to the eye during the accident event. The investigation is by University of Tennessee.

12-12-84 Gallipolis, Ohio—Airbag deployed when the 1983 Plymouth Gran Fury police cruiser impacted a tree after losing control. Another car turned in front of the cruiser as the cruiser passed through an intersection while enroute to an accident scene. The cruiser swerved off the road to avoid the other car and struck a 3ft-diameter tree with the left front corner. The motion of the cruiser continued, with the tree producing about 6in of damage (crush) down the left side of the cruiser. The cruiser separated from the tree before coming to its final rest position. The fully belted police officer received a bruised spleen and ribs from the driver's door armrest. The police officer was very pleased with the airbag performance in this crash. The investigation is by Calspan, Buffalo, NY.

12-15-84 Tucson, Arizona—Airbag deployed when the 1983 Ford Crown Victoria police cruiser impacted the side of a 1974 Oldsmobile Cutlass. The police cruiser was enroute to another accident scene when the Oldsmobile turned left in front of the cruiser. The impact produced about 5in of crush to the front of the police cruiser and about 8in of crush to the right side of the Oldsmobile. The fully belted police officer did not sustain any injury whatsoever. He was particularly pleased that he "didn't even have any bruises." The investigation is by Dynamic Science.

1-22-85 Marion, Ohio—A 1983 Plymouth Gran Fury police cruiser was parked heading southbound off the road on U.S. 23 just north of State Road #231. Its occupants, two police officers, were attending another accident. A northbound Ford Granada, whose driver was distracted by the first accident and lost control of the car, struck the police cruiser head-on in a full frontal collison. The airbag deployed. The two police officers in the Gran Fury were belted and uninjured. The driver of the Granada was also belted and uninjured. The investigation is by University of Michigan.

1-24-85 Clement, Maryland—A 1984 Ford LTD Crown Victoria police cruiser struck the right side of a 1979 Oldsmobile Cutlass Station Wagon. The airbag in the Ford deployed. The driver of the police cruiser had a contusion on the inside left upper arm and small laceration on the outside surface of the right hand. The right front passenger had a small contusion of the right knee. Both officers stated they were belted. The impact speed was about 10mph. There was 18in of crush to the side of the Oldsmobile. The investigation is by Calspan, Washington, DC.

1-31-85 Globe, Arizona—A 1983 Ford LTD Crown Victoria police cruiser struck an embankment and rotated. The airbag deployed as the left

front corner of the vehicle was displaced rearward about 7in. There was about $1,500 damage. The unbelted driver suffered a minor abrasion to the left arm and an abrasion and contusion on the left side of the forehead from the roof rail. The investigation is by Dynamic Science.

2-9-85 Los Angeles, California—A 1983 Dodge Diplomat police cruiser was stopped on Interstate 5 as its driver (a police officer) was out of the vehicle assisting a motorist with a disabled car. The unoccupied police cruiser was struck in the rear by a third vehicle travelling in the same direction, and moved forward into the rear of the disabled vehicle. The bag deployed during the frontal strike by the police cruiser. All parties involved received minor injuries except for a lower leg fracture to one pedestrian. The police cruiser was totaled. The investigation is by Dynamic Science.

3-10-85 Starkville, Mississippi—Airbag deployed when the Ford Crown Victoria police cruiser went off the road and impacted a shallow ditch in the pursuit of a high-speed subject. The driver was lapbelted but had about 2 to 3ft of slack in the shoulder belt to facilitate the radar equipment that had been in use. The driver incurred a black left eye, contusion to the left eyelid, and redness to the left side of his face. The right front passenger was not belted and received a sprained ankle and sore wrist (apparently from windshield contact). Both occupants were very positive about the airbag performance in this crash. The investigation is by University of Tennessee.

Summary of the Accident Experience of 1970 Vehicles Equipped with Airbags as of July 1, 1985

Fleet Vehicles*	
1972 Mercury's	831
1973 Chevrolet's	1,000
1975 Volvo's	75
Privately-owned Vehicles	
1974-76 GM Cars (Buick, Cadillac, and Oldsmobile)	10,281

Airbag Crash Experience**

As of July 1, 1985, NHTSA knows of 279 airbag deployment crashes. The vehicles involved had 397 front seat occupants, sitting behind airbags, who had the following injury levels:

None-Minor (AIS 0-1)	321
Moderate-Serious (AIS 2-3)	53
Severe-Critical (AIS 4-5)	4
Fatal (including 2 drownings)	12

In these accidents, the airbag vehicles had primary damage as follows:

Front	208
Side	49
Undercarriage	22

NHTSA also has information on 161 accidents involving airbag vehicles where the vehicle frontal deceleration was not great enough to deploy the airbag. The vehicles involved had 220 front seat occupants who had the following injury levels:

None-Minor	196
Moderate-Severe	10
Serious-Critical	0
Fatal	2

In these accidents, the airbag vehicles experienced primary damage as follows:

Front	106
Side	33
Undercarriage	2
Rear	8
Rollover	3

Exposure: The following is an estimate of the number of vehicle-years of operation of automobiles equipped with airbags. It was made using data on new car sales, registration data from R.L. Polk, and general vehicle scrappage data.

Models	**Car Years of Operation (1-1-84)**
1972 Mercury Fleet	8,088
1973 Chevrolet Fleet	9,205
1974-76 GM Cars	84,008

* The data include a very small number of vehicles with prototype airbag systems, including a 1980 Oldsmobile and a small number of 1982 Lincolns.

** Some data may be missing due to individuals who did not wish to provide us with information and vehicles that had been repaired prior to an investigation.

Summary of the Accident Experience of 1983 and Later Airbag-Equipped Vehicles as of October 1, 1985

Fleet Vehicles	
1985 Ford Tempo's-U.S. Gov't.	5,300
1983-1985 Police Car Retrofits	530
1985 Other Fleets (1)	2,100
Privately-Owned	
1983-85 Mercedes	11,500 (latest estimate)

Airbag-Equipped Vehicle Exposure

Vehicle	**Total Estimated Mileage**
Tempo's-U.S. Gov't.	25 million
Tempo's-Other Fleets	10 million
Police Fleets	21 million
Mercedes-Benz	Unknown

Results of Fleet Experience to Date

Experience with the current generation airbag fleet has been very positive. The airbags deployed in cases where crash protection was desirable, and there have been no failures to deploy when needed. Airbags have deployed only in accidents where they were designed to deploy. When airbags deployed, injuries were relatively minor.

(1) Airbag-equipped Ford Tempo's in private fleets.
(2) There were two deployments in police cars struck while parked with engines running.
(3) Some data may be missing because individuals were unwilling to provide information or vehicles had been repaired prior to the investigation.
(4) The accident notification criteria and level of injury information available on nondeployment accidents vary with each fleet of cars.

Deployment Accidents (**)

The Breed All-Mechanical Airbag Module

Allen Breed
Breed Corporation

For almost a quarter of a century, Breed Corporation has engaged in the quest of finding simple mechanical solutions to complicated engineering problems in both the military ordnance and civilian arenas. In the field of automotive safety, Breed Corporation pioneered retrofit installation of conventional electrical driver side airbags. We are presently producing the electrical crash sensors used in the airbag-equipped Ford Tempo/Topaz vehicles. However, my presentation today will focus on our all-mechanical airbag module.

We approach our problems analytically. Our standard procedure is to develop a computer simulation, via math modelling, as our major problem-solving and design tool. Once we arrive at a mathematical solution, we design as simple a mechanical device as possible for use in the field. That is the road—long, tortuous, and hard as it is—that we followed in the airbag case.

We developed three basic proprietary computer math model simulations for our airbag work. First was our sensor simulation model to predict the sensor trigger time for various types of crash sensors. We further developed our VODS 1 and VODS 3 (Vehicle Occupant Dynamics Simulator) models to predict the occupant injury measures for various vehicle crashes and occupant sizes as a function of airbag system design. In conjunction with these computer models, we worked with our own extensive automobile proving ground crash library of more than 1,000 instrumented crashes. With these tools, we constructed an acceptable sensor response curve for a sensor mounted outside the crush zone—in the steering wheel for the driver side and in the instrument panel for the passenger side. We designed a sensor with a response curve that would not allow the airbag to deploy in minor accidents or bumps, but would act in sufficient time in a crash to keep injury levels well below those specified in FMVSS 208. We then built such a sensor and married it to a simple mechanical military type initiator. Finally, we placed our Breed Sensor/Initiator inside the gas generator itself to create, with the addition of a fabric bag, the Breed All-Mechanical Airbag Module.

Figure 1 depicts the Breed All-Mechanical Sensor/Initiator. In a crash with a deceleration of more than four G's, the ball-sensing mass will move forward. If airbag deployment is needed, the ball will push the bias lever far enough to release a cocked firing pin, which initiates a prime, thereby initiating the gas-generating material and inflating the airbag. We build two separate and independent sensor/initiators into each of our units to provide high statistical reliability.

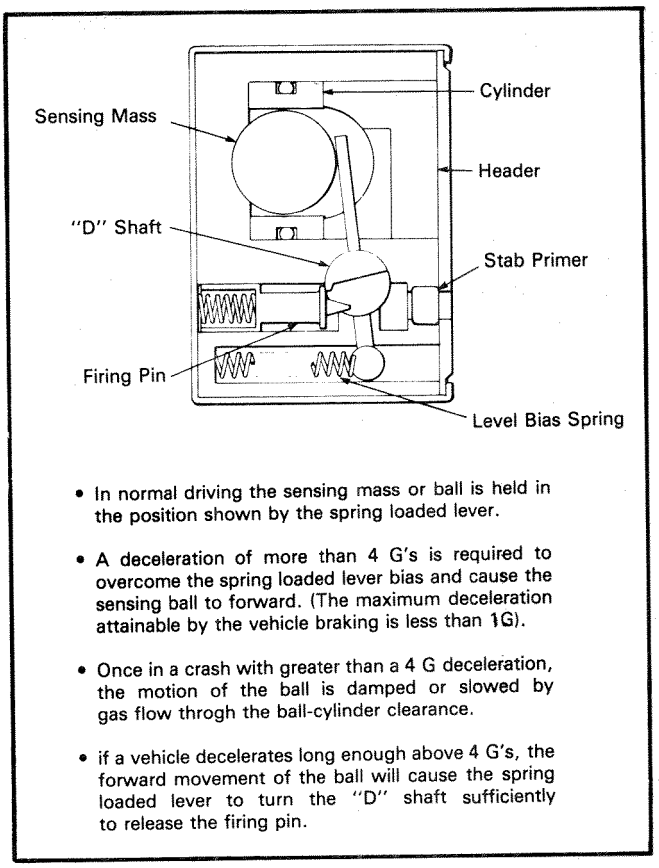

Figure 1. Breed airbag crash sensor initiator

Most airbag systems place crash sensors in the vehicle's frontal crush zone (Figure 2). In a crash, these sensors act as an electric switch connecting the battery to an electric squib in the gas generator, which then initiates airbag deployment. These conventional systems also require electrical wiring connecting the sensors to the battery and up the steering column; a slip ring; an electric squib; an auxiliary power supply; and an electronic diagnostic system that monitors all airbag wiring and components for opens or shorts. All of these elements are eliminated in our All-Mechanical Airbag Module (Figure 3). As such, it is substantially simpler to both build and install, providing higher reliability at significantly less cost.

When working with individual automobile manufacturers, we design an appropriate airbag system, using our computer math modelling to define the desired knee bolster, steering column, gas generator, sensor, and airbag characteristics for the specific vehicle under consideration.

Because of confidentiality arrangements, it is not possible to discuss our present activities with specific automobile manufacturers. We can, however, talk in detail about our crash test results in a demonstration contract we have with Mike Finkelstein's Office of

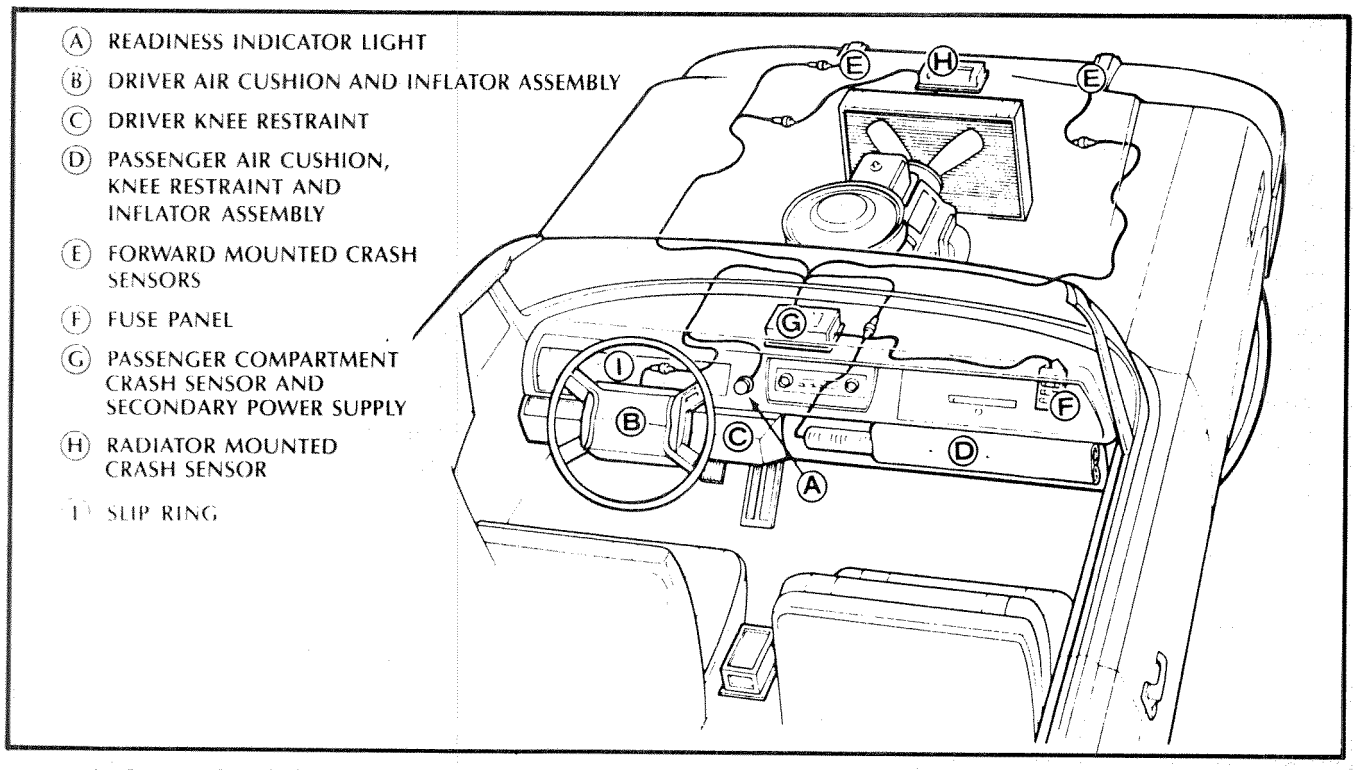

Figure 2. Conventional air cushion safety system

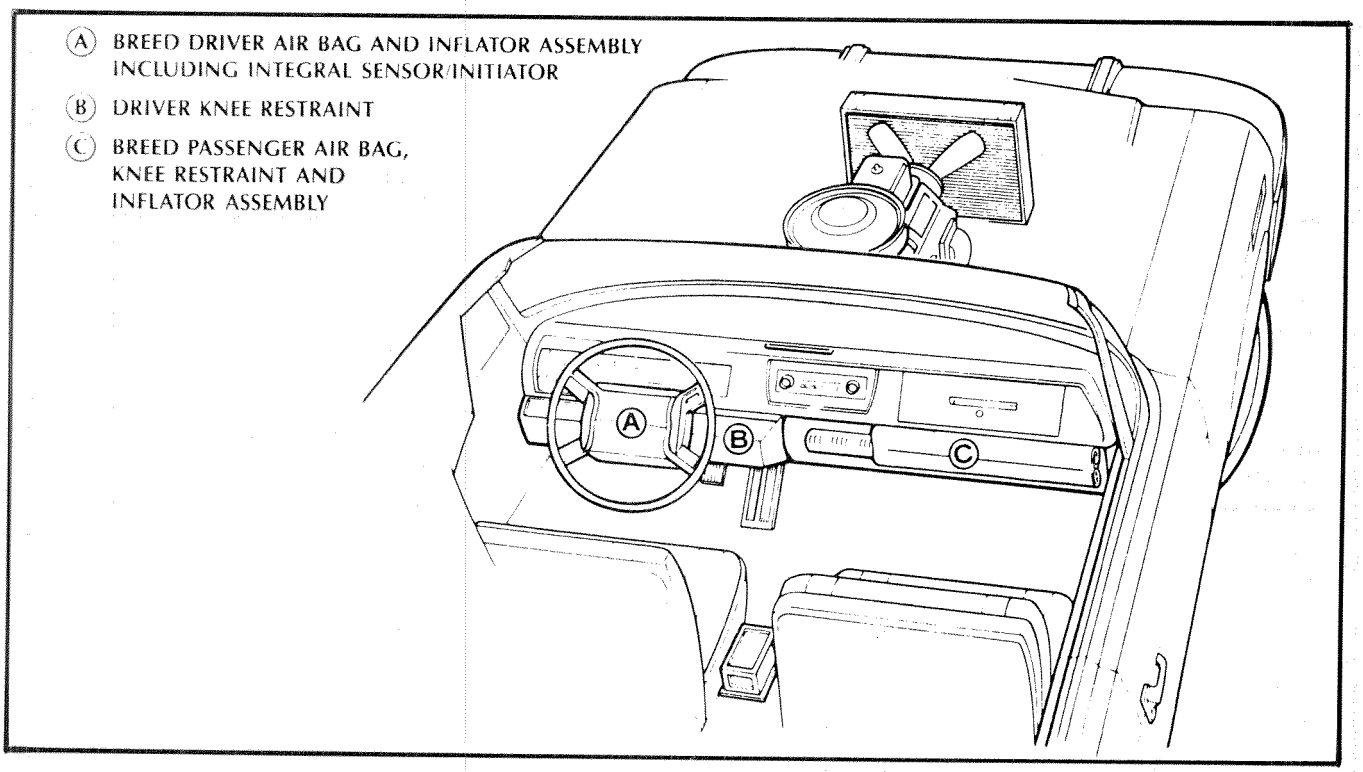

Figure 3. Breed airbag module

Research & Development at the National Highway Traffic Safety Administration. We now have had and analyzed five successful crash tests of our driver side All-Mechanical Compact Airbag System retrofitted into three Ford LTD's, a Dodge Diplomat, and a Chevrolet Impala. The test results are summarized in Table 1. Suffice it to say, the dummy injury levels achieved in these tests have been highly satisfactory.

We have also run a series of Chevrolet Impala sled tests, again with excellent results. Table 2 highlights these results. Probably the two most significant sled test conclusions are that: (1) the Breed All-Mechanical Compact Airbag System provides highly effective crash protection on its own, and (2) when used in conjunction with a 2- or 3-point belt system, it dramatically improves the performance of the seatbelt system.

Finally, I would like to address the five specific points presented to all panelists.

1. In considering optimum airbag performance, how critical is it to tune an airbag system to the characteristics of a specific vehicle?

An airbag system must at least be tuned to each generic vehicle type, based on the stiffness of the crash pulse and the occupant seating position. The use of sophisticated computer math modelling is critical to tuning an airbag system for specific vehicle types. To optimize airbag performance, we must concern ourselves with the candidate vehicle's crash pulse, its interior ergonomics, the steering column and knee bolster characteristics, the sensor and gas generator response curves, and the airbag size and venting parameters.

Table 1. Breed all-mechanical airbag crash tests

NATURE OF CRASH TEST	DATE	HIC	CHEST G'S	LEFT FEMUR	RIGHT FEMUR
1979 Ford LTD 30 mph Frontal Barrier	6/26/84	247	44	1,450	1,820
1979 Ford LTD 12 mph Frontal Barrier	7/26/84	25	20	1,100	1,015
1980 Ford LTD 30 mph Centerline	8/08/84	187	43	1,350	1,310
1983 Dodge Diplomat 30 mph Frontal Barrier	12/20/84	461	49	2,100	1,500
1983 Chevrolet Impala 30 mph Frontal Barrier	1/10/85	289	44	1,850	1,000

Table 2. Chevrolet Impala sled test results

		50% Male and 5% Female 30mph Barrier Equivalent Velocity					
Test Condition	Injury Measures	Breed A/B System Only	Breed A/B Sys. & 2-pt	Breed A/B Sys. & 3-pt	3-Point Belt Only	2-Point Belt Only	No Restraint
50% Male 30mph	HIC	215	160	291	855	734	651
	Chest G	32	30	39	39	72	90
	Femur L	1,080	750	670	170	290	2,540
	Femur R	1,250	460	460	390	500	1,220
5% Female 30mph	HIC	551	228	585	1,635		
	Chest G	46	45	51	58		
	Femur L	550	340	300	300		
	Femur R	700	280	500	200		

After analyzing many crash pulses, it appears the response curve of the Breed All-Mechanical Sensor/Initiator probably will remain the same from vehicle to vehicle. After all, the crash pulse that activates the interior crash sensor is the same pulse that propels the occupants forward.

2. Airbag applications in small cars, both at the driver and passenger position.

We believe we will be able to supply suitable All-Mechanical Compact Airbag Modules for the driver and passenger side of small cars as well as large ones, if steering column and dash intrusions are not severe.

Using our sensor and VODS models, we have analyzed more than 600 crashes of various types of vehicles, including many small cars. The spectrum of crashes included head-on barrier and pole crashes, angled crashes, and car-to-car collisions. Results indicated that in all but two cases, the Breed All-Mechanical Airbag System would have kept injury measures below 80 percent of the requirements of FMVSS 208. Even for the two cases, the FMVSS limits were not exceeded(1).

3. Prospects for passenger airbag systems in vehicles with two designated seating positions and in vehicles with bench seats.

To date, we have dealt only with vehicles having two designated front seating positions. We believe the automobile manufacturers will follow the Federal administrative rule providing for active seatbelt protection for a center front seat passenger.

4. Prospects for reducing system costs.

There have been at least three independent cost estimates to date of the driver side Breed All-Mechanical Airbag Module. A summary breakdown of these estimates is shown in Table 3. The first column is our own estimate, based on an automated production volume of 1 million units per year. The second is by Mr. Ed Clary, a retired senior automotive engineer, at the same 1 million per year production rate; the third is an in-depth cost analysis under an independent NHTSA contract by Corporate Tech Planning along with Pioneer Engineering. This last set of figures is based on 300,000 units per year only and does not assume automated production.

Each of these estimates confirms that the Breed All-Mechanical Airbag Module would be substantially less expensive than conventional electrical airbag systems.

For the passenger side, a Breed All-Mechanical Airbag Module should cost, at maximum, no more than double that of the driver side. Accordingly, if current overall production were to exceed 300,000 units per year, the cost to any individual car manufacturer for a complete driver and passenger side Breed All-Mechanical Airbag Module System would be under $165. And, if current overall production were to exceed 1 million units per year, a complete driver and passenger module system would drop to under a $95 dealer cost.

5. FMVSS 208 injury criteria and its impact on airbags.

We were pleased to see a General Motors proposal in the recent DOT/NHTSA proposed rulemaking that suggested different injury level limits for airbag/belt restraints. For a new injury level measurement of chest deflection, General Motors suggested a 3in chest deflection limit for distributed loading restraint systems such as airbags and a 2in chest deflection limit for the lap/shoulder belt. We agree. We also feel the occupant safety industry, automobile manufacturers, insurance companies, con-

Table 3. Independent cost estimates of drivers side Breed all-mechanical compact airbag module

	BREED	CLARY	CTP/ PIONEER
(Units Per Year)	(1 Million)	(1 Million)	(300,000)
Sensor	$ 5.00	$ 7.56	$11.49
Gas Generator	15.00	25.21	16.45
Airbag/Cover/Mounting Plate	8.00	8.00	20.35
Total Manufacturing Cost	28.00	40.77	48.29
Manufacturer Profit (15%)	4.00	6.12	7.24
Cost to Distributor/Dealer	32.00	46.89	55.53
Dealer Profit (30%)	10.00	14.07	16.66
Installation	5.00	5.00	8.05
Total Cost to Consumer	$47.00	$65.96	$80.24

sumer groups, and the government should now focus on establishing different injury criteria for airbag restraints, active and passive seatbelt restraints, and friendly interior protection systems because of the different character of loadings produced by these systems. Current evidence indicates that present safety criteria of 1,000 HIC and 60 chest G's are conservative estimates for injury criteria using an airbag system.

I would like to thank our Chairman, Mike Finkelstein, for inviting me to participate in this panel discussion about state-of-the-art airbag technology. I would be happy to answer any questions you might have.

Acknowledgments

I wish to acknowledge the invaluable contribution provided by Thomas C. McGrath, Jr., Dr. Russel Brantman, Dr. Ria Breed, and Ms. Cynthia Werthamer in the preparation of this paper.

Supplemental Driver Airbag System—Ford Motor Company Tempo and Topaz Vehicles

Roger E. Maugh
Director, Automotive Safety Office,
Ford Motor Company

Abstract

This paper describes Ford's supplemental airbag system that is available to commercial fleet users in the United States on Tempo and Topaz car lines. Several key components of the system were based on designs used in a 1981 experimental program. Design considerations in adapting that experimental system to a smaller production vehicle are presented.

In my discussion, I would like to describe the supplemental driver-side airbag system currently being sold as a commercial fleet option in the United States on Ford's Tempo and Topaz compact front-wheel-drive car lines. This system went into production early this year. It was developed in part on the basis of experience we gained with an experimental design originally developed for the full-size 1981 Lincoln Town Car. The Town Car is a large luxury car, approximately 43in (1,088mm) longer and 1,540 lb (700kg) heavier than the Tempo/Topaz. Since the focus of our panel discussion is on airbag technology and optimizing airbag system performance, I would like to describe a few of the changes Ford made during a nearly 2-year program to adapt the experimental Lincoln-based airbag system to the much smaller Tempo/Topaz vehicles.

First, the Ford supplemental driver-side airbag system consists of—

- An airbag module mounted in the steering wheel
- A unique steering wheel and column
- An airbag readiness indicator light
- Five crash sensors mounted in four locations
- A unique wiring harness
- An electronic diagnostic module

Each of these airbag system components had to be redesigned and/or recalibrated in order to work in the smaller Tempo/Topaz models.

The process of redesigning the airbag system for the Tempo/Topaz involved two basic aspects of system performance:

- Meeting crash sensing requirements
- Meeting occupant restraint requirements, including
  - — Inflation geometry/dynamics
  - — Dummy test "injury criteria" (with and without belts)

Let's discuss these in more detail. First, the Tempo Topaz crash sensing system has been designed to do the following:

- To detect and deploy in frontal impacts above a 14mph (22.4kph) perpendicular barrier crash equivalent
- To not deploy in frontal impacts below an 8mph (12.8kph) perpendicular barrier crash equivalent
- To detect impacts that are concentrated inboard (pole), outboard (offset and angular), high (truck), and low (fixed object)
- To differentiate between impact and nonimpact signals
- To supply the firing signal to the bag assembly on a timely basis

To meet these objectives, the sensing system uses three primary sensors and two secondary sensors. All of the primary sensors are located across the front of the vehicle; two are mounted low outboard and one is mounted high at the vehicle centerline. One of the two

secondary sensors, which confirm the crash, is mounted at this same high centerline position and the other is mounted back on the dash panel.

Electrically, the three primary sensors are wired in parallel and the two secondary sensors are wired in parallel. The firing circuit consists of a series loop formed by the parallel group of primary sensors, the ignitor, the parallel group of two secondary sensors, and the battery. Firing occurs when any primary sensor and any secondary sensor are simultaneously closed for at least 3ms.

The sensors, which are manufactured by the Breed Corporation, use a bias magnet to hold a ball that, at a specified deacceleration, will pull away from the magnet and move through a tube to touch two electrical contacts that close the circuit. These sensors are sealed in a shock-mounted assembly so the motion of the ball is not impeded by off-axis vibrations.

Selection of the sensor design for each location is an iterative process. The first step is to run a series of crash tests to obtain the vehicle's crash signature at the desired sensor locations. This is followed by computer modeling of the crash sensor by the sensor manufacturer to select the sensor component specifications that will provide the sensor design objectives specified by Ford. Design variables within the sensor, such as magnet bias, ball-to-tube clearance, and ball travel, can be adjusted to meet the design objectives. The final system design can then be confirmed by an additional series of fully instrumented crash tests.

On the Tempo/Topaz program, we ran 17 crash tests at different speeds and angles to get crash signatures at a number of prospective sensor locations. Some locations were eliminated, based on the lack of a good acceleration signal at that point. Based on these data and modeling work by the sensor manufacturer, sensor locations and tentative "calibrations" were selected as follows:

	Location	Calibration (at Location)
Primary Sensors		
Left	Left front fender apron	10mph (16kph)
Center	Center of radiator support	10mph (16kph)
Right	Right front fender apron	10mph (16kph)
Secondary "Safing" Sensor		
Forward	Center of radiator support	3.5mph (5.6kph)
Rear	Centerline of dash panel	1.1mph (1.8kph)

I should point out that when we identify a primary sensor calibration as 10mph (16kph), the speed refers to the speed of the test device used by the sensor manufacturer to insure compliance with Ford's 14mph (22.4kph) closure design objective. In other words, the 10mph (16kph) haversine test device pulse is equivalent to an actual 14mph (22.4kph) crash pulse in terms of causing sensor closure.

Each sensor must pass six individual production acceptance checks—three for insuring that it will close or fire at a 10mph (16kph) velocity change with soft/medium/hard g (haversine) pulse widths—and three for insuring that it will not close or fire when subjected to 6.5mph (10.4kph) velocity change with soft/medium/hard g (haversine) pulse widths. And might I add that all of these checks are performed twice on every sensor shipped to Ford, once during the manufacturing process and again after final sensor assembly.

After the sensors were designed by the sensor manufacturer, the system was subjected to a series of nine validation crash tests. The test program included crashes at various speeds and types. For example, we ran angular, perpendicular, truck underride, car-to-car, and pole-type tests. The end result of this process is shown on the attachment. For all crash pulses above the shaded area, sensors will close and a firing signal will occur (such as the 31mph and the 14.8mph pulses shown on the chart). For crash pulses in the shaded area, sensor closure and a firing signal may occur. For all crash pulses below the shaded area (about 8mph), no closure or firing will occur.

The system was also tested in the laboratory and on the track for durability, corrosion resistance, and other normal vehicle operating conditions. However, even with all of this test and development work, we still need extensive on-the-road experience to confirm our sensing system design. This is one of the primary benefits we hope to get from the NHTSA-GSA fleet program and the other fleet units now going into service.

The second major area of airbag system performance involved in redesigning the system for the Tempo/Topaz was to meet the occupant restraint requirements. As I mentioned earlier, this involved—

- Inflation geometry and dynamics
- Dummy test injury criteria (with and without belts)

Since the basic relationship between the driver and the steering wheel is essentially common in most cars, it was initially assumed that the driver airbag module developed experimentally for the Lincoln could be used with little change for the Tempo/Topaz installation. A study of the crush characteristics of the Tempo/Topaz showed that even though it is substantially smaller than the 1981 Lincoln, there is still sufficient crush space—approximately 24in (610mm)—with its resultant delay of the crash pulse reaching the occupant compartment—to permit the use of the nonaggressive bag fill incorporated in the original Lincoln airbag design. However, a crash test identified another reason for making significant changes to the Lincoln airbag module. The experimental Lincoln design used a firm unvented airbag that transmitted virtually all of the dummy energy into the steering column. It was concluded that the smaller Tempo/Topaz

models needed a softer bag that would absorb some energy through a vent system.

Our engineers also decided to add a strap system to the bag to control bag shape during inflation. These two bag changes (vents and straps) required a comprehensive sled test program to evaluate alternative bag sizes, inflator calibration levels, and vent sizes. Following the sled test program, our engineers selected a 26-½in (64.8cm) diameter bag with two 1.1in (28mm) vents and the original experimental Lincoln inflator or gas generator calibration.

This package was then put through a series of development crash tests primarily aimed at confirming that the 30mph (48kph) belted and unbelted GSA contract requirements would be met. Typical test levels for the system at this point in the program were as follows:

30mph (48kph) Perpendicular Barrier Test Results

Driver	Belted	Unbelted
HIC	823	524
Chest G	46	47
Left Femur (#)	414	1,663
Right Femur (#)	1,346	1,750

Throughout the development program, the primary focus had been on meeting the 30mph (48kph) contract criteria, although several tests had been run at 35mph (56kph) with HIC results (belted) within the 1,000 range.

Just before production startup, production level vehicles were tested at 30mph (48kph) to demonstrate the contract requirements had been met. In addition, we tested one at 35mph (56kph) to confirm the results were not out of line at this higher speed.

The results were good at 30mph (48kph) but not what we expected or wanted for 35mph (56kph) tests.

	30mph (48kph)		35mph (56kph)
	Belted	Unbelted	Belted
HIC	653	721	1,202
Chest G	49	58	55
Left Femur	675	1,258	967
Right Femur	898	1,198	1,922

At this point, it was clear that if we wanted lower test results at 35mph (56kph), we were going to have to soften the bag some more. Another sled test series was run to evaluate the effects of larger vents at different speeds, belted and unbelted. From this work, it was determined that 1.6in (40mm) vents could be used to provide lower test results at 35mph (56kph) for the belted configuration and still not "strike thru" at 30mph (48kph) for the unbelted configuration.

New production level vehicles were then prepared and tested with the revised 1.6in (40mm) vent system.

	30mph (48kph)		35mph (56kph)
	Belted	Unbelted	Belted
HIC	540	377	550
Chest G	52	52	52
Left Femur	505	1,340	452
Right Femur	622	1,804	1,175

Test results were acceptable, and production started in January 1985. We are satisfied that the Tempo/Topaz airbag provides good supplemental protection at test speeds up to at least 35mph (56kph). Although we have not tested the system at test speeds above 35mph (56kph), we believe it also will provide added protection at higher speeds.

Designing the supplemental airbag system to meet NHTSA's injury criteria at both 30 and 35mph (48/56kph) probably affected its performance characteristics at other speeds. As test speeds increase, the possibility of upper torso or head "strike thru" also increases. As we move ahead to future airbag installations, we think it will be important for NHTSA and manufacturers to learn more about injury thresholds when impacting airbags and the relationship between test speed and "strike thru" to be sure we aren't sacrificing real-world protection just to satisfy an artificial test objective.

The Daimler-Benz Supplemental Restraint System

Prof. Dr. Ing. W. Reidelbach
Daimler-Benz AG

We at Daimler-Benz consider safety belts as the fundamental and absolutely essential restraining system in all vehicle crash modes. Everything else, including airbags, are supplements to a comprehensive occupant protection system. This principle has been the guideline for our airbag development activities.

As early as 1966, Daimler-Benz began investigating the potential of airbags as a further possible element of the crash protection system already a part of the Mercedes-Benz safety concept. Static airbag testing using liquified or pressured gas as a deployment agent was first carried out. It soon became apparent the dimensions of the bulky devices available at this time were impractical for installation in Mercedes-Benz passenger cars.

In 1969 we turned to an entirely new technology of bag deployment and materials because of our earlier experience and knowledge; in 1970 we initiated the development of a solid propellant gas generator that could be packaged into the hub of the Mercedes-Benz steering wheel without sacrificing the protective function of the kinetic energy-absorbing elements of the wheel. This was done in cooperation with Bayern-Chemie, and later with Morton-Thiokol. Today a German or an American gas generator is used to inflate the 60-liter driver airbag.

To trigger the system, we have selected an electronic solid state deceleration sensor. The prime function of the sensor is to measure deceleration forces and determine whether the impact speed is above the predetermined triggering threshold. If the threshold has been exceeded, the triggering signal will initiate the firing sequence. The

sensor is also responsible for monitoring and registering system readiness.

Considerable testing of the performance of the components and the total system has been conducted since 1970, including thousands of gas generator performance tests, static bag inflation tests, impact simulations on sleds, and full-scale crash tests. Several hundred company cars were equipped with the driver airbag system and field tested.

In 1980 the mileage accumulated during field operation of the test fleet exceeded 80 million road kilometers, and the system was released for production.

We started offering as an option the Supplemental Restraint System (a driver airbag system, together with an emergency tensioning belt retractor for the passenger) in December 1980 on the S-class models only, then, in spring 1982, on all models in certain European countries. For model year 1984, the system was offered also in the United States and Canada. As of June 1985, about 60,000 Mercedes-Benz cars with driver airbags had been delivered worldwide, about 14,000 of these in North America.

The functional reliability of the system has proved very satisfactory. We were informed on accidents with or without airbag deployment. All nondeployment cases occurred at a very low impact severity level, i.e., below the triggering threshold.

In all cases with an impact severity level at or above the threshold, the bag was inflated. There was no inadvertent deployment. The system has functioned as designed.

The Police Fleet Airbag Retrofit Program

David Romeo
Romeo Kojyo Co., Inc.

The Police Fleet Airbag Retrofit Program has been progressing successfully. With initial placement of systems into police vehicles in December 1983 and approximately 450 airbag-equipped vehicles on the road, there have been—

1. No occurrences of airbag deployment without a reportable accident
2. Approximately 25 to 30 accidents of varying intensity resulting in 18 deployments
3. No significant injuries in any of the accidents
4. No cases where an accident occurred in which the airbag should have deployed and did not

Evaluation of the system is continuing.

Since a progress report on the program was submitted to the conference in written form (paper by Romeo and Morris), no further discussion of the program will be presented. Instead, this presentation will respond to the chairman's specific areas of interest, which were—

1. Considerations for optimizing airbag performance. How critical is it to tune an airbag system to the characteristics of a specific vehicle?
2. Airbag application in small cars both at the driver and passenger position.
3. Prospects for passenger airbag systems in vehicles with two designated seating positions and in vehicles with bench seats.
4. Prospects for reducing system costs.
5. FMVSS 208 injury criteria and its impact on airbags.

Succinctly these concerns are addressed as follows:

1. Optimizing airbag performance.

From the standpoint of designing an airbag system less sensitive to vehicle design considerations than manual belts, there is less need to tune. The need to tune an airbag is driven more by subjecting its performance to FMVSS 208 dummy criteria evaluation (as opposed to the manual belt, which has no such requirement) than it is to any inherent sensitivity of airbag systems to vehicle differences. (One acknowledged exception to this are systems that use sensors located remote from the crush zone.)

Quite a bit has been said by automobile manufacturers regarding the difficulty of fitting an airbag to different cars. It is interesting to note, however, that there is in fact little or no difference across car line in the systems offered by each of the three companies that produce driver airbags. These car lines range in size from compact to luxury.

2. Airbag use in small cars was addressed very recently by John B. Morris in a paper entitled "Airbags For Small Cars," SAE Paper 851200, May 1985.

He compared predicted driver airbag performance in a large car, full size, or Ford LTD versus a subcompact Chevrolet Chevette. The fatality risk for drivers of cars of these classes based on an analysis for two vehicle crashes by Cerrelli (see above paper) is five times greater for the small car. Yet, airbag restraint capability degrades only from 17.9 to 35.6 percent of allowable HIC and 47 to 65 percent of allowable C_R between these cars.

Therefore, the obvious conclusion is that although on an absolute basis airbag system performance is degraded in a small car, on a relative basis the potential benefits of the airbag in the small car are far greater than they are in a large car. Putting it another way, both my Toyota Corolla and my Datsun Pickup have airbags.

3. With regard to passenger airbag systems, with recent FMVSS 208 exemption for automatic protection for the center front passenger, one can forget about a full bench seat (three front passengers) airbag system. Besides, airbag technology is now being led by the Europeans (spelled Mercedes and BMW) and they do not have a bench seat. For the right front passenger, introduction of airbag systems are imminent.
4. Cost reduction can be effected in two ways:
   - Make the system simpler
   - Make a large number of systems

Holding quantity of production constant, i.e., 1,000/yr, 10,000/yr, 100,000/yr, etc., the recently reintroduced "all-mechanical system" promises a cost reduction of approximately 15 percent through elimination of diagnostic, wiring harness, and connector coil. Holding system design constant and increasing production from 1,000/yr to 10,000/yr or 100,000/yr shows cost reductions of 50 and 75 percent, respectively. It is obvious, therefore, that in the near future quantity considerations will overwhelm all others with regard to potential cost reduction.

5. Regarding FMVSS 208, it has been concluded that the evaluation criteria of this rule are clearly inadequate for making comparable evaluations of the performance of belt and airbag systems. This is due primarily to the concentrated versus the distributed loading capabilities of belts versus airbags. An excellent discussion of this point appears in the proceedings of the 20th Stapp Car Crash Conference in a paper by Walsh and Romeo, "Results of Cadaver and Anthropomorphic Dummy Tests in Identical Crash Situations."

Passive Safety Belt Developments

Clement A. Detloff
General Motors, Fisher Guide Division

Abstract

The U.S. Department of Transportation National Highway Traffic Safety Administration MVSS 208 requirement for passive restraints and dynamic performance on 1987 vehicles confronted virtually every auto manufacturer selling in the U.S. market with the problem of equipping vehicles with passive restraint systems. This presentation touches on some of the problems and concerns associated with providing a passive belt system.

Introduction

From a manufacturing standpoint, the U.S. requirement for passive restraints in 1987 U.S. vehicles has created more changes to safety belt restraints and more challenge for the related businesses than any action since safety belts were legislated into U.S. vehicles in 1968. For the vehicle manufacturer, the performance of the restraint system in the vehicle becomes an added concern since the injury performance criteria required in the standard must be met by all vehicles. Dynamic performance repeatability and the ability to meet requirements at different test facilities with different test personnel present some concern. For the hardware manufacturer, the compliance to world seatbelt laws covering the components must still be met along with the added requirements of the vehicle manufacturer to assure vehicle system dynamic performance compliance.

System Selection

The selection of any restraint system must take into consideration complying with the MVSS 208 requirements, providing overall safety to the system users, and also providing a usable and marketable product to the customer. The user comfort and convenience of the system is a major concern as well as compatibility with the vehicle, such as rear seat passenger entry, driver visibility, and overall appearance. GM's previous experience with the passive safety belt systems and other passive restraint systems has not been good from a customer acceptance standpoint. Air restraint and passive safety belt vehicles produced by General Motors in the past were difficult to market due to lack of customer acceptance, and the sales projections were not achieved. Although some limited clinical data indicate that acceptance of passive restraint systems has improved and our state-of-the-art safety belt systems are more acceptable to the potential buyer, we do not have clinical data to definitely establish the system that customers prefer today. The time limitations to meet the 1987 production also provide limitations in tooling and manufacturing of some possible restraint systems. In addition, the interior styling and general configuration of a vehicle can provide some limiting factors. Examples are door frames or frameless glass. The differences in legal requirements between countries also provide some concern and limitations with regard to system selection. They have an effect on anchorage locations and actual performance of system hardware.

Body-Mounted 2-Point Passive Belt Systems

Body-mounted retractor 2-point passive restraint systems (Figure 1) use a single retractor that is body-mounted in the center of the vehicle with the upper or shoulder belt anchor located on the upper frame or B-pillar. Instrument panel knee bolsters or knee restraints are required with the system. The B-pillar-mounted anchor requires a power means to move the anchor forward on a guide track to allow vehicle entry and exit. From an engineering standpoint, the system presents limitations on center seating positions, use of center-mounted consoles, and proper placement of anchorages for optimum dynamic performance. Also, webbing tends to drag across the occupants when the system is operated during entry and exit. This type of system does not generally provide an emergency release latch, but an emergency or override of the retractor lock could be provided.

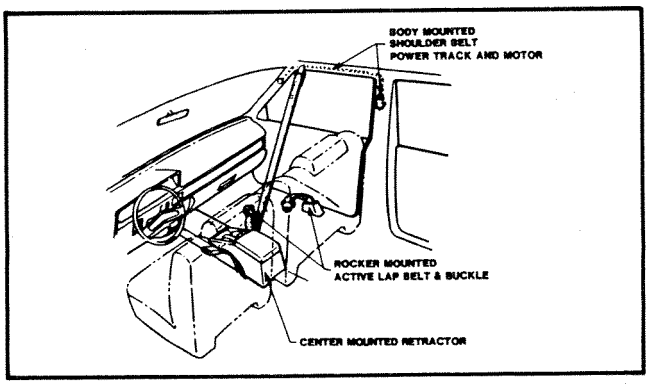

Figure 1. Body-mounted 2-point passive belt system

Door-Mounted 2-Point Passive Belt System

Door-mounted retractor 2-point restraint systems (Figure 2) use a single retractor mounted on the tunnel with an emergency release latch assembly mounted in the door area of the vehicle with instrument panel knee bolsters. The upper or shoulder anchorage of this system is door-mounted and moves with the door to allow for entry and exit. Two-point systems present some unique challenges both from a performance standpoint and from an engineering standpoint. From a performance standpoint, this type of system presents engineers additional challenges to provide adequate protection for various size occupants through the full range of seat adjustment travel. Like all restraint systems, these systems require tuning each vehicle system to assure performance over the full range considering all variables.

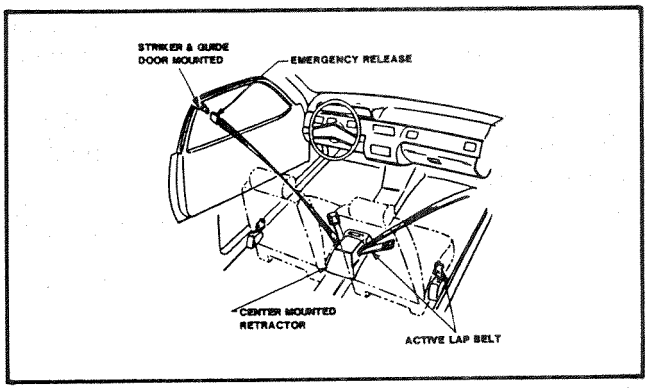

Figure 2. Door-mounted 2-point passive belt system

Door-Mounted 3-Point Passive Belt Systems

The door-mounted 3-point system (Figure 3) would use two door-mounted retractors with the shoulder belt and lapbelt anchorages located on the door, allowing the belts to move with the door for entry and exit and providing conventional safety belt restraint for the two outboard front seat occupants. By using door-mounted retractors, a center seating position still can be incorporated and the intrusion on center console space is eliminated. The instrument panel knee restraints are not required in most cases; however, in some specific vehicles, such a restraint may be required to insure proper dynamic performance. Dynamic performance with 3-point systems is similar to the conventional manual system; however, placement of anchorages and the use of any belt snubber has to be tuned to the vehicle to assure proper kinematics. This system allows flexibility of anchorage locations.

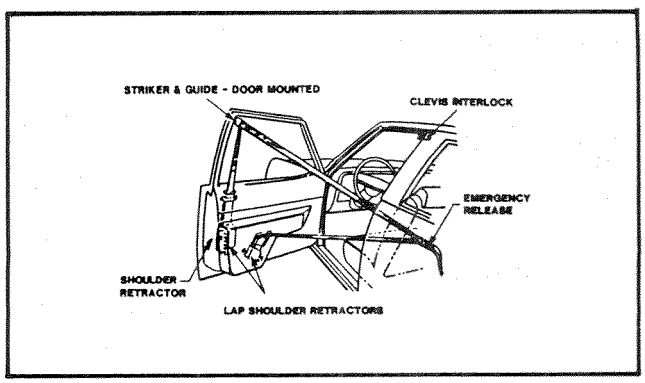

Figure 3. Door-mounted 3-point passive belt system

Complementary Interiors

The passive interior concept (Figure 4) would not require the use of conventional restraint systems to meet

the performance criteria but would use occupant kinematics and the interior services of the vehicle to control energy absorption. Any such system would be considered supplemental to the 3-point lap/shoulder belt system that would be provided in the vehicle, and its use would be recommended.

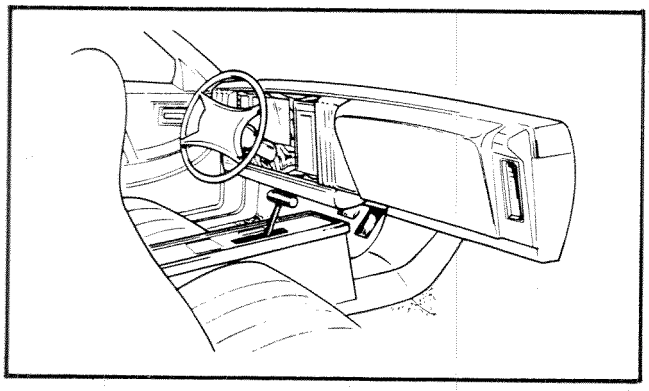

Figure 4. Complementary interior

Summary

In conclusion, various systems can be used to comply with the passive requirements. Any system requires evaluation of the vehicle configuration, vehicle crash performance, compatibility with vehicle environment, and overall acceptability aimed at the vehicle purchased to assure acceptance in the marketplace.

Automatic Belt Restraint Systems for Motor Vehicle Occupants

H. George Johannessen, P.E.
OmniSafe, Inc.

Abstract

Following early U.S. Government regulatory action requiring passive occupant crash protection for vehicle occupants covered by Motor Vehicle Safety Standard 208, intensive development began on passive seatbelts as promising alternatives to the inflatable systems being considered. The general types of passive seatbelt systems are identified. Passive systems that have been offered to date as optional installations in production car lines are described. Design considerations are discussed. Recent usage rates of installed passive systems are compared with manual belts.

Introduction

The U.S. Congress enacted the Highway Traffic Safety Act of 1966 to address the problem of traffic fatalities and injuries on American roadways. The National Highway Safety Bureau was quickly established to carry out the provisions of the new law. (The National Highway Safety Bureau later became the National Highway Traffic Safety Administration.) The late Dr. William Haddon, Jr., was appointed to head the new agency. He was a medical doctor with a long and distinguished role in public health and traffic safety in the State of New York. He viewed traffic fatalities and injuries as a public health problem of epidemic proportions that could best be overcome by passive means—that is, by means requiring no overt action on the part of the parties affected. He cited past examples of successful passive solutions to major public hazards, such as inoculation of entire populations to overcome dread diseases, pasteurization of milk, and use of automatic sprinkler systems to control fires.

Passive Systems for Passenger Cars

In November 1970, the U.S. Federal Motor Vehicle Safety Standard 208, which addresses vehicle occupant crash protection, was amended to incorporate the original requirements for passive restraints in the front seating positions of all passenger cars manufactured on or after the first day of July 1973 for sale in the U.S. car market. Challenges to these original requirements and original effective date resulted in a series of subsequent actions from 1970 to the present by legislative and judicial branches of the U.S. Government, in addition to the responsible regulatory agency, NHTSA, which reconsidered and revised requirements and effective installation schedules for passive occupant protection. The most recent action calls for passive occupant protection in front outboard seating positions on a phased-in schedule with installations in a minimum of 10 percent of the manufacturers' car build after September 1, 1986, 25

percent after September 1, 1987, 40 percent after September 1, 1988, and 100 percent after September 1, 1989. The passive requirement will be rescinded if States representing two-thirds of the Nation's population enact mandatory seatbelt usage laws before April 1, 1989, that will be in effect and enforced by September 1989.

The passive system for vehicle occupant protection that received immediate attention following the issuance of the original rulemaking in 1970 was the inflatable restraint, or airbag. Alternative noninflatable means, however, were considered as well. Many categories of such noninflatable passive candidate systems were identified, as shown in Table 1. These included transparent shields, deployable nets and blankets, cushions, restraining arms and barriers, integrated seat systems, and seatbelt systems.

Table 1. Noninflatable automatic occupant restraints

- Transparent Shields
- Deployable Nets
- Deployable Blankets
- Integrated Seat Systems
- Restraining Arms
- Cushions
- Seatbelt Systems

Developmental Passive Seatbelts

Of these various categories, passive seatbelts showed the greatest promise by far. Passive seatbelts were developed in many variations. Several distinctive classes may be identified. These are listed in Table 2. They may be 2-point, 3-point, or 4-point systems based on the number of load-bearing connections to vehicle structure. They may be all mechanical or may be all or partially motorized. They may have retractors located in either inboard or outboard locations and fixed anchors located either inboard or outboard. Some may require knee bolsters to control lower body movement. All must have some provision to permit disengaging the seatbelt after an accident. Prototypes of all these classes of systems have been developed and installed in production cars.

Table 2. Typical automatic seatbelt systems

2-POINT — Passive Shoulder Belt Only

3-POINT — Passive Lap and Shoulder Belts

4-POINT – Separate Passive Lap and Shoulder Belts

- Mechanical and Motorized Models in All Types

Installations in Production Car Lines

Some of the more promising developmental designs have been offered to the public in production cars. These are described in Table 3. The first production model to appear was a 2-point system, installed as an extra-cost option in a Volkswagen Rabbit in model year 1975 and subsequent years. Figure 1 shows the conceptual design of the Rabbit installation. This system includes a 2-point

Table 3. Production automatic seatbelt systems

CAR LINE	MODEL YEAR INTRODUCED	TYPE
VW RABBIT	1975	2-POINT
GM CHEVETTE	1978 ½	2-POINT
GM CHEVETTE	1980	3-POINT
TOYOTA	1981	2-POINT — MOTORIZED

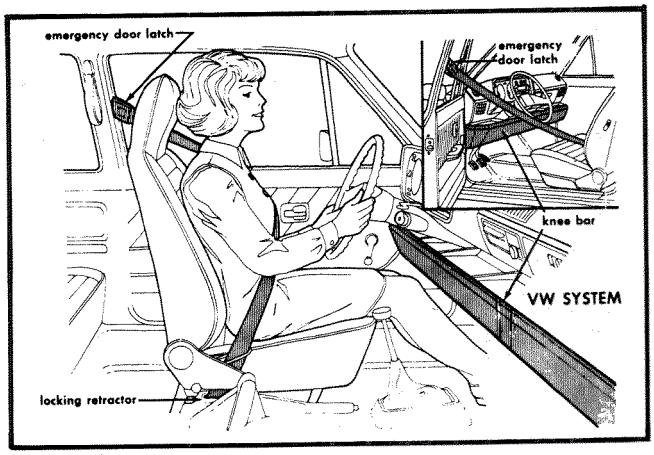

Figure 1. First automatic seatbelt system in production car line

upper torso belt with the retractor inboard and the fixed anchor attached outboard on the door. The door connection incorporates a buckle for emergency disconnection. The buckle has an electrical interlock with the starter system to insure that the buckle is connected in normal driving use. The lower body movement is controlled by a knee bolster and a specially designed seat pan. Figure 2 shows the appearance of the VW system as installed in the Rabbit.

The first production installation in a car produced in the United States appeared in the Chevette manufactured by the Chevrolet Division of General Motors in model year 1978. It was quite similar to the VW installation in the Rabbit, except that it used a seat of conventional design and included a manual lapbelt. Figure 3 shows the conceptual design, with a passive 2-point shoulder belt, a knee bolster, and a lapbelt.

Figure 2. VW automatic seatbelt installation

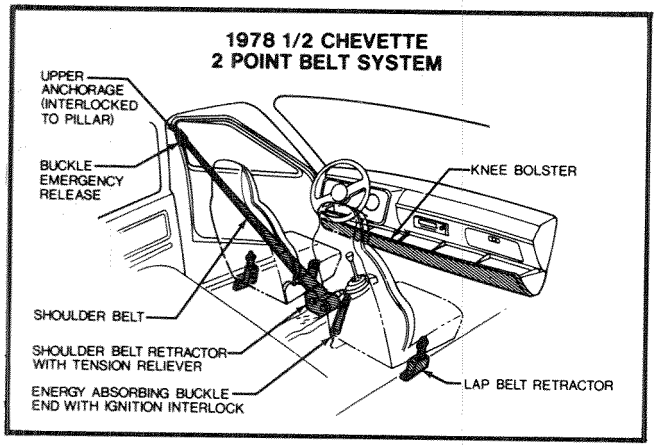

Figure 3. First automatic seatbelt system in U.S. domestic production car line

The next production installation appeared in the Chevette in model year 1980. This was a 3-point system with an inboard retractor and two fixed anchor points on the door. Figure 4 shows the conceptual design of this system. A buckle on the lower anchor on the door was provided for emergency release. This buckle also incorporated a switch to provide an electrical connection with a buzzer to insure that the buckle was engaged during normal use.

The most recent automatic system has been installed in the Toyota Cressida since model year 1981. It is a 2-point system with an inboard emergency-locking retractor and an outboard anchor location on the B-pillar. Figure 5 shows the conceptual design of the Toyota system. A manual belt is included to control lower body movement. The lower portion of the instrument panel provides a knee bolster as well. The motorized outboard anchor point is routed along the roof rail and the upper portion of the A-pillar. This action moves the shoulder belt forward out of the way for easy occupant ingress into the vehicle, and then returns it to don the shoulder belt on the occupant after he is seated and the door is closed. The

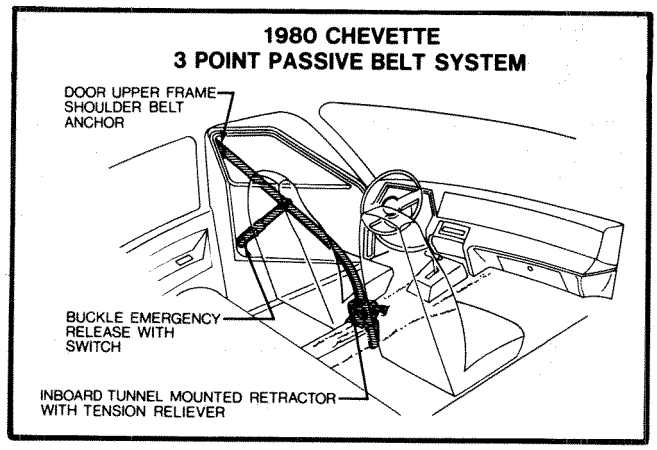

Figure 4. Second generation automatic seatbelt system in U.S. domestic production car line

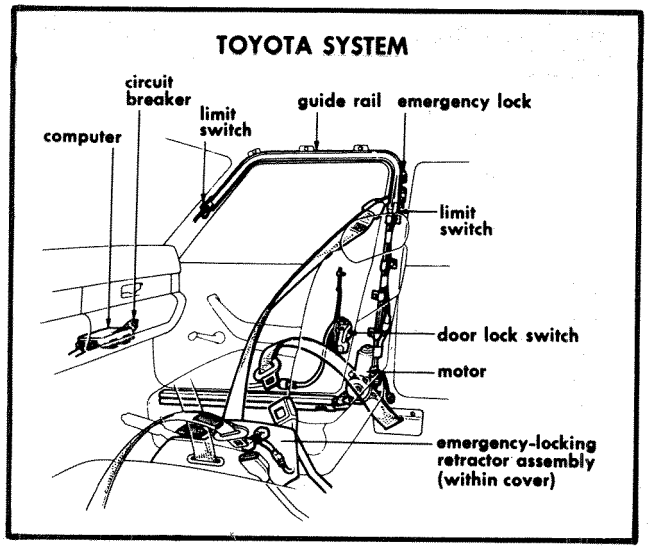

Figure 5. Motorized automatic system

traverse of the belt has been carefully timed to move the belt quickly, yet not so quickly as to startle the occupant. Figure 6 shows the relative movement and location of the motorized shoulder belt.

Design Considerations for Automatic Seatbelt Systems

The general design considerations for all seatbelts are shown in Table 4. The list includes performance in accidents and evasive maneuvers, simplicity in design and operation, reliability, durability, vulnerability to damage during normal use or in accidents that could render them inoperable, comfort during use, convenience in use, packaging size and shape for accommodation in the vehicle, esthetics, and cost. Automatic seatbelts have the added requirement for automatic donning and doffing.

In any given system design, tradeoffs inevitably are encountered such that optimization of one variable is

Figure 6. Toyota automatic shoulder belt system

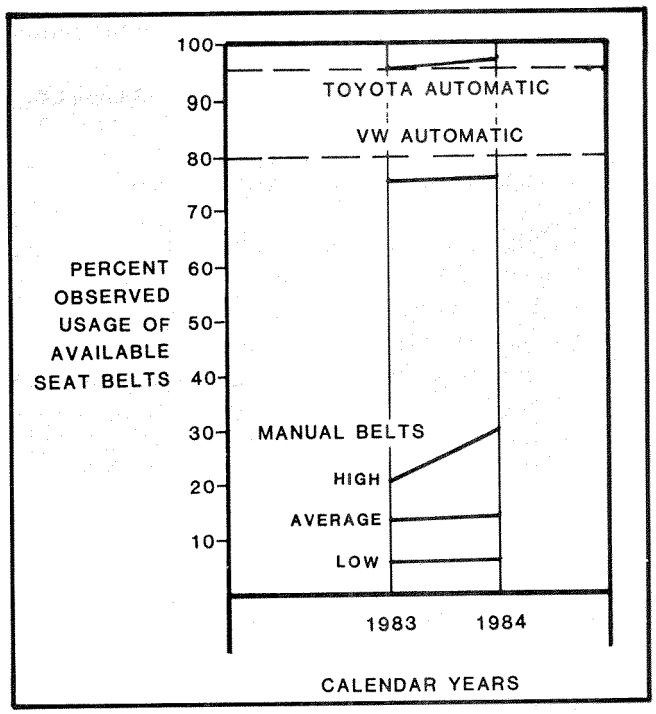

Figure 7. Recent seatbelt usage rates in US.A.

accompanied by some sacrifice in optimization of another. Some obvious examples are (1) the possible degradation of performance in emergencies for the sake of increased comfort in normal usage by means of a tension-relieving device on the shoulder belt, and (2) the possible decrease in simplicity and reliability for the sake of increased convenience and improved stowage through the use of retractors.

Table 4. Design considerations

● Esthetics
● Cost

Usage and Performance

The usage rates and performance of these automatic seatbelts in the field have been very satisfactory. Figure 7 shows the usage rates for automatic systems as compared with the usage rates for manual belts, representing data obtained in the ongoing program sponsored by the National Highway Traffic Safety Administration in which usage rates are monitored in 19 cities across the United States. Average driver usage of manual belts in these 19 cities increased from 13.3 percent in 1983 to 14.4 percent in 1984 and 15.3 percent in the last quarter of 1984. The upward trend was due mainly to the intensive efforts of NHTSA and others in the safety community to increase seatbelt usage in the United States. Usage rates varied appreciably from one city to another in the 19-city study, with a low rate in 1984 of 7.1 percent and the highest rate of 30.1 percent. The principal predictors of usage, in the absence of mandatory use laws, are age and sex of the driver (with the greatest usage in the age range of 25 to 49, and women consistently being more frequent users than men); size of car (with greater usage in smaller cars); foreign versus domestic U.S. cars (with drivers of foreign cars more than two times as likely to be wearing seatbelts); and the age of the car (with seatbelts more likely to be in use in later model cars).

The usage rate for the VW system has persisted in the range of 80 percent through the years since 1975, when it was introduced, with observed usage rates of 75 percent in 1983 and 76 percent in 1984. The Toyota Cressida system has done even better, with usage rates of more than 95 percent observed in the NHTSA 19-city program. The Chevette system's usage rates are in the same general range as the VW, but somewhat lower.

Performance data for these systems in accidents are limited because of the relatively short time they have been exposed on the roadways and the relatively small number involved in accidents. The data acquired to the present through the National Accident Sampling System operated in the United States by NHTSA, referred to as the NASS data, indicate the performance of these automatic systems

in the real world is generally comparable to the performance of manual systems.

The Future of Automatic Seatbelts

The key to the need for automatic belts is the usage rate of seatbelts. In the many countries and jurisdictions around the world having mandatory seatbelt use laws, starting with Australia in 1970 and including England more recently, usage rates of 75 to 95 percent are achieved with manual seatbelt systems when minimal—but continuing—enforcement is observed and nominal fines are imposed. In the State of New York, where a mandatory usage law became fully effective on the first day of January of this year, the usage rate is becoming acceptably high. Seatbelt performance in New York, in terms of reduction in fatalities and serious injuries, has followed the patterns observed in other countries having successful mandatory use laws.

Automatic seatbelts are not inherently better performers than manual belts, but they do appear to induce higher usage rates when installed as extra-cost options. The public acceptance of automatic seatbelts when installed as standard equipment remains to be seen. The degree of success in enacting and enforcing mandatory seatbelt usage laws in the United States will determine whether automatic seatbelt systems will be required in the long term.

Safety Belt Development

S. Sano
Honda Research & Development

Last summer, NHTSA issued a rule under MVSS 208 that created the regulation to equip automobiles with passive restraints under a phase-in schedule.

Beginning with model year 1987, 10 percent of all automobiles sold will be equipped with passive restraints. That percentage will increase unless enough States representing more than two-thirds of the entire U.S. population pass legislation mandating seatbelt use by drivers and passengers.

I believe the ideal situation would be the use of manual 3-point seatbelts in conjunction with the adoption of seatbelt use laws by all the States. It is my hope that effective regulation will be in place, as I feel this is the most effective way of providing adequate protection to automobile occupants, rather than by mandatory regulation requiring automatic restraints beginning with the 1987 model year.

We are, of course, preparing to comply with the passive restraint requirement and are considering an automatic seatbelt. Before considering what type of system should be used, at this point I would like to discuss the requirements of a system and the utilization of it.

First, I want to discuss the occupant protection performance, especially the performance of the system in restraining a driver or occupant at the moment of impact. Discussions for the passive belt system have involved both the 2- or 3-point types. However, the important issue is not whether the system is 2-point or 3-point, but how efficiently the automatic system works for a particular car; that is, how efficiently any system can be integrated with other crashworthy characteristics of an automobile, such as crush characteristics, impact duration, and the survivability space available for the occupants.

Another consideration surrounds the system performance during a postcrash emergency escape, either by the occupants or by outside rescue personnel. This relates to the selection of a detachable or nondetachable system and to the related issues of decreased seatbelt usage by user tampering or disconnection of the system. I do not think that whether the system is detachable or nondetachable will have a lasting influence on the restraint usage rate, especially in the long term. For example, during model year 1974, there was a starter-interlock device that was adopted for improving seatbelt usage rates. This rate was raised for a short period, but the interlock system was subsequently defeated, and there does not appear to be any significant difference in the usage rate of seatbelts between the 1974 models and any other year model.

It is my opinion that adopting a nondetachable system for the purpose of improving the restraint usage rates might have the same results as the earlier use of the interlock. Furthermore, it is quite possible that users would subvert the restraint system by removing the belts, which would require a subsequent replacement by any future vehicle owners that would want the protection of the system. The most effective way to improve the rate of restraint system usage is to adopt legislation making seatbelt or restraint use mandatory, which would certainly make the question of whether to use the detachable or nondetachable system no longer a point of discussion.

When considering most emergency escapes in accident situations or rescue of an occupant by outside personnel, it is obvious the detachable system is far superior to the nondetachable system. Because of these considerations, I

am proceeding toward the adoption of a detachable system as my passive restraint system of choice.

There are two considerations affecting acceptance by consumers. One is that the car equipped with a passive restraint system will be acceptable from a cost/benefit standpoint on the open marketplace, and the second is that the system will be used in an unaltered configuration. In the initial stages of the phase-in program, there will be a mixture of cars with passive restraints and cars with the current active seatbelts on the market. This will allow consumers to choose from among them. During the phase-in period, especially before most of the cars being sold are equipped with the passive system, we can assume that those who decide to purchase the cars with the passive belts will have the intention and desire to use that system.

If a consumer, given the choice, decides to purchase a car with the passive restraint, he has considered the benefits and determined they outweigh any detriments such as increased cost, perceived difficulty in entering and exiting the vehicle, or what we may call the spiderweb appearance of the vehicle's interior.

The degree of perceived benefit of the automatic system will depend on the mind-set of the purchaser. People who presently use seatbelts regularly and like the manual system will probably not care for an automatic system; while people who don't like the inconvenience of manual belts but use them because of the perceived safety benefits will most likely prefer an automatic system. Finally, people who are uninformed or simply don't care about the added safety of seatbelts probably won't like the automatic restraint system and are most likely the ones who will take the opportunity to disengage or defeat the system.

As a consequence, we feel the focus during the phase-in period will be on those consumers who do utilize seatbelts, although they feel seatbelts are difficult or inconvenient to use.

Next, I would like to discuss the motorized system. Certainly a motorized system will improve the application and removal situation when a vehicle occupant enters or exits the automobile; however, it does not eliminate all the problems of putting on and removing a belt. Moreover, certain discomforts will be generated for some occupants, such as the belt rubbing against a user's face or neck since the belt moves automatically regardless of user's intention.

A motorized unit will increase the cost substantially when compared to the cost of the belt itself, either under the present system or a nonmotorized passive restraint system. Additionally, there is no doubt a system that has simple component parts will have superior reliability when compared to the complexity of the motorized system.

Again it is very difficult to evaluate the cost/benefit of the passive restraint systems. Because no system is a perfect system in every aspect, one approach could be to evaluate various manufacturers' systems over a period of time.

We began to develop the automatic seatbelt system in the early 1970's and exhibited a motorized version 11 years ago at the ESV meeting held here in England. We abandoned that system after an evaluation program because of concern about injury-causing potential from the positioning of the mechanical arm.

Since that time, we have tried many different combinations, such as a motorized arm operating on the door side, a motorized arm operating from the mid-portion of the car interior, a system without a motorized arm, one with a convenience hook, another system with an ELR set in the middle of the automobile interior as well as an ELR on the door, 2-point systems, 3-point systems, and every combination of all the elements mentioned.

From our extensive experience, we concluded no perfect system exists that is acceptable and satisfies every single consideration. The 2-point restraint system and the motorized arm system are not favored by people accustomed to the traditional manual belts, since space is further restricted by a knee bolster and is not considered by those persons as a benefit. System users are influenced apparently more by the discomforts caused by the passive restraint system than by any improvement of the putting on or removal of the system.

Therefore, we consider the simple, nonmotorized 3-point passive restraint system that is similar to the current manual belt system to be the most adequate during the phase-in period.

However, we are well aware that the situation concerning development of automatic restraints keeps changing. We are keeping an open mind as to appropriate forms of automatic restraints that are most desirable from the standpoint of safety, efficiency, and comfort, and will change the system any time substantial and significant advancements are made in accordance with our ongoing research programs.

Dietmar K. Haenchen
Volkswagen-Research

I would like to talk about four related topics:

1. VW seatbelt features
2. Belt use in VW Rabbits
3. Performance of automatic and manual belts in the field
4. Whether measures to improve the vehicle structure for 35mph barrier crashes would result in improved accident statistics

Let me now describe the main features of the Volkswagen belt systems:

Slide 1. You are all familiar with the manual belt. Note that in VW's 3-point belt system, the buckle is mounted to the seat. This assures good fit of the belt in all seating positions.

Slide 2. The VW automatic belt has the same geometry of the upper torso belt. In this case, the retractor is mounted under the seat. This also assures good fit because the belt moves with the seat when it is adjusted. The lower torso restraint is provided by the knee bolster.

Slide 3. The advantage of this simple automatic belt is that it is easy to use—just open the door, get into the car, and close the door.

When we introduced this automatic belt system in 1975, we were curious how this system would perform in the field. Although crash test data indicated good performance, real-world performance could have differed due to the many accident types we have in the real world.

When using the collective Fatal Accident Reporting System (FARS) data from 1975 through 1983, it turned out the overall effectiveness of automatic belts in VW Rabbits is about 19 percent better than the effectiveness of manual belts.

Slide 4. Observed belt usage in Volkswagen Rabbits has been relatively high for both the manual and automatic belts, as shown in this slide. It is around 30 percent for manual belts and around 80 percent for automatic belts.

However, belt use in severe accidents is much lower, due to the fact that those occupants who don't wear seatbelts also tend to be more involved in severe accidents.

Slide 5. John van Dyke of NHTSA's Center for Statistics and Analysis investigated whether the difference in fatality rates is compatible with the observed usage rate for both restraint systems. Using belt use data from accident statistics in three different States, he assumed that both the manual and automatic belts in Rabbits are 45 percent effective in preventing fatalities and serious injuries. Van Dyke concluded that the 19 percent fatality rate difference is reasonably consistent with the difference in observed usage rates.

Slide 6. Volkswagen researchers recalculated the data the other way round. Taking the FARS data and using the 45 percent effectiveness of both belt systems, they calculated the usage rate.

As you can see in the slide, there is good agreement of the calculated usage rate with the observed usage rate. Van Dyke concluded that, "This evidence supports the conclusion that the lower fatality rate for occupants of automatic restraint Rabbits is attributable to the higher restraint use by these occupants."

With this in mind, it is obvious that further significant decreases in traffic fatalities and serious injuries can be achieved if we continue to increase belt use.

Slide 7. This slide illustrates the remaining lifesaving potential of seatbelts. For reasons of simplicity, we have assumed an effectiveness of 50 percent for all belts.

The first column shows zero lifesavings if no belts are worn; the second shows 25 percent usage (this is about the usage we see in accidents with Rabbits with manual belts); and the third shows the 50 percent usage that we see in accidents with Rabbits with automatic belts. The last column shows the improvement we would get with 100 percent belt use.

Mandatory belt use laws have reduced fatalities and injuries in many countries, and I am convinced they will also work in the United States.

Let me touch the topic of improving seatbelt performance by modification of the vehicle structure.

Using computer simulation, Volkswagen researchers developed force-deflection curves that would give optimum injury criteria for 3-point belts in 30mph barrier tests. Two optimized structures were developed, one for a seatbelt system without preloader and one for a seatbelt system with preloader. Both of these systems had about the same overall benefit.

Slide 8. The diagrams show the force-deflection curves of the vehicle front structure. In the left diagram, we see the optimum curve of the vehicle without preloader; in the central diagram is the system with preloader. The dashed lines represent a present vehicle structure.

Our researchers also calculated a force-

deflection curve for an optimum performance of the belt system at the 35mph barrier impact velocity. As you can see in the right diagram, this optimized curve is very different from the present curve. The optimized structure for the 35mph system requires a very high initial force to achieve the optimum performance.

It is obvious that such a structure would be very aggressive to other vehicles, especially in side impacts. Consequently, the overall safety benefit in the field would be produced by such a structure.

Let me conclude with a summary:

1. Manual and automatic belts show similar effectiveness when worn.
2. The difference in overall effectiveness between manual and automatic belts is basically related to the difference in belt use only. Mandatory belt use laws will help to further increase the effectiveness of both types of belt systems.
3. Optimizing the vehicle structure to improve injury criteria for 35mph crashes does not necessarily lead to better overall accident performance in the field.

Biomechanics of Diffuse Brain Injuries

Lawrence E. Thibault
Thomas A. Gennarelli
University of Pennsylvania

Abstract

This report discusses the development of brain injury tolerance criteria based on the study of three model systems: the primate, inanimate physical surrogates, and isolated tissue elements. Although we are equally concerned with the neural and neurovascular tissue components of the brain, the report will focus on the former and, in particular, the axonal elements. Under conditions of distributed, impulsive, angular acceleration loading, the primate model exhibits a pathophysiological response ranging from mild cerebral concussion to massive, diffuse white matter damage with prolonged coma. When physical models are subjected to identical loading conditions it becomes possible to map the displacements and calculate the associated strains and stresses within the field simulating the brain. Correlating these experimental models leads to predictive levels of tissue element deformation that may be considered as a threshold for specific mechanisms of injury. Isolated tissue studies in the axon then serve to confirm the relationship between ultimate strain, for example, and the pathophysiological consequences. At this time, we have found that elongating strains of between 5 and 10 percent at strain rates of greater than 50sec^{-1} produce membrance depolarization and a concomitant decrease in excitability that recovers in minutes. The degree of depolarization is directly proportional to the magnitude of the stretch. Further, total structural failure of the axonal membrane (diameters 400-750.jmm) occurs between 25 and 50 percent elongation at comparable strain rates. These observations are in reasonable agreement with the estimations of critical strains obtained from the primate and physical model studies.

Introduction

The development of head injury tolerance criteria for specific forms of brain injury remains one of the many challenging problems in the biomechanics of central nervous system trauma. Part of this problem is to describe the variety of head injuries that occur and to associate with each injury a severity index. Additionally, it becomes necessary to elucidate the mechanisms that produce each injury and to develop tolerance (or failure) criteria for the components that constitute the brain. Finally, a method to relate the kinematics of dynamic mechanical loading of the head to the deformations of the brain tissue is required.

This report will discuss the use of three model systems selected to address these issues and, further, it will focus on diffuse brain injury. Although the neural and neurovascular tissue injuries may be of equal importance in terms of injury severity, the scope of this study is restricted to the axonal structures of the brain. The three models therefore include the primate, simplified, inanimate, structural models of the skull brain system, and isolated axonal tissue preparations. Previous studies have found(1,2,3) that inertial loading, and in particular rotational acceleration, is capable of producing diffuse injury to the brain of the primate. We have more recently shown that the severity of this injury can be varied to include mild cerebral concussion as well as prolonged coma with axonal damage bilaterally in the hemispheres and in the corpus colossum and brain stem. Results to date suggest that as the brain experiences inertial loading

with significant rotational components it undergoes a deformation that depends not only on the details of the loading but obviously on the local geometry and the tissue material and structural properties.

Simple physical models of the skull-brain structure under carefully controlled inertial loading experiments allow one to study the temporal and spatial variation of these deformations as a function of the magnitude, direction, and time history of the rotational accelerations. These deformations result in strains and stresses that, when excessive, are manifested in functional and structural changes in the tissue elements. To demonstrate the latter, it is most practical to use isolated tissue elements. We will discuss the giant axon of the squid as a model of axonal structures of the brain. Electron miscroscopic examination of the brain's deep white matter reveals intracellular injury to the axons in the regions of the nodes of Ranvier, and this particular injury has been associated with prolonged coma(4). Although the squid axon is non-myelinated, we feel it is a reasonable model for this nodal region that is probably the most vulnerable from a structural point of view. Changes in the electrophysiology of the axon under conditions of variable strain-rate uniaxial extension are then related to the animal and physical model results.

Methods

Primate Model

A standard 6in diameter HYGE® (Bendix) shock tester has been modified in the following manner:

- The stroke length was reduced to 3.125in.
- The internal acceleration and deceleration metering pins were redesigned to produce the desired acceleration-time characteristics.
- A kinematic linkage was designed that converts the translational motion of the HYGE thrust column into an angular motion.
- A helmet system was designed to rigidly couple the primate head to the kinematic linkage.

This system is used to provide controlled inertial loading to the primate as well as the physical models. Figure 1 depicts the kinematic linkage whose angular displacement is set at approximately 65°. Also shown in the figure is a typical acceleration-time history expressed as tangential acceleration.

The primates used in these studies were baboons ranging in weight from approximately 5 to 10kg. Standard physiological monitoring was performed including intracranial pressure, arterial pressure, respiration, respiratory carbon dioxide, respiratory oxygen, EKG, EEG, and multimodality evoked potentials. Upon sacrifice, both light and electron microscopic studies were performed on the brain tissue. With particular emphasis on the axonal structures, the lesions are mapped according to anatomic location and degree of severity.

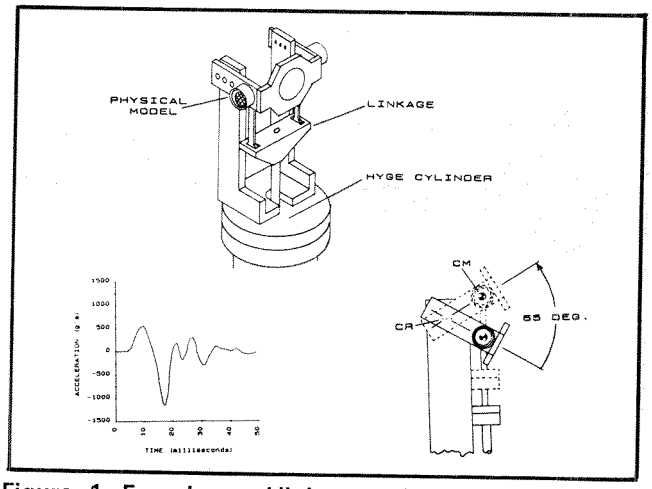

Figure 1. Experimental linkage and typical acceleration profile

Fresh brain weights are recorded in all cases immediately post-mortem and in this study range from approximately 110 to 170g.

The rotational axis was varied to include the three mutually perpendicular planes of sagittal, coronal, and horizontal.

Physical Models

A surrogate brain material in the form of a silicone-based gel, known as Silicone Gel System (Dow Corning), was used for these studies. The material is supplied as a two-part mix of polymer and catalyst. By varying the relative concentrations of these two components, it is possible to alter the modulus of elasticity of the gel by several orders of magnitude. For these experiments, the material properties were closely matched to brain tissue. The gel is an optically transparent substance cast at room temperature and can be layered with no mechanical discontinuity (i.e., the gel in a liquid state will adhere to a polymerized surface upon curing). It is therefore possible to cast the surrogate brain in layers and print or paint an orthogonal grid on selected surfaces that can be entrained in depth within the model. As depicted in Figure 2, both idealized right circular cylindrical geometries, as well as realistic skull boundaries, can be studied.

The physical models are mechanically fastened to the kinematic linkage of the HYGE system in such an orientation that deformations of the grid within the gel can be filmed in the plane of interest. Photography is performed at 4,000 frames per second on 16mm film. Individual frames of interest are printed and then digitized using a Hewlett Packard 9836 computer and bit pad. From the digitized data, one can then compute the field parameters of displacement, strain, and stress at node points within the grid. Therefore, both the strains and strain-rates at a particular location can be determined for any given loading condition.

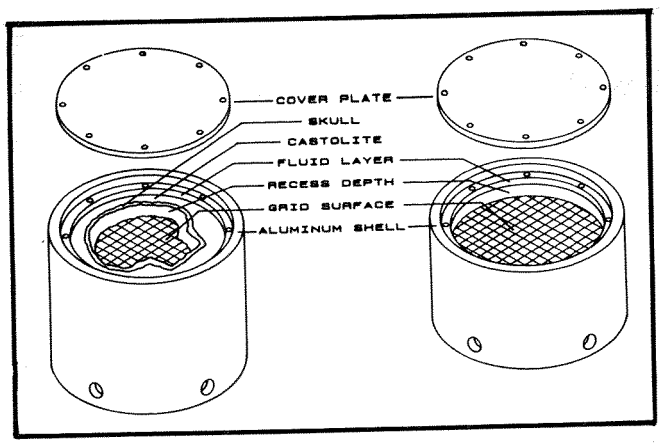

Figure 2. Construction of the physical models

Isolated Tissue

A system has been developed that permits one to study the electrophysiology, morphology, biochemistry, and transport properties of the giant axon of the squid as a function of variable strain-rate and variable magnitude of stretch in uniaxial extension.

Approximately 5cm of dissected axon is mounted in a chamber where glass cannulae are inserted through small cuts in the membrane. As portions of the membrane are allowed to dry to the glass cannula, a tight grip is formed between the glass and the internal circumference of the axon. This procedure produces a viable length of axon of approximately 1.5cm, which is immersed in the physiologically suitable fluid. The glass cannulae are part of platens that on one end attach to an isometric force transducer and on the other to a movable linkage. The linkage is driven by an audio speaker that can be programmed to move a predetermined displacement at a given velocity. This constitutes a small materials testing machine with a specimen environmental chamber. For purposes of this study, a wire electrode is inserted axially into the preparation to obtain membrane potential measurements. The system is depicted schematically in Figure 3. The entire device is integrated onto the movable

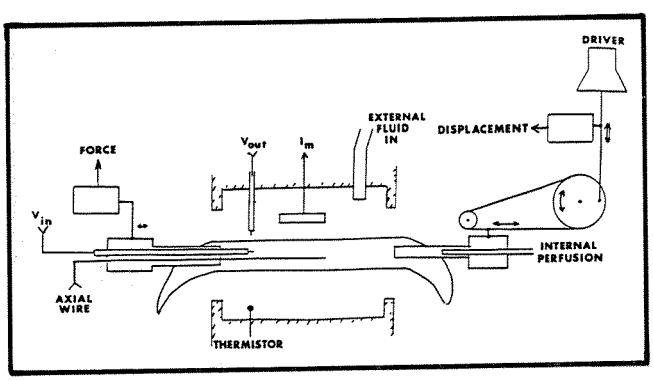

Figure 3. Experimental apparatus for isolated tissue studies

stage of an inverted phase contrast microscope. With this arrangement, it is then possible to obtain axonal mechanical properties as well as the neural tissue element electrophysiological response to mechanical stimulation.

Results

Primate Model

Thus far we have been able to programmably reproduce the following brain injuries in the primate model:

1. The acute subdural hematoma with varying degrees of severity.
2. Cerebral concussion from mild to periods of unconsciousness of up to 2 hours.
3. Diffuse axonal injury with prolonged coma.

The subdural hematoma as part of a class of neurovascular injuries will not be presented here.

The cerebral concussion and diffuse axonal injuries are shown in Figure 4. These same data are presented in Figure 5 where the peak rotational acceleration is shown plotted against the change in angular velocity. The data are scaled based on Holbourn's(5) suggested relationship as a function of brain mass to an average human brain of approximately 1,400g.

In the case of cerebral concussion, the period of unconsciousness varied from less than 1 minute to approximately 2 hours. For those animals listed as having diffuse axonal injury with prolonged coma, the longest survivor was sacrificed at 6 weeks. At this point in our experiments, the threshold levels for cerebral concussion and diffuse axonal injury when scaling the primate data to man appears to be 5,000 rad/s^2 (75 rad/s) and approximately 15,000 rad/s^2 (150 rad/s), respectively. The symbols □ and x in both figures refer to diffuse axonal injury and cerebral concussion.

Physical Model

Depicted in Figure 6 are the digitized and computer-reconstructed still frames of the grid deformations within an idealized riqht circular cylindrical geometry. Time is shown beneath each frame and is expressed in milliseconds. As the frames are presented, the cylinder is rotating in a counterclockwise direction. Recalling the asymmetric acceleration-time history character of the loading, the peak deformation is seen to occur at a point that temporally corresponds to the peak of the tangential deceleration waveform. Once the deformation field is digitized, the computation of the field parameters can be performed. Shown in Figure 7 is a plot of one component of the nonlinear strain tensor, E_{12}, as a function of the nondimensional cylinder radius. This type of analysis is

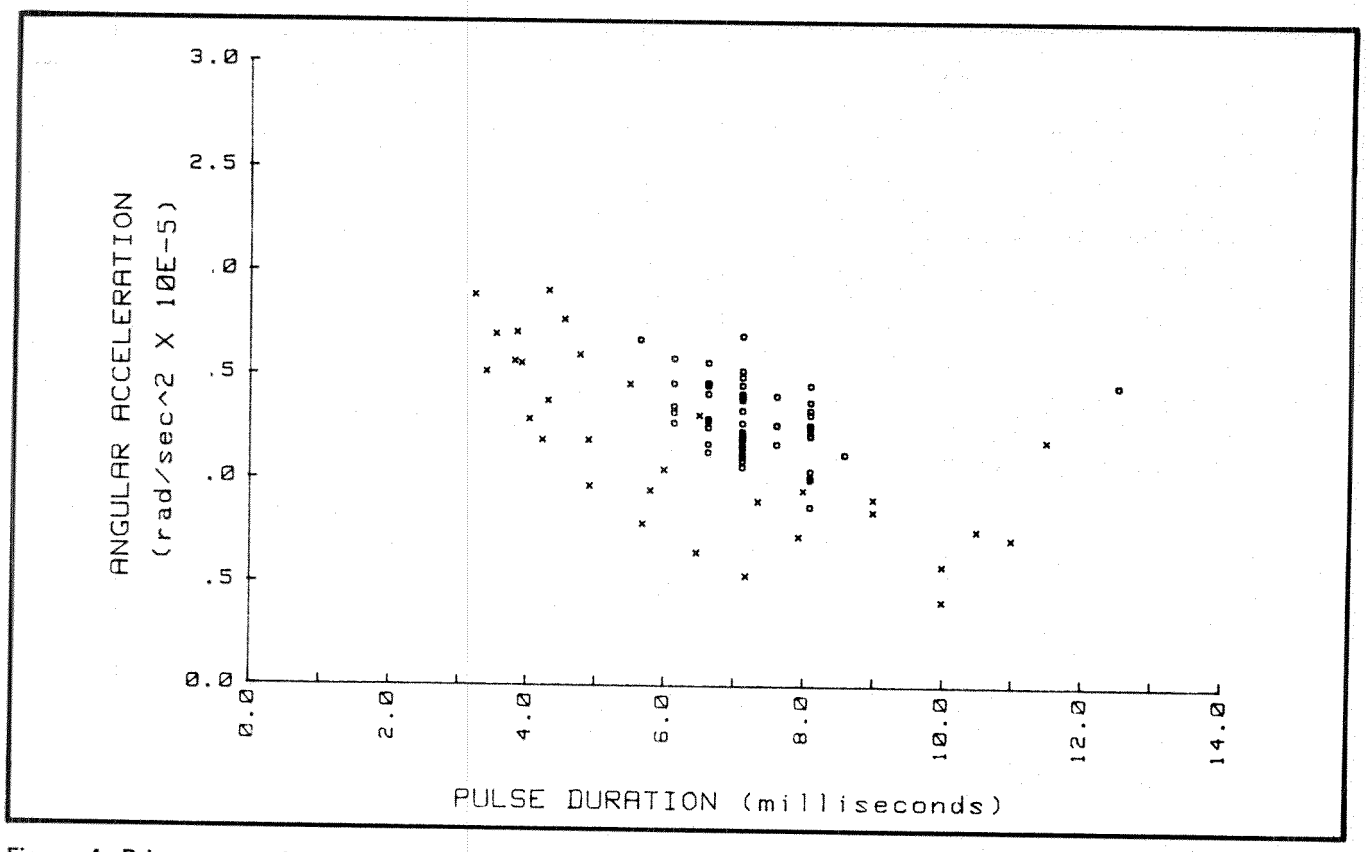

Figure 4. Primate experiments—angular acceleration versus pulse duration

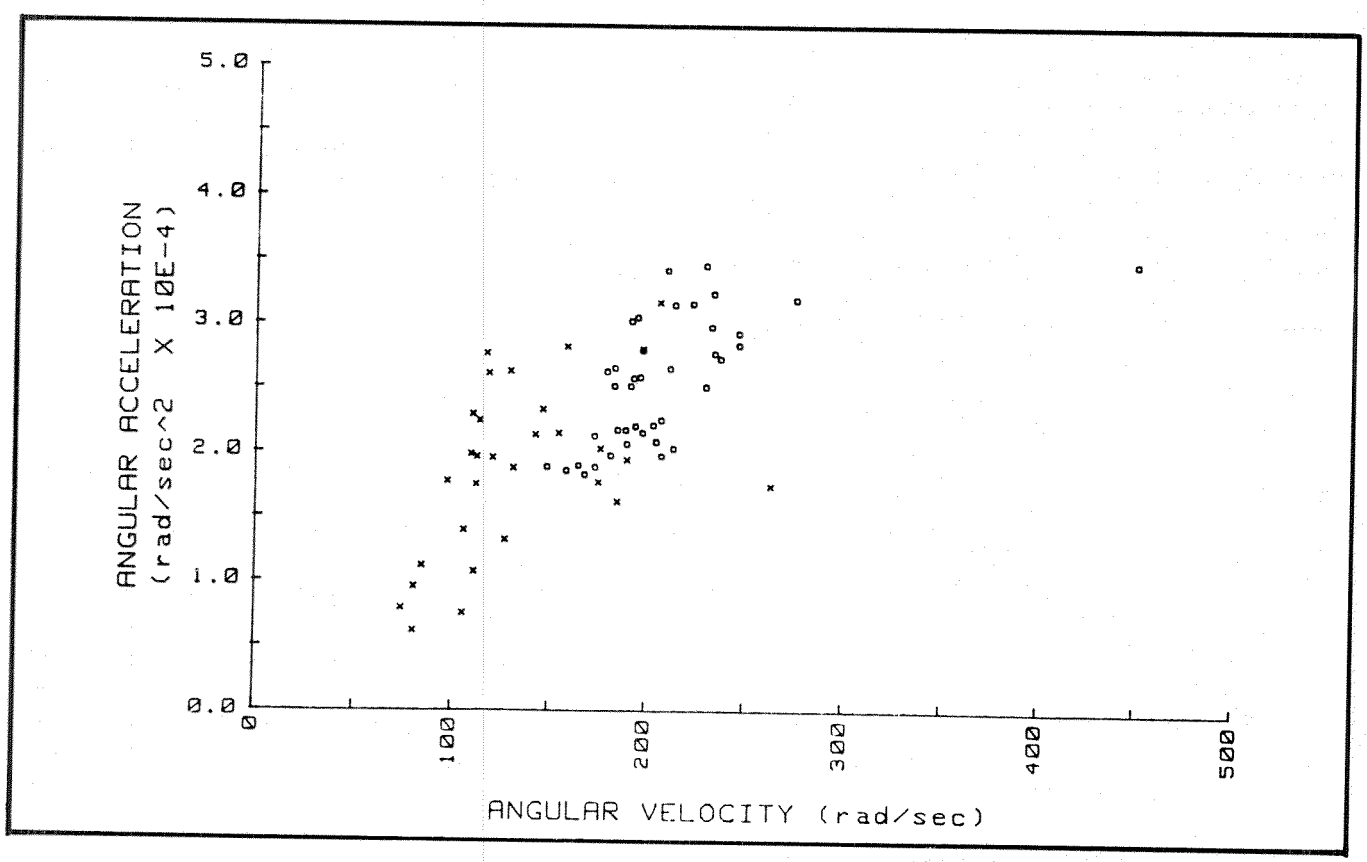

Figure 5. Primate experiments—angular acceleration versus angular velocity

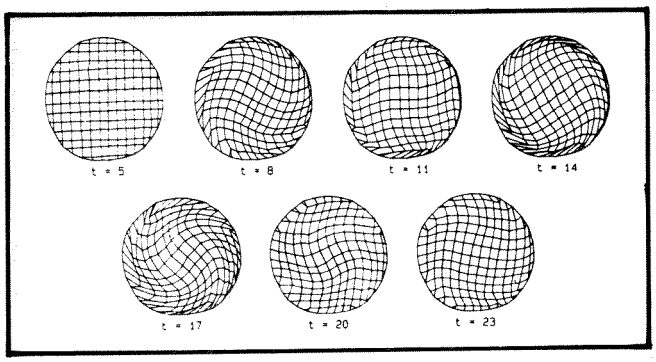

Figure 6. Digitized reconstruction of still frames for the right circular cylinder model

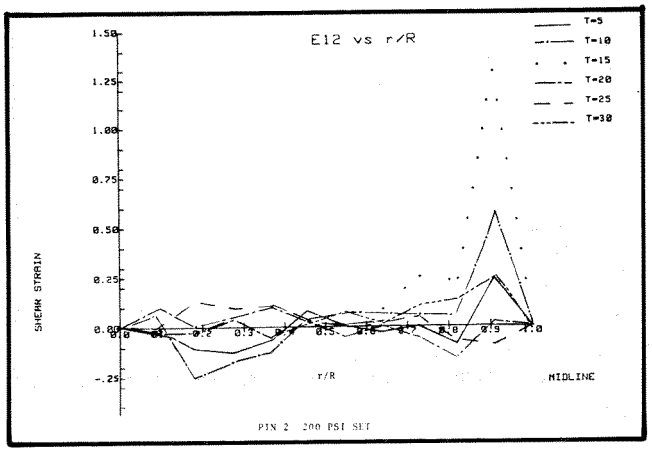

Figure 7. Strain versus nondimensional radius

presented to demonstrate the somewhat asymmetric strain field expected in the case of a noncentroidal rotation and to show an example of the many kinds of analysis that can be performed with the physical model data.

Figure 8 represents a comparison of the maximum elongating strains in three cylindrical models of different radii as a function of the peak rotational acceleration. The curves are labeled A, B, and C, representing cylinder diameters of 11.12cm, 7.94cm, and 6.35cm. Experiments such as these enable one to test scaling relationships such as the one proposed by Holbourn given as

$$\frac{\ddot{\Theta}_m}{\ddot{\Theta}_p} = \left(\frac{M_p}{M_m}\right)^{2/3}$$

Figure 9 shows the relationship between the maximum strain and the peak rotational acceleration when this scaling relationship is applied. The data in this case are scaled to the average brain mass of the baboon from the mass of each of the three cylinder models.

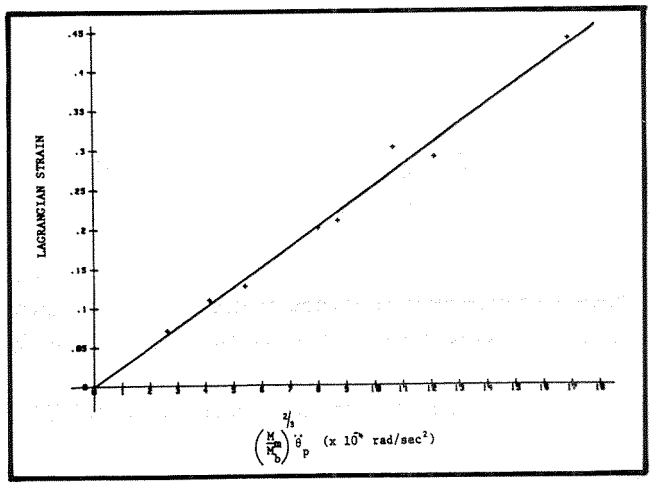

Figure 8. Strain versus angular acceleration for three cylindrical models A, B, and C of mass m_1, m_2, and m_3

Figure 9. Strain versus angular acceleration from the three cylinder experiments scaled to the primate brain mass

Isolated Tissue

Figure 10 shows examples of the mechanical testing performed on the giant axon of the squid. The load-elongation curve exhibits the nonlinear behavior characteristic of soft tissue. Hysteresis and stress-relaxation studies also depicted are representative of the viscoelastic behavior of this class of biological materials. Under conditions of high strain-rate uniaxial extension, there is an associated depolarization of the axon. Figure 11 shows two such experiments where the magnitude of the axial elongation is increased from approximately 15 percent in the first case to 30 percent in the second study. A proportionate increase in the depolarization is observed. We believe that this phenomena and the accompanying decrease in membrane excitability are analogous to the cerebral concussion observed in the primate model. Figure 12 shows the time course of recovery of the resting membrane potential following a high strain-rate ($50s^{-1}$) uniaxial extension (20 percent). The exponential

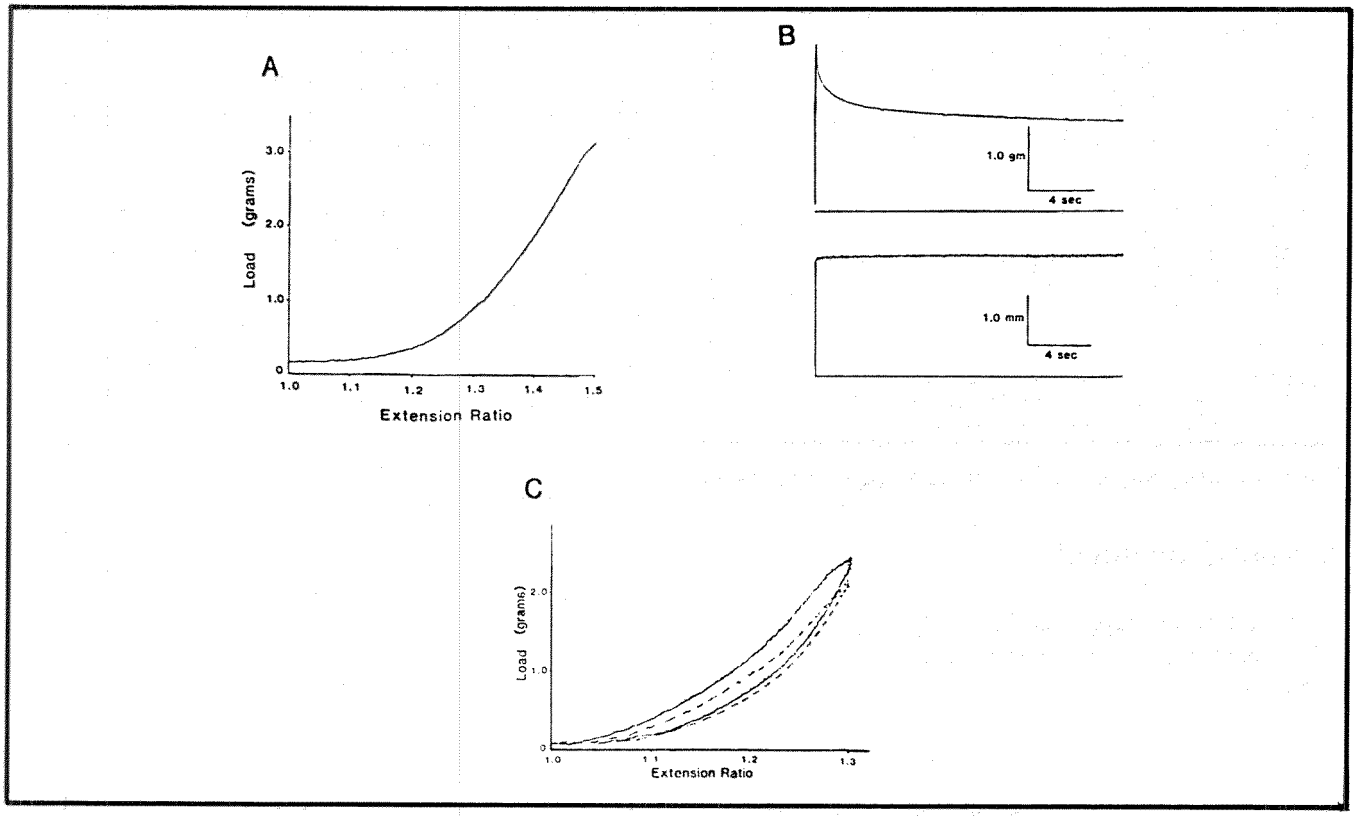

Figure 10. Mechanical properties of the isolated squid giant axon

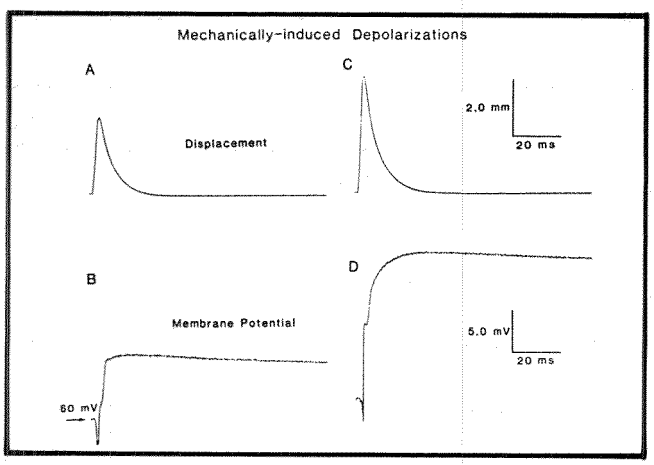

Figure 11. Changes in membrane potential associated with high strain-rate uniaxial elongation

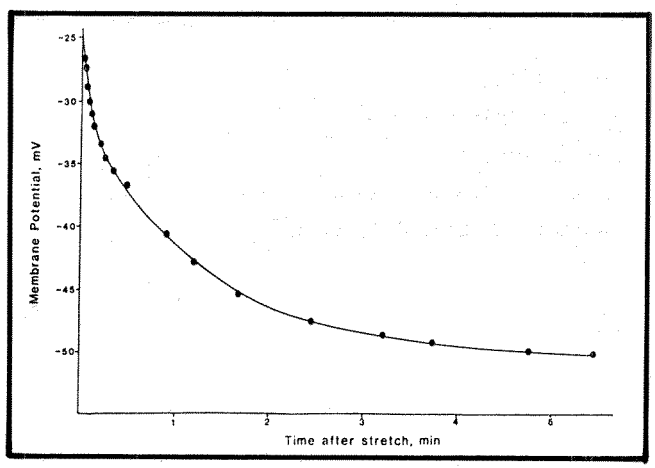

Figure 12. Membrane potential time course of recovery following mechanical stimulation

recovery has a characteristic time constant of the order of several minutes.

Discussion

The experiments described herein are designed to provide methods of improving on existing head injury tolerance criteria and to develop model systems whereby it is possible to study the mechanisms of injury with the ultimate goal of therapeutic intervention. These two distinctly different objectives share a common approach that we describe as the cellular basis for injury from both the biomechanics and pathophysiological points of view.

Figure 13 represents our first approach to developing injury criteria based on tissue response to mechanical strain. The physical models, which are highly idealized at this point, enable one to transform the inertial loading data into tissue deformation. The predicted thresholds for cerebral concussion and diffuse axonal injury ap roximate the isolated tissue response.

Effects of Different Types of Headrests in Rear-End Collisions

Ake Nygren,
Hans Gustafsson, and
Claes Tingvall
Folksam Traffic Safety Group, Karolinska Hospital, Stockholm, Sweden

Abstract

Nygren(1) showed that whiplash injuries in rear-end collisions often lead to permanent disability. Ten percent of those initially complaining about neck pain after a rear-end collision had remaining problems 5 years after the accident and were judged as permanently, medically disabled.

It was also shown that fitted headrests had little effect in preventing whiplash injuries. Fixed headrests reduced the incidence of whiplash injuries by 24 percent, while adjustable headrests reduced the risk by only 14 percent. The results of whiplash injuries in terms of permanent disability were not affected by headrest fitting and type.

The present study is based on 339,675 accidents and determines if the variations of the effects of headrests in different car models could be explained by their type and position.

Background

Neck pain seems to be an increasing problem in Sweden(2). No other diagnosis has so increased its proportion among those leading to sickness or disablement pensions during the past 5 years. The origin of such neck problems is mostly occupational strain injuries, but trauma will accelerate this problem. Nygren(1) showed that neck injuries due to car accidents led to disablement pensions to a higher degree than was recognized earlier. This paper discusses neck injuries in car accidents, especially those coded as AIS 1 in rear-end accidents.

Severe neck injuries in car accidents occur mostly among unbelted car occupants, while slight neck injuries occur among belted ones in frontal collisions(3,4). One specially defined slight neck injury occurs among car occupants in rear-end collisions(3). This problem was discussed in the fifties and sixties, and at that time vehicle manufacturers started designing headrests to extend the seat back.

Neck injuries in rear-end collisions are supposed to be a noncontact injury(5). The crash causes the trunk to accelerate in a forward direction. The unsupported head cannot follow this motion, which results in a hyperextension of the head. The head moves backward and sharply around its initial position and then rapidly

forward. Normally this type of injury leaves no visibly palpable or radiologically distinguishable indication of injury. That could explain why the medical society has not taken this type of injury into special consideration. There are no investigations or treatment recommended for this type of injury. Nevertheless, it is the second most common diagnosis among car occupants with permanent disability(1).

Neck injuries in rear-end collisions often occur in accidents with low speed(6,7). The initial pulse of acceleration when the rear bumper of the car is struck is apparently sufficient to bring about forces producing injury.

The injuries are supposed to be ligament or muscle damage with bleeding. This bleeding may cause an inflammation that can influence the cervical nerves(3). These patients have pain, weakness or abnormal response in the shoulder areas or upper back areas enervated by the cervical nerves. Some authors have reported headache, blurred eyesight, hearing disturbance, or other symptoms involving the central nervous system(5,8).

This type of injury often occurs in accidents of low severity, which might explain why car manufacturers until quite recently have not done much to improve headrests. The injury-reducing effect is 24 percent for fixed headrests and 14 percent for adjustable ones. These figures are fairly low(1).

Objectives

The aim of this study was to investigate the effectiveness of different types of headrests. Special attention was paid to—

- Investigation of the outcome of rear-end collisions in cars with the same construction except type of headrests
- Adjustment of headrests in real traffic
- Evaluation of the influence of the starting year of production on the incidence of neck injuries in rear-end collisions
- Evaluation of the influence of the weight of the car on the incidence of neck injuries in rear-end collisions
- Evaluation of the influence of the horizontal and vertical position of the headrest on the incidence of neck injuries in rear-end collisions

Material and Methods

The material consists of data from car accidents reported during a 5-year period to Folksam, the largest motor insurance company in Sweden with a market share of 27 percent. The study comprises 339,675 private cars involved in accidents. In these cars, 8,592 drivers and 5,878 passengers were injured or killed.

The accident reports contain data about impact direction, and 90 percent of the reports with bodily injuries also contain hospital records or doctors' certificates. The material has been used in a thesis(1) in which a more detailed description of the material can be found.

For this presentation, special measurements made by Autograph in Sweden(9) have been added to the computerized data, such as the vertical and horizontal position of the headrests to the head of a normal-size dummy. Horizontal and vertical positions were collected for 39 car models.

The horizontal position was defined as the distance between the head (base of the skull) and the lowest position of the headrest. The vertical distance is the distance between the highest position of the headrest and the head (Figure 1). A roadside observation study, where cars were stopped by the police, was conducted to evaluate the normal position of adjustable headrests.

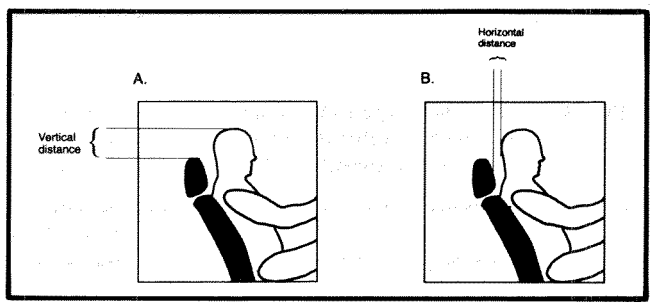

Figure 1. Headrest, vertical (A) distance and horizontal (B) distance
SOURCE: Autograph HB, Sweden

Results

Table 1 shows the severity of injuries in rear-end collisions correlated to different car weights. It can be seen that the injury severity is fairly low expressed in ISS, especially in large cars. The majority of ISS 1-3 is neck injuries.

Table 2 shows the risk of medical disability is much higher for neck injuries in rear-end collisions than for other injuries coded as AIS 1.

Table 3 shows the coefficient of variation for neck injuries in rear-end collisions compared to other directions of impact for 39 car models with headrests. The results show that the incidence of neck injuries in rear-end collisions is more dependent on car model than neck injuries in other directions of impact.

The variation of incidence of neck injuries in rear-end collisions is due to a number of factors, e.g., car weight, horizontal position between head and headrest, as well as

Table 1. Injury severity in rear-end collisions correlated to car weight

Type of car	N	ISS 1-4	ISS 5-10	ISS 11-	Fatally injured
Small car	344	91.0	8.4	0.3	0.3
Medium-size car	763	92.3	6.2	1.2	0.4
Large car	405	94.3	5.2	0.5	0.0

Table 2. Risk of medical disability >10% among car occupants who sustained neck injury in rear-end collisions (AIS 1) compared to all injuries coded as AIS 1 except whiplash

Type of injury	Risk of permanent medical disability
All injuries except neck injuries	0.1%
Neck pain due to rear-end collision	9.6%

Table 3. Coefficient of variation for 39 car models with headrests, a comparison between rear-end and other directions of impact

	Rear-end impact	Other direction
Total CV in %	58	47

vertical position. To study the influence of these three variables, a regression model was fitted to the data.

$$Y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \varepsilon$$

Y = Frequency of neck injuries in rear-end collisions

X_1 = Vertical distance between the head of a normal-size dummy and the headrest (see Figure 1)

X_2 = Horizontal distance between dummy head and headrest (see Figure 1)

X_3 = Car weight

ε = Error term

$$Y = 0.101 + 0.0295\, X_1 - 0.00012\, X_2 - 0.0695\, X_3$$
$$(2.05) \qquad (-0.042) \qquad (-2.68)$$

$R^2 = 0.27$

The coefficient of variation of injuries in rear-end collisions was 58 percent. The model explains 27 percent of the variance, which is fairly low. The rest of the variation was due to reasons other than difference in position of headrest and car weight. The car weight and vertical distance were significant, but the horizontal distance between head and headrest was nonsignificant. The range of the horizontal distance was 7-15 and of the vertical distance 4-15 (1 = 2cm).

In Figure 2 it can be seen that the injury frequency of neck injuries in rear-end collisions increased with increased vertical position.

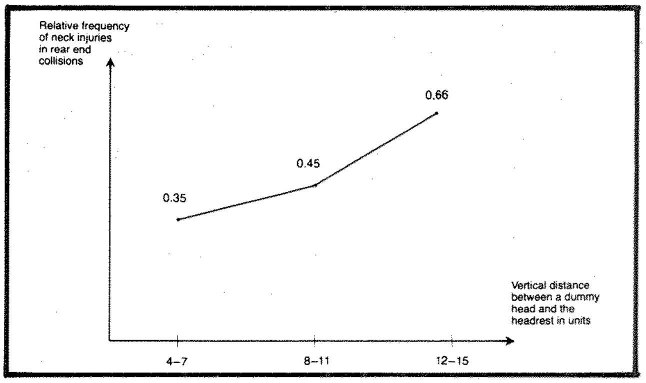

Figure 2. Relative frequency of neck injuries in rear-end collisions correlated to the vertical distance between headrest and dummy head (1 unit vertical distance = 2 cm.)

In connection with the analysis of the relationship of how the position of the headrest affects the incidence of neck injuries a pilot study was made in real traffic. One hundred eighty-seven cars with adjustable headrests were stopped by the police, and it was found that 83 percent of the drivers had their headrests in the lowest or second lowest position. This indicates that the analysis of the position of the headrest in vertical and horizontal distance to the head is adequate.

The variation of incidence of neck injuries correlated to the starting year of production of the studied cars can be seen in Figure 3. The incidence of neck injuries varies for cars with different starting years of production, but there is no reduction of injuries in newer cars.

To determine what happens in newer car models concerning neck injuries, two car makes were studied. The relative incidence of neck injuries in three model year

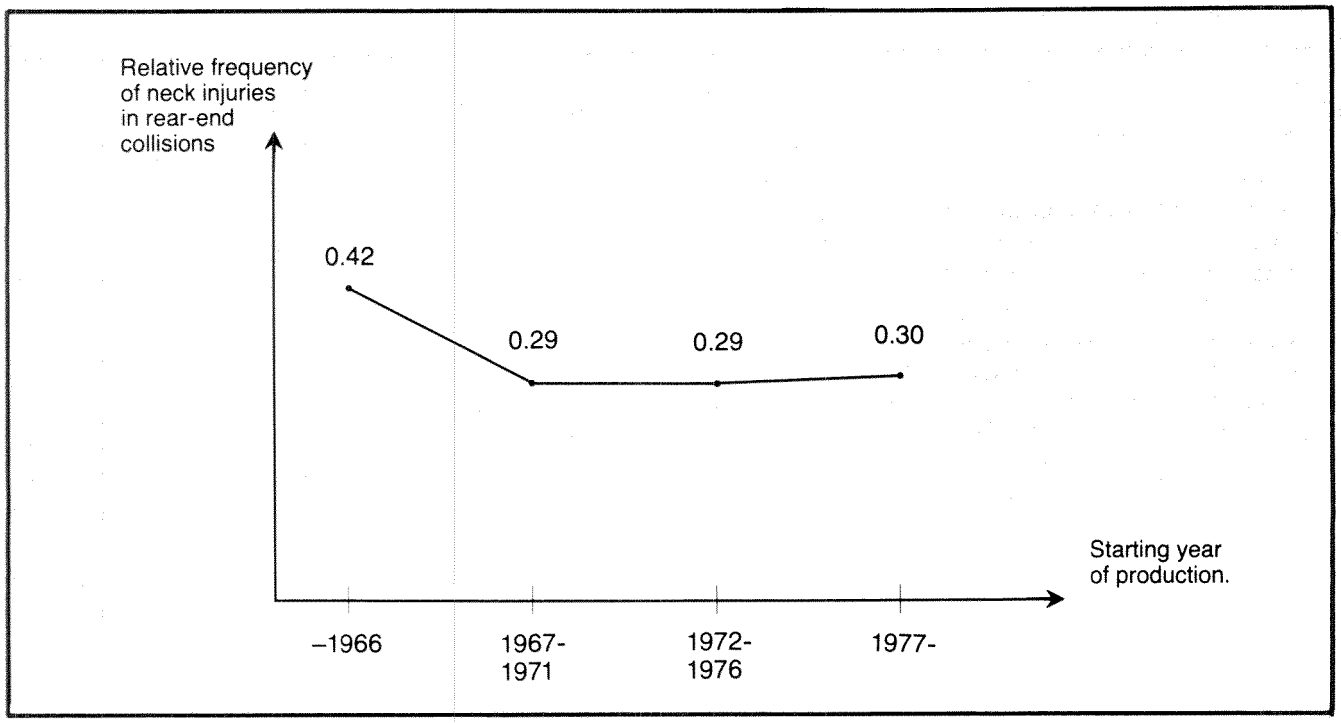

Figure 3. Relative frequency of neck injuries (AIS = 1) in rear-end collisions for different starting years of production

periods for each make was studied where the car models were similar during the period but with different types of headrests. It can be seen that Car A has a reduction of injuries for newer models while there is no such reduction for Car B. This explains why the total incidence of neck injuries does not decrease for newer models. It also indicates that the knowledge of how the headrest really functions is low. Further studies, therefore, are necessary.

Discussion

Neck injuries classified as AIS 1 have not been recognized earlier as a special medical problem. Nygren(1) showed that neck injury is a common reason among car occupants for medical as well as financial disability. It could be estimated that so-called minor neck injuries (AIS 1) cost Swedish insurance companies 100 million

Table 4. Relative frequency of neck injuries in rear-end collisions for two car makes with different headrest designs

Type of car	Production start	N	Relative frequency of neck injuries in rear-end collisions
Car A			
No Headrest	-1969	11,439	0.52
Adjustable	1970-1974	49,003	0.44
Fixed	1975-1983	30,499	0.28
Car B			
No headrest	-1973	11,760	0.37
Fixed	1974-1979	16,714	0.33
Adjustable	1980-	3,863	0.50

kronor a year and society at least the same sum. Measures taken by the car industry and the medical society have not had the desired effect on incidence of neck injuries in rear-end crashes.

In a rear-end collision, the occupant of the struck car will accelerate forward. The unsupported head cannot follow that movement immediately. The head will bend backward in relation to the torso and then flex forward. During that time, the ligaments, muscles, nerves, and vessels of the neck can be damaged. For a person with degenerative changes in the neck, the damage may be even worse. The patient will have problems relating from the neck, but only about half of those injured will go to the doctor immediately. In many cases, medical care is delayed by 3 days or more. This phenomenon with late-appearing symptoms leads to the fact that the patients with such neck injuries go to different doctors, e.g., to the doctor at the emergency care, at their work, to the family doctor, or to a specialist in either neurology, orthopedic surgery, or neurosurgery. The different specialists give different treatments, and no specialty recognizes neck injury as a big problem. The normal course of neck problems in rear-end collisions can be seen in Figure 4.

Rear-end collisions normally cause little damage, and the repair costs are also low(6,7). That is probably why the car industry, until recently, has looked upon neck injuries in rear-end collisions as a very small problem, since many manufacturers make studies only on accidents above a certain repair cost.

This study shows that the vertical distance between head and headrest is important. Owners having cars with adjustable headrests must be instructed how to fix the headrest in a correct position. Since the effectiveness varies, it is important to study rear-end collisions, both under experimental conditions and in real life.

The actual analysis shows there are characteristics other than just the position of the headrest that are important in reducing such injuries. These characteristics must be found to increase the effectiveness of the headrest and avoid neck injuries in rear-end collisions. It has been shown earlier that fixed headrests are more effective than adjustable ones(1). This could be explained by the fact that fixed headrests are in a better position than adjustable ones.

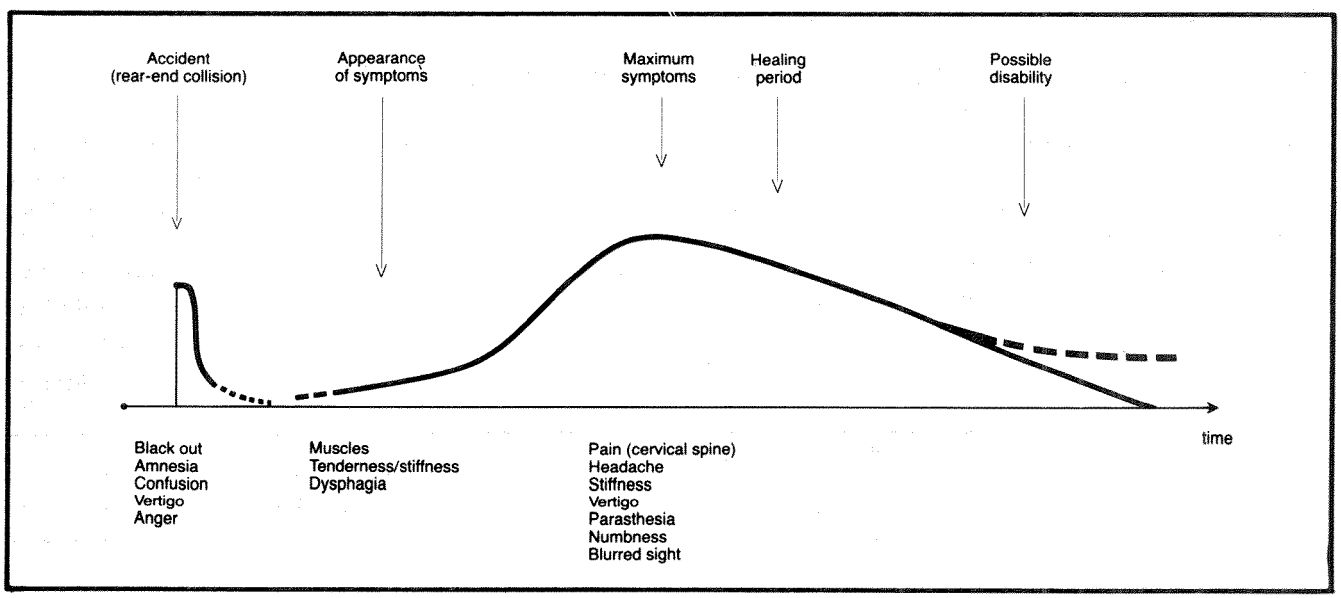

Figure 4. Normal course of neck pain (AIS 1) after rear-end collisions (according to Spangfort)

Conclusions

1. Neck injuries classified as AIS 1 are a great medical problem, especially those that occur in rear-end collisions.
2. Headrests have a certain influence on the incidence of neck injuries in rear-end collisions.
3. There are big differences in effectiveness between different types of headrests shown in a large-scale study.
4. There is no reduction of neck injuries in rear-end collisions for newer car constructions.
5. The vertical position has some influence on the incidence of neck injuries in rear-end collisions.
6. Adjustable headrests are normally adjusted in the lowest position.
7. The weight of the car influences the risk of neck injuries in rear-end collisions.
8. Further studies on headrests, both experimentally and in real life accidents, are necessary.

Production of Injury in Blunt Frontal Impact

Rolf H. Eppinger and Jeffrey Marcus

U.S. Department of Transportation, National Highway Traffic Safety Administration

Introduction

Blunt thoracic impact as experienced by automobile occupants in frontal impact has received considerable research attention over the past 20 years. These efforts have provided the basis for the development of test dummy impact response specifications as well as evaluation criteria to be used in conjunction with the dummy to evaluate the hazard of various crash situations. This paper will attempt to extend the current understanding of thoracic injury production by examining the results of 82 impact tests to determine the effects that several fundamental parameters have on the production of injuries in the thorax.

Pendulum Tests

While several pioneering efforts investigated the interaction of the driver with the steering system during a frontal crash, most notably those of Gadd(1) and Patrick(2) that led to the development of the characteristics of the energy-absorbing steering column, the efforts of Kroel(3,4), Nahum(5), Neathery(6), and Lobdell(7), using well-controlled pendulum impacts, have led to the current understanding of the dynamics of the thorax under impact conditions and have provided the basis for the generally accepted relationship between thoracic chest compression and the severity of the expected thoracic injuries.

Characterizations of the thoracic response were made by cross-plotting the observed impact force imparted by the pendulum to the thorax against the observed normalized thoracic chest compression (chest compression divided by the original chest depth) for repeated tests in two distinct impact situations: a 51.5-lb linear pendulum striking the thorax at an initial velocity of either 14 or 21ft/s.

Additional testing with various pendulum speeds and masses provided sufficient data for the authors to observe and propose the relationship between chest compression and the degree of thoracic injury severity(6), the severity measure being the Abbreviated Injury Scale. This relationship is linear in nature and combines deflection together with age as the independent variables predicting injury severity. Viano(8), after reexamination of the experimental pendulum impact data as well as extensive manipulations of Lobdell's thoracic model, concluded

that chest deflection was still the most viable injury measure.

Examination of one of Viano's figures (reproduced here as Figure 1), however, reveals that for all averaged injuries in the AIS severity classifications of 3 or greater, the averaged normalized chest deflection is almost uniformly 40 percent. The proposed linear regression model linking AIS with chest deflection merely passes through the midpoint of this vertical portion of the data and the lower injury data points. A truer characterization of the injury versus deflection relationship would show injuries increasing in severity up to the 40 percent deflection level; then any additional increase in injury severity would not be accompanied by an increase in chest deflection.

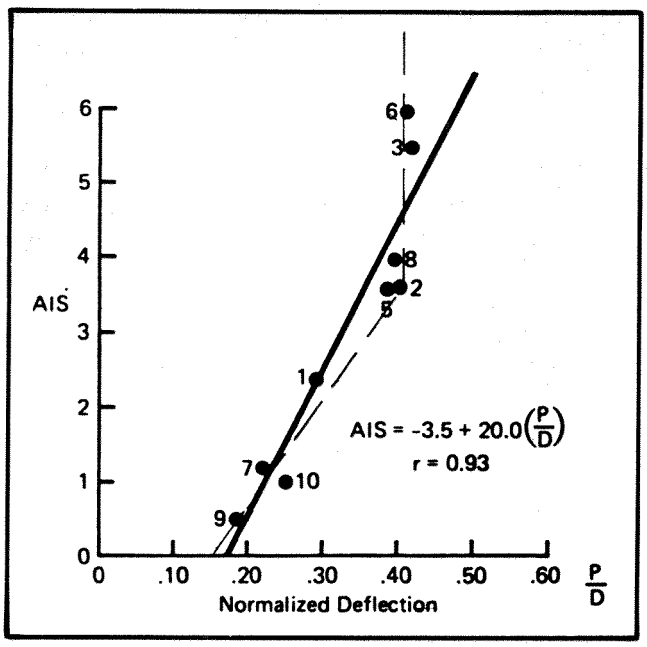

Figure 1. Averaged normalized deflection versus averaged AIS (8)

Since the Viano plot used averages of grouped data that might have masked the real characteristic, a graph (Figure 2) of deflection versus AIS using the individual test points was examined. This also shows the reduced dependence of high AIS injuries on chest deflection. It appears that the thorax reaches its maximum deflection limit at about the AIS 3 level and that other factors influence whether the injury outcome is more serious. This bottoming phenomenon was also recognized by Viano in a subsequent analysis(9)

Energy Considerations

Since the Kroell series of pendulum tests were well controlled and many of the geometrical conditions invariant, i.e., the impact pendulum remained a flat, 6in diameter rigid surface and the point of impact remained

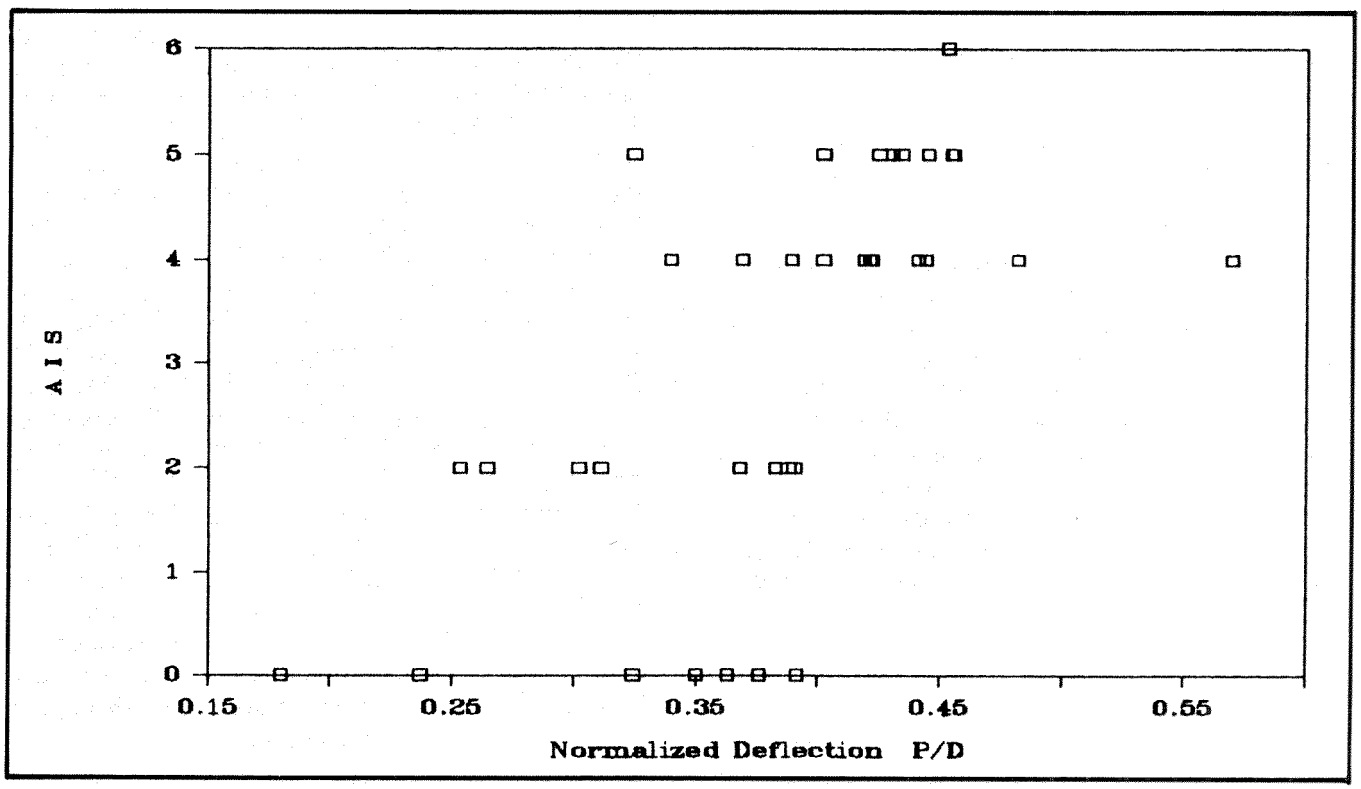

Figure 2. Normalized deflection versus AIS: 6in diameter pendulum

at the fourth costal interspace, it was decided to investigate if thoracic injury (AIS) is a function of the amount of energy that the thorax absorbed in each test. Since rigid pendulums of known masses traveling at known initial velocities struck cadavers of known weight and stature, it was assumed that both momentum and energy balances could be made using reasonable assumptions. These assumptions were: (1) the pendulum was effectively a rigid body and therefore could not absorb energy internally, (2) the pendulum interacted only with the thoracic mass, which is some constant proportion of the total body mass, (3) there is a point during the impact event at which all of the thoracic mass is traveling at a common velocity with the pendulum, (4) as a result of 1 and 3 and enforcing the conservation of energy, the difference between the initial kinetic energy of the pendulum and the kinetic energy of the pendulum and the thorax at the time of common velocity must be absorbed by the thorax, and (5) it is this absorbed energy that produces injury. Analytically, the absorbed energy was calculated using the following relationship . (A detailed derivation of this relationship is given in Appendix A.)

$$E_{abs} = ((k * M_s) / (M_p + k * M_s)) * E_{pend}$$

where:

E_{abs} is the thoractic absorbed energy

k is ratio of active thoracic mass to total body mass (determined to be 0.35)

M_p is mass of the striking pendulum

M_s is mass of the subject

E_{pend} is the initial kinetic energy in the penduluim

Assuming that larger and more massive subjects would be able to sustain greater doses of energy than smaller and less massive subjects, it was decided to develop a parameter, called specific absorbed energy (SAE), calculated by dividing the thoracic absorbed energy by the total body mass of the test specimen. This can be viewed as a primitive or overall energy density function. The relationship of this parameter versus AIS is shown in Figure 3.

Several interesting things can be noted when comparing this figure with Figure 2. First, it can be seen in Figure 2 that the greater portion of the AIS>=4 injuries occur at a normalized chest deflection between 40 and 45 percent while in Figure 3 for these same tests the specific absorbed energy continues to increase. This suggests that while the thoracic deflection capacity is limited to approximately a 45 percent level, the thorax continues to have the capacity to absorb ever greater quantities of energy. Second, it can be seen that as the quantity of specific absorbed energy increases, the likelihood of higher and higher levels of thoracic injury increases, suggesting that this parameter better explains the production of injury in the thorax and may indeed be the causal factor

Additional Data

Over the past several years, NHTSA and other organizations have sponsored several programs that have impacted cadaveric specimens in a variety of simulated frontal collisions. The impact conditions range from pendulum tests very similar to the Kroell tests but which have used impact surfaces of different areas(10) or a diagonal torso belt strap(11) to sled impact tests using either a 2-point shoulder harness(12) or an airbag restraint(13) with knee bar. Five human volunteer pendulum impacts by Patrick(14) are also included. (Table 1 summarizes the type, number, source, and essential parameters of all of the tests used in this analysis.) Since the specific absorbed energy explained the production of injury so well in the Kroell pendulum tests, it was decided to analyze the additional available tests to see if this parameter could explain injury production in these conditions as well.

Several additional processing techniques, which are described in Appendixes B and C, were developed to calculate the specific absorbed energy for these other test conditions. The results are shown in Figure 4 where the SAE from all tests is cross-plotted against AIS. It is interesting to note there appears to be a progression of increased energy-absorbing capacity as one considers first the 6in diameter pendulum tests, then the increased area pendulum tests, the belt tests, and the airbag tests. This increased energy-absorbing capability is greatest when comparing the airbag to the 6in pendulum where it can be seen that it requires approximately six times more absorbed energy to produce the same level injury in an airbag test than it does in a pendulum test. Figure 5 graphically illustrates this point. Here, all calculated pendulum SAE's were multiplied by 6, the belt-related SAE's were multiplied by 1.25, and the airbag SAE values were left unchanged. The data were replotted against each observed AIS. This process significantly compresses the spread in the data and shows that the relationship between specific absorbed energy and injury is similar for a variety of restraint types except for the various constant factors.

Additional Factors Influencing Injury

The available data for all of the tests analyzed for SAE were further scrutinized for factors that might explain the large differences in absorbed energy needed to produce a certain level of injury. The first and most obvious

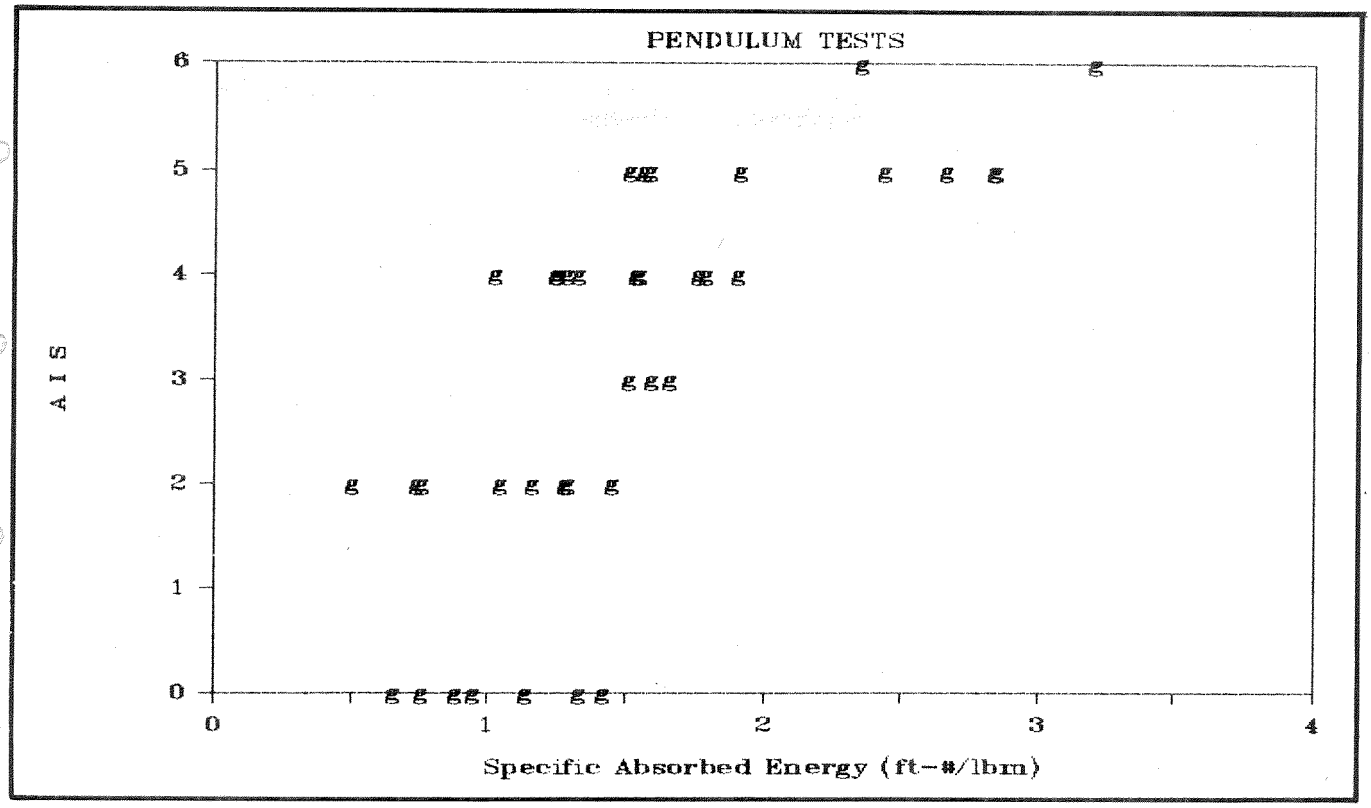

Figure 3. Specific absorbed energy versus AIS

difference between the various tests was that the impact contact area varied greatly. Reasoning that, if a certain dose of energy were to be delivered to the thorax, it would produce more injury if it were delivered through a small contact area than if it were delivered through a large area because the local energy density would be higher, all SAE's were divided by the area of the contact surface delivering the impact force. The exact area of each type of pendulum face was calculated and approximations were made for both the shoulder belts and the airbag systems. Figure 6 shows the result of this effort. Clearly, consideration of area effects alone does little to explain the large differences in absorbed energy tolerances between the various restraint configurations.

Further analysis of the data revealed that the time required for the body to acquire the absorbed energy varied considerably over the variety of test conditions. Therefore, using the reasoning that, if a certain dose of energy were delivered in a short time period, it would be more harmful than if it were delivered over a longer period of time, the SAE's were divided by the observed time thus generating a larger value of shorter time durations. Figure 7 shows the result of this effort. Again, this factor by itself does not provide any better explanation of the events.

Since the arguments supporting the influence of area and time duration were both considered reasonable, it was decided to evaluate their combined influence. This was done by dividing the specific absorbed energy by the product of the effective contact area and the time duration. It can be seen in Figure 8 that this function, SAE/(A*T), does make the different restraint-loading conditions cluster around the same level for each of the various injury severity levels.

Discussion

The above analysis strongly suggests that the production of trauma in the thorax is dependent on three factors:(1) the amount of energy (nonkinetic) that the thorax absorbs during an impact, (2) the area over which the impact forces are applied to the thorax, and (3) the length of time needed for the thorax to acquire the nonkinetic energy delivered to it. Since the analysis identifying these factors was totally an empirical one, additional theoretical and experimental evidence characterizing the effects of these factors in producing structural failures would provide additional support for the validity of this proposed injury production hypothesis.

The first factor, the amount of absorbed nonkinetic energy per pound of body weight, is clearly analogous to a variety of strain energy or energy density functions that are the basis of several currently employed failure criteria. It can be reasoned that the process of an automotive crash event start- with the subject possessing

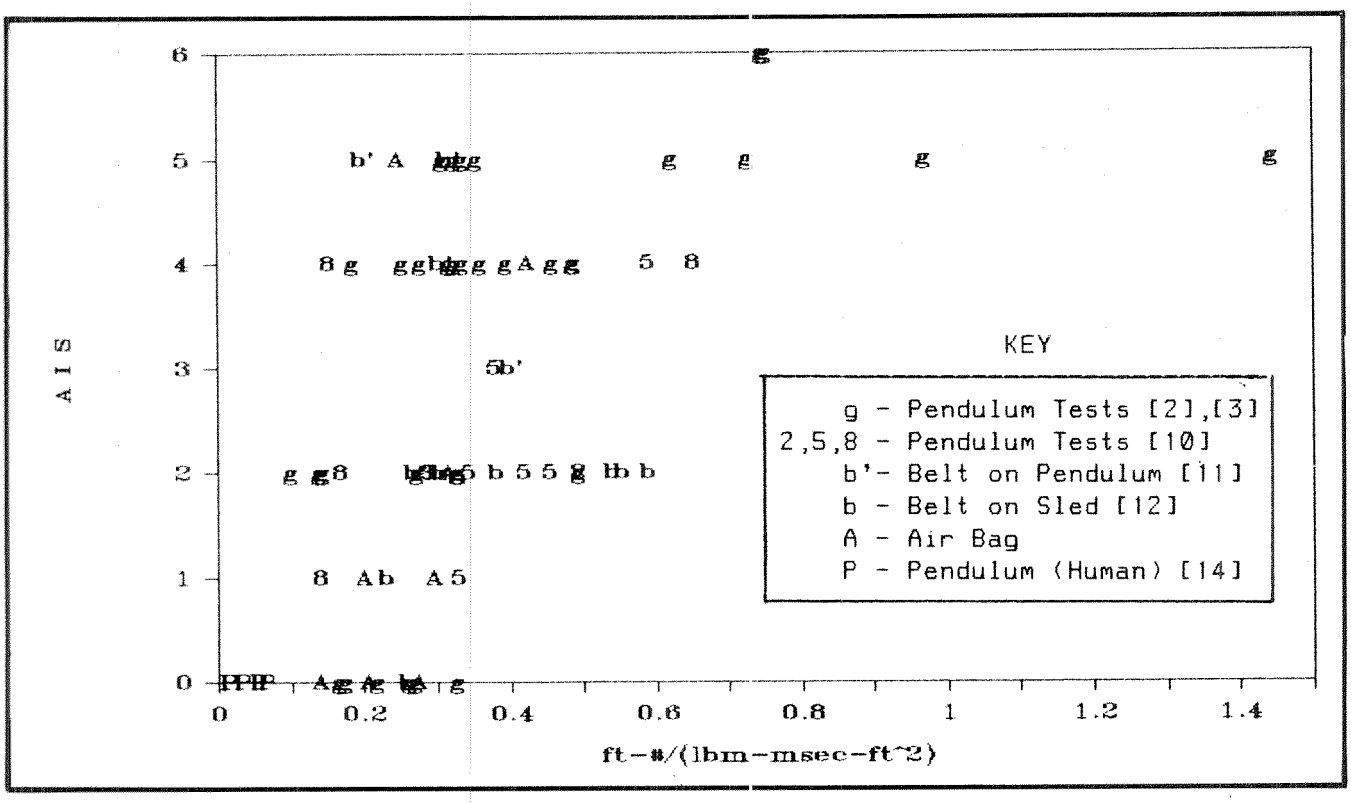

Figure 8. Specific absorbed energy/(area * time) versus AIS

a specific amount of kinetic energy and that after the event is over, this kinetic energy is no longer present. The principle of the conservation of energy requires that this kinetic energy either be removed from the body or converted into other forms of energy within the body. Therefore, as the internalized absorbed energy exceeds the energy capacity of the structure, it could be expected that it will fail and the extent of failure would be proportional to the degree to which the absorbed energy exceeds the threshold capacity.

Arguments in support of the observed effects of area can be easily derived from simple beam theory by considering two extreme loading conditions of a simply supported beam: a point force loading the beam exactly midspan and a load equal to the point load but uniformly loading the beam over its entire length. Beam theory shows that the outer fiber stresses and strains are twice as high for the point load than for the uniformly distributed load condition. Therefore, the point-loaded beam would fail at a load of one-half the load of the uniformly loaded beam if a maximum stress or strain failure mechanism were in effect.

A possible explanation of why area increases by themselves do not explain the injury variation seen in the experimental data can also be derived from the beam theory. That is, beam theory also shows that the deflection of the uniformly loaded beam is only 62 percent that of the point-loaded beam and therefore the effective stiffness and the natural frequency of the uniformly loaded beam is higher. This would imply that under similar time histories of total load, the uniformly loaded beam would respond quicker and, if the time allowed to absorb the energy is also critical, this quicker response would offset some of the gains obtained by increasing the area. The pendulum tests that varied the impactor surface area bear out this phenomenon of faster response with greater area. The data indicate that the average time to acquire the absorbed energy when using the 26in^2 impactor was 20ms. This decreased to 16.2 and 15.7ms as the area was increased to 56 and 80in^2, respectively. The pendulum belt tests also confirm this effect with an 18.8ms absorption period as compared to 21.5 for all the Kroell tests.

Other arguments in support of time dependence can be found or developed. Alternative experimental evidence can be offered by examining the work of McElhaney(15) in which he tested human and bovine femurs to failure at strain rates between 0.001 and 1,000 percent/s. He observed that both the energy to failure and the strain at failure decrease at strain rates above 1 percent/s. This critical strain rate is well below those experienced in thoracic impacts. Reduced energy-absorbing capacity as a function of strain rate may also be a factor in soft tissue failures. Alternative qualitative arguments in support of time dependence can be made by considering the Kroell tests. Since most of the AIS>=4 injuries were produced at close to the maximum chest deflection, which can be surmised to be close to the point at which the posterior surface of the sternum contacts the anterior surface of the

spinal column, the higher rates of loading would either require the internal organs to displace more rapidly from their normal positions and produce organ failure due to higher stresses, strains, and inertial forces or cause physical crushing of the organs due to the increased inability of the organs to move rapidly out of the way because of their visco-elastic stiffening behavior at high loading rates.

The airbag and torso belt tests examined in this analysis have, by virtue of the "ride down effect," greatly extended energy absorption time periods (averages of 45 and 62ms for the bag and belt, respectively) while maintaining contact areas similar to impact events of much shorter duration. Since the total specific absorbed energies for the sled belt and bag tests were much greater than with the short duration events, but the injuries were equivalent, it can be deduced that modulation of the energy absorption time periods has a profound effect on injury production.

The instrumentation and experimental techniques employed by the studies used in this analysis were not designed to measure energy transfers directly and, therefore, all results presented herein were calculated from the data by using a variety of assumptions and judgments. These assumptions and judgments may have contributed to both systematic and random errors in the calculated values of the independent variables finally considered significant, i.e., absorbed energy, area of contact, and time duration, and ultimately degrade somewhat the quality of the injury severity-dose relationship as presented in Figure 8. However, even in light of these computational uncertainties, it is felt that the strength of the proposed injury hypothesis is undeniable because of the diverse data it is capable of explaining.

Conclusions and Recommendations

This study strongly suggests that the severity of injury produced in the thorax is proportional to the amount of specific energy that the thorax must absorb during an impact and inversely proportional to the area over which the impact energy is either delivered or extracted and the length of time over which this is all accomplished. The magnitude and diversity of the impact data used in this analysis lend greatly to the support of the proposed injury production hypothesis and suggest that further investigations should be pursued that will directly address the viability of the hypothesis. The rationale for the selection of specific measurements in these studies should be guided in part by their demonstrated capability in measuring the parameters identified in this study.

Since the specific absorbed energy, the area over which it is delivered, and the time required to transfer the impact energies are not measures currently available from test dummies, direct evaluation of thoracic impact hazards using the proposed injury hypothesis is not possible at this time. Initiation of efforts to make specific absorbed energy a realizable dummy-based measurement is recommended as are continued efforts to develop injury relationships based on current body-based measures.

The lack of capability in current test dummies to measure these factors directly should, however, not preclude their use because they can be deduced by analytical methods or by additional dedicated experimental instrumentation. It is therefore recommended and encouraged that the proposed injury production hypotheses be considered in the development of automotive safety systems.

Computation of SAE for Pendulum Tests

In a pendulum test, a rigid impactor of known mass and known initial velocity struck a stationary test subject. In this study, it was assumed that the effective mass of the thorax was 35 percent of total body mass. This figure has been reported and used by others(1,2,3,4,5,6,7). The impactor struck the test subject and some time later the test subject and the impactor moved with a common velocity. From momentum considerations

$$M_p\ v_i = (M_e + M_p)\ v_f$$

where:

M_p = mass of pendulum

M_e = effective mass of the thorax

v_i = initial pendulum velocity

v_f = final speed of pendulum and thorax

rearranging

$$v_f = \frac{M_p\ V_i}{(M_e + M_p)}$$

Now perform an energy balance on the system.

$$E_i = E_f = E_{ke} + E_{abs}$$

where:

E_i = initial energy

E_f = final energy

E_{abs} = absorbed energy

E_{ke} = kinetic energy

then

$$\tfrac{1}{2} M_p v_i^2 + \tfrac{1}{2} (M_p + M_e)\ v_f^2 + E_{abs}$$

after substitution

$$E_{abs} = \frac{M_p}{(M_p + M_e)}\ E_i$$

$$\text{Specific Absorbed Energy} = \text{SAE} = E_{abs} / M_{total}$$

M_{toal} = Total Body Mass

Appendix B

Computation of SAE for Airbag Tests

Calculation of absorbed energy for airbag tests was based on energy and impulse-momentum considerations. Seven frontal tests were performed on the sled at Wayne State University at a nominal 30mph impact speed. The airbag was a standard production General Motors airbag mounted on a standard production airbag steering wheel. The wheel in turn was mounted on a horizontal, rigid, nonstroking column. The airbag was fully inflated prior to the test, and there was no venting of the gas in the bag.

In addition to the standard signals recorded from the test subject (9 head accelerations, 12 thoracic accelerations, 3 pelvic accelerations, and pulmonary pressure), a number of data signals were recorded external to the test subject. Data of interest from this group included the initial sled velocity, the deceleration of the sled, the pressure within the airbag, the compressive load on the steering column, and the impact force on each knee.

Human cadaveric test subjects were used. The test subjects were unrestrained except for the airbag and knee bolsters. In the following analysis, it was assumed that frictional forces were negligible, and that all forces that stopped the test subject were measured by the three load cells present (steering column, left knee, right knee). It was also assumed that energy absorption by the knee bolsters was negligible.

The first step in computing thoracic absorbed energy was to determine the effective thoracic mass. This determination used impulse-momentum. Recall that

$$\int F(t)\ dt = \int M_e\ dv = I$$

where

$F(t)$ = force at time t

M_e = effective mass

dv = differential velocity

dt = differential time

I = impulse

It was determined that when the steering column force was at maximum, the test subject had stopped (dv = test velocity) and begun to rebound. The three forces (left knee, right knee, steering column) were integrated from time = 0 (t_1) to the time of maximum steering column force (t_2).

$$M_e \Delta v = \int_{t_1}^{t_2} F_{SC}\, dt$$

where

M_e = effective thoracic mass

Δv = change in velocity of thorax (= test speed in the test analyzed)

F_{SC} = steering column force

t_2 = time of max F_{SC}

t_1 = time 0 (= 0)

$$M_e = \frac{\int_{t_1}^{t_2} F_{SC}\, dt}{\Delta v}$$

When this analysis was performed, the resulting thoracic masses as a percentage of total body weight ranged from 39 to 57 percent, with most values closely clustered around 50 percent. It was decided to set the effective thoracic mass in airbag tests to 50 percent of the total body mass.

Having determined an effective thoracic mass, and knowing the initial speed of the sled (and the test subject), the initial thoracic kinetic energy was computed as:

$$KE_o = \frac{M_e v_o^2}{2}$$

where

KE_o = kinetic energy

M_e = effective thoracic mass

v_o = initial velocity

At some point during the test, the thorax stopped (velocity = 0) and began to rebound away from the airbag. When the velocity was 0, the thoracic kinetic energy was also 0. It was assumed that when airbag pressure reached its maximum value the thorax had stopped and begun to rebound.

Now consider the work done by the airbag on the sled. Given the pressure and initial volume of the airbag it was possible to calculate the change in potential energy of the gas in the bag. Then, given the force of the airbag on the steering column as a function of time, and the velocity of the steering column (rigidly mounted to the sled), the work of the airbag on the column was calculated.

The energy balance for the system is

$$KE_o = PE_{AB} + W_{SC} + KE_{t_2} + E_{abs}$$

where

KE_o = initial kinetic energy in thorax

PE_{AB} = change in potential energy of the gas in the airbag

W_{SC} = work done on the steering column by the airbag

KE_{t_2} = kinetic energy at time t_2

E_{abs} = absorbed energy in the thorax

It was assumed that when airbag pressure was at its maximum, the thorax had stopped and thus thoracic kinetic energy was 0.

$$E_{abs} = KE_o - PE_{AB} - W_{SC}$$

By knowing the test subject's initial velocity and effective thoracic mass, KE_o was computed.

Changes in potential energy of the gas in the airbag were computed knowing the pressure time history and initial volume of the system. It was assumed that the impact occurred so quickly that there was no heat transfer and no mass lost, i.e., an adiabatic event. The change in energy of the gas therefore was

$$PE = \int_{V_2}^{V_1} P\, dV$$

where

PE = change in potential energy

P = pressure (absolute)

V_1 = initial volume

V_2 = volume at peak pressure

The following is true for a perfect gas undergoing adiabatic compression.

$$pv^n = \text{constant}$$

For air (used to inflate the airbag in these tests) n = 1.4.

$$P_1V_1^{1.4} = P_2V_2^{1.4} = C$$

P_1, P_2, and V_1 are known.

$$V_2 = \left(\frac{C}{P_2}\right)^{(1/1.4)}$$

$$P(V) = \frac{C}{V^{1.4}}$$

$$PE = \int_{V_1}^{V_2} P\,dv = C\int_{V_1}^{V_2} V^{1.4}\,dV$$

$$= \frac{-C\,V^{-0.4}}{0.4}\Bigg|_{V_1}^{V_2}$$

$$= \frac{-c^{1.4}(V_2^{-0.4} - V_1^{-0.4})}{0.4}$$

This represented the total change in potential energy of the gas within the airbag. However, some of this change arose from work done by the atmosphere on the airbag.

$$PE_{total} = PE_{AB} + \int P_{atm}\,dV$$

PE_{total} = total change in the potential energy of the gas in the airbag

PE_{AB} = change in potential energy of gas due to work done by thorax on the airbag

P_{atm} = absolute atmospheric pressure (constant)

$$PE_{AB} = PE_{total} - P_{atm}(V_2 - V_1)$$

To compute the work done on the steering column, the signal from the steering column load cell was used as well as the sled acceleration signal.

$$\text{Work} = \int F\,dx$$

$$= \int F\frac{dx}{dt}\,dt$$

$$= \int F\,v\,dt$$

where

F = force

dx = displacement of sled with respect to laboratory reference frame.

$\frac{dx}{dt}$ = v = velocity with respect to laboratory reference frame.

dt = incremental time

In the case at hand, F was the steering column load cell measurement, and v(t) was the integrated sled acceleration subtracted from the initial sled velocity. The time limits ranged from $t_1 = 0$ to t_2 = time of maximum pressure in the airbag.

$$W_{SC} = \int_{t_1}^{t_2} F_{SC}\,v(t)\,dt$$

Thus, knowing an effective thoracic mass, an initial velocity, and an initial airbag volume, the thoracic absorbed energy was computed using the steering column load signal, sled acceleration signal, and airbag pressure signal.

$$E_{abs} = KE_o - PE_{AB} - W_{SC}$$

The specific absorbed energy was obtained by dividing the absorbed energy by the total body mass.

SAE = Specific Absorbed Energy = E_{abs}/M_{total}

M_{total} = Total Body Mass

Appendix C

Computation of SAE for Belt Tests

The belted tests used in this study were nominal 30mph frontal sled tests conducted by Wayne State University. The restraint system was a 2-point belt (i.e., there was no lap belt) with knee bolsters. The knee bar was segmented and mounted on load cells so the load imposed on each knee could be measured. In addition, the tension in the belt was measured as well as the sled acceleration.

The first step was to compute an effective thoracic mass. This was accomplished in a manner similar to that used with the airbag system using impulse momentum.

$$M_{total}\,v_i = I_{LK} + I_{RK} + I_{thorax}$$

where

M_{total} = total subject mass

v_i = initial velocity

I_{LK} = impulse of left knee

I_{RK} = impulse of right knee

I_{thorax} = impulse of thorax

where impulse - $\int F\ dt$

The above relationship assumed that the test subject stopped when time equaled the upper time limit of the integration. Examination of the data revealed that this assumption was invalid because, when belt force peaked, some sled velocity remained. The assumption was then changed to be that the test subject had the same velocity as the sled at peak belt force. This changed the impulse-momentum relationship to be

$$M_{total}\,\Delta v + \int_{t_1}^{t_2} F_{LK}\,dt + \int_{t_1}^{t_2} F_{RK}\,dt + \int_{t_1}^{t_2} F_{thorax}\,dt$$

where

Δv = change in velocity of thorax
initial sled velocity - sled velocity at time = t_2

F_{LK} = force on left knee

F_{RK} = force on right knee

F_{thorax} = force on thorax

t_1 = 0

t_2 = time of peak thoracic force

While the horizontal forces acting on each knee were directly measured in these tests, the force acting on the thorax was available only indirectly through the belt tension force. It was assumed that the thoracic force-time signal had an identical signature, and differed in magnitude only by a constant when compared to the belt tension force.

$$F_{thorax} = c\,F_{belt\ tension}$$

where c is a proportionality constant. To determine c

$$M\Delta v = \int F_{LK}\,dt = \int F_{RK}\,dt = c\int F_{belt\ tension}\,dt$$

$$c = \frac{M\Delta v - I_{RK} - I_{LK}}{\int F_{belt\ tension}\,dt}$$

The value of c ranged from 1.5 to 1.98, clustering around 1.95. These values give confidence that the assumptions are valid.

The effective thoracic mass is then

$$M_e = \frac{c\,F_{belt\ tension}\,dt}{\Delta v}$$

Now consider the energy balance of the thorax.

$$KE_o = KE_{t_2} + E_{belt} + W_{sled} + E_{abs}$$

where

KE_o = initial kinetic energy of thorax

KE_{t_2} = kinetic energy of thorax at time t_2

E_{belt} = strain energy absorbed by belt

W_{sled} = work done on the sled by belt

E_{abs} = energy absorbed by the thorax

If m_e is the effective thoracic mass, then the kinetic energy at any time is

$$\frac{M_e\,v^2}{2}$$

The velocity of the sled just prior to impact was used to compute the initial kinetic energy KE_o. The velocity used to compute ke_{t2} was the sled's velocity at time t_2 (time of maximum belt force)

The strain energy absorbed by the belt was

$$E_{belt} = \frac{K\,x^2}{2}$$

where

K = stiffness of belt (=10,416lbs/ft
This is equivalent to 6% strain at 2,500lb for a 4ft belt

x = total elongation of belt

$$= \frac{F_{tension}}{K}$$

$F_{tension}$ = peak belt tension

$$E_{belt} = \frac{(F_{tension})^2}{2\,K}$$

The work done on the sled by the belt was computed in a manner similar to the computation of the work done by an airbag on the sled. Here

$$W_{sled} = c \int_{t_1}^{t_2} F_{belt\ tension}\ v(t)\ dt$$

$v(t)$ = sled velocity

Next the SAE was computed

$$E_{abs} = KE_o - KE_{t_2} - E_{belt} - W_{sled}$$

$$= \tfrac{1}{2} M_e (v_o^2 - v_{t_2}^2) - \frac{F_{tension}^2}{2k} - c \int_{t_1}^{t_2} F_{belt\ tension}\ v(t)\ dt$$

$$SAE = E_{abs} / M_{total}$$

where

M_{total} = total Body Mass

Thoracic Impact: A Viscous Tolerance Criterion

David C. Viano and
Ian V. Lau
General Motors Research Laboratories

Abstract

There are currently two accepted criteria for assessment act exposures. Our studies have shown an interaction between the deformation velocity and level of compression during impact, resulting in a greater compression tolerance for low-speed impact than for high-speed loadings. High-speed thoracic impact can cause critical or fatal injury in physiologic experiments before exceeding the acceleration or compression tolerance. The velocity-sensitive tolerance is represented by the maximum product of velocity of deformation and compression, which is derivable from the chest compression response. As the magnitude of this "viscous" response increases, the risk of serious or fatal injury increases. This paper discusses the analysis of available literature and results from our laboratory and demonstrates the need for a viscous tolerance criterion to assess chest impact protection in high-velocity impact.

Introduction

Whole-Body Deceleration Tolerance

To provide improved protection of military personnel exposed to rapid decelerations, Stapp(1) conducted a series of rocket-sled experiments demonstrating the whole-body tolerance with belt restraints. Information from these experiments on the long-duration, whole-body deceleration tolerance and information from other tests enabled Eiband(2) to demonstrate that the whole-body deceleration tolerance increased as the duration of the exposure decreased. This led to a well-accepted deceleration tolerance (Figure 1), which for the first time information over orders of magnitude in duration of deceleration. However, the tolerance was based primarily on accelerations measured on the sled fixture, not on the test subject. The data did provide useful guidelines for the development of restraint systems for occupant protection in crash situations involving military and civilian personnel.

The basis for the whole-body deceleration tolerance criterion is Newton's second law where the deceleration of a rigid mass is in proportion to the force on the moving mass. Thus, the greater the deceleration, the greater the force and risk of injury. The increase in tolerable deceleration for shorter durations of exposure implies a based on an equivalent energy transfer, since an equivalent change in velocity (V) can be achieved by reciprocal changes in the level and duration of acceleration (for a velocity change (V=AT) the deceleration (A) can increase the duration (T) decreases).

Force Tolerance

In the early 1960's, automotive safety engineers were seeking information on the force tolerance of the thorax.

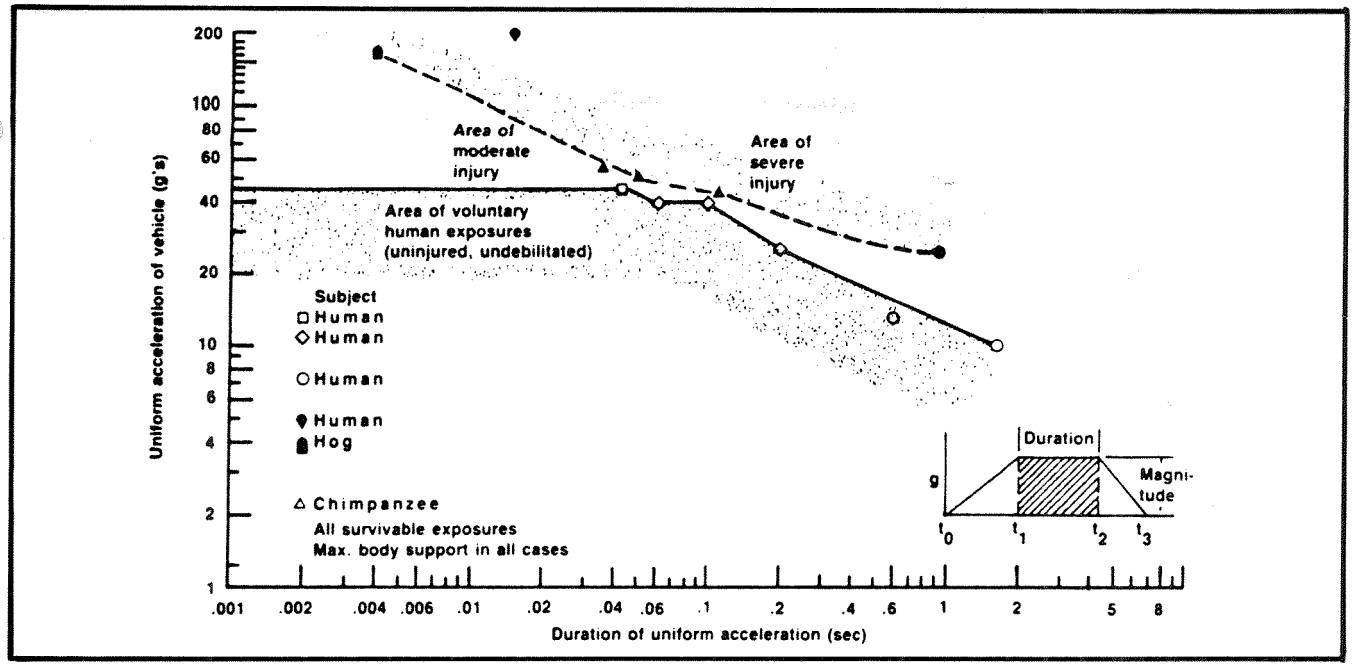

Figure 1. Duration and magnitude of vehicle decelerations endured by various subjects(2)

This information was needed to develop the energy-absorbing steering column. The energy-absorbing column included a device that limited force to a maximum level beyond which the structure would deform and absorb energy as it compressed. However, the available human tolerance data (see the review by Snyder(3)) did not provide specific information on the appropriate yield force for the system. The basic safety objective was to design the yield force as high as practical, consistent with tolerance, to maximize the energy-absorbing capacity and extend the range of safety function of the system.

Faced with uncertain information on the force tolerance of the chest, a collaborative program was undertaken between General Motors Research Laboratories and Wayne State University to develop a crash simulation facility and conduct experiments on human tolerance in automotive crash situations. The first series of experiments by Patrick et al.(4) involved sled tests with embalmed cadavers simulating the response of an unrestrained occupant interacting with load-measuring surfaces. Head, chest, and knee contacts against padded load-cells provided the first information on human tolerance to impact force. The resulting force tolerance of the thoracic rib cage provided the necessary information to biomechanically design the energy-absorbing element in the steering system.

Subsequent experiments by Gadd and Patrick(5) with prototype energy-absorbing steering system confirmed that a 3.29kN (740-lb) maximum hub force on the sternum and an 8.00kN (1,800-lb) maximum load on the shoulders and chest allowed column compression with only minor risk of skeletal damage in the rib cage for a impact. These experiments provided new human tolerance data and enabled the introduction of the energy-absorbing steering column which has proven to be a highly effective built-in safety feature for driver protection(6).

Chest Compression Tolerance

In the course of the cadaver impact experiments, it became clear that the concept of whole-body deceleration and force did not adequately describe the response of the thorax during blunt impact. In fact, force applied to the sternum was shown to compress the chest, thus bending the ribs and leading to fractures when the level of compression exceeded the tolerance of the rib cage. Analysis by Kroell(7) of a large series of blunt thoracic impact experiments confirmed that the maximum acceleration of the thoracic spine was a poor indicator of injury potential for blunt frontal thoracic loading and that the maximum level of chest compression was a superior predictor of chest injury (Figure 2).

Kroell's tests(7) with human volunteers showed that chest compression up to 20 percent during moderately long duration loading produced no detectable injury and was fully reversible. Impact tests with human cadavers at of compression greater than 20 percent showed that as the compression increased, the risk of skeletal fractures in the rib cage increased. At 40 percent compression, there was multiple skeletal injury indicative of flail chest. As protective function of the rib cage was destroyed by multiple fractures causing an unstable structure, direct loading of intrathoracic vital organs was possible (Figure 3) and there was risk of injury to the heart, lung, and great vessels (see the discussion by Viano(8)). Analysis of these

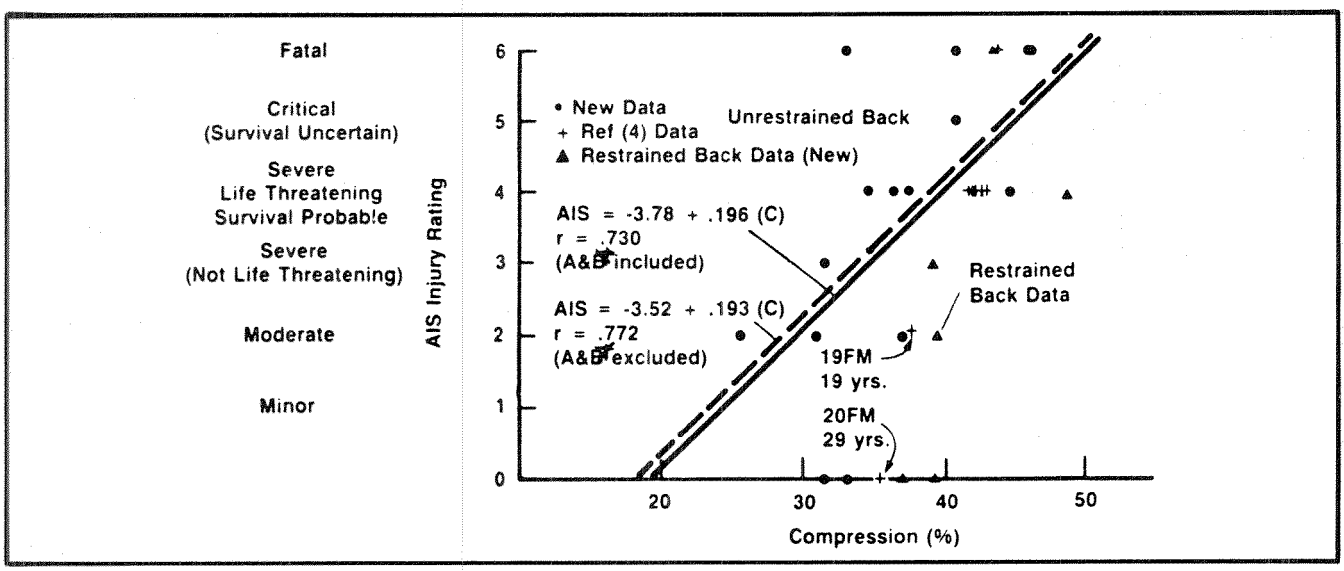

Figure 2. Injury rating and chest compression for University of California, San Diego, unembalmed cadavers subjected to blunt frontal impact(7). A and B are the responses of the 19- and 20-year old subjects

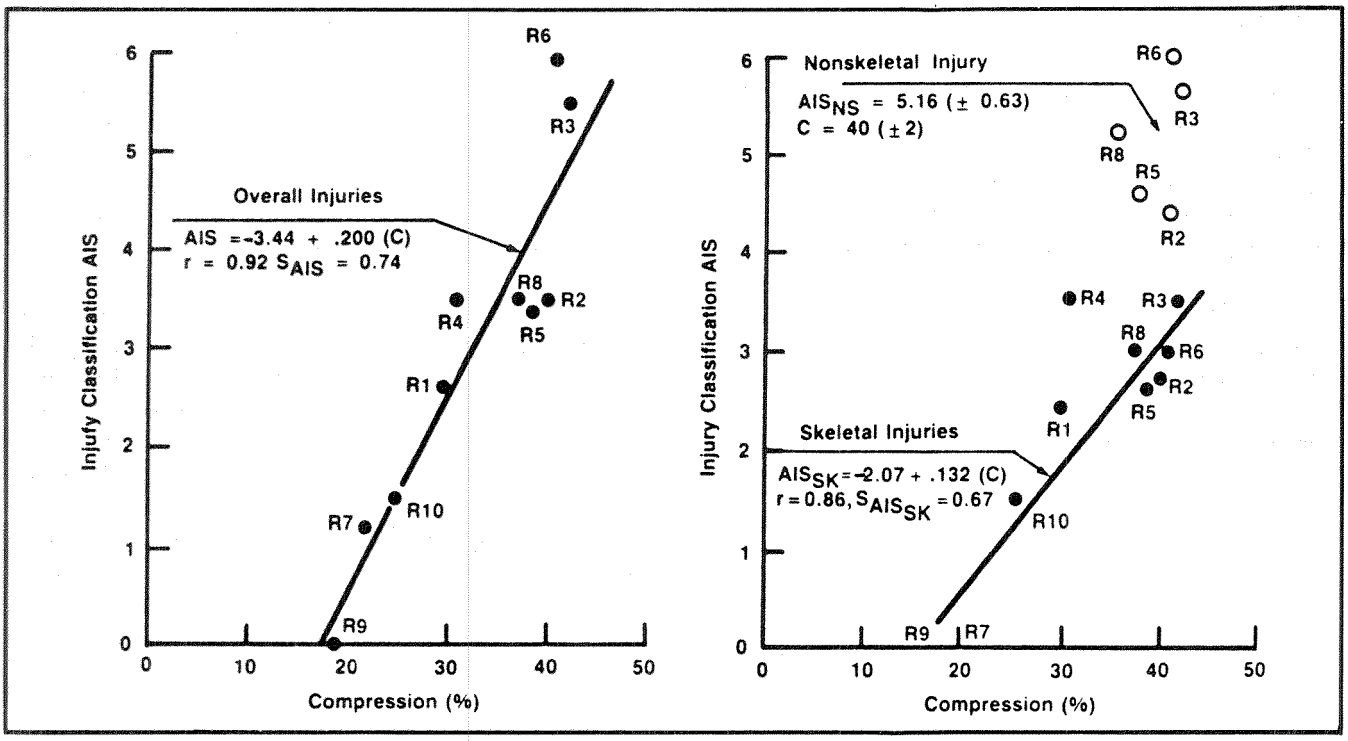

Figure 3. Injury rating and chest compression for University of California, San Diego, unembalmed cadavers subjected to blunt frontal impact showing increased severity of rib fractures with compression and cluster of soft tissue injuries at high compressions where the stability of the ribcage is compromised(8). Each point represents the average response of a group of similar tests identified by R1-R10(8)

data led Neathery et al.(9) to develop a criterion of maximum chest compression for the evaluation of injury risk for blunt frontal impact.

Evaluation of the time-varying force and compression response of the chest in human cadaver experiments also provided information on the dynamic stiffness of the thorax. The experimental data on biomechanical responses allowed Neathery(10) to define corridors predicting the impact response of the 50th percentile male cadaver. These data were pivotal to the development by Foster et al.(11) of an improved anthropomorphic test device with chest biofidelity, and ultimately led to the

Hybrid III dummy chest. Improved thoracic stiffness and structure have allowed the Hybrid III to be identified as most appropriate test tool to be used for the evaluation of the steering system in a wide range of sled test environments (see Horsch and Viano(12)).

In an effort to further understand the mechanisms of soft tissue injury, the literature was reviewed for various impact exposures, including experimental simulations of blast-wave injury. A comprehensive series of physiologic experiments on lateral thoracic impact confirmed a new observation: the chest compression tolerance is not a fixed maximum value for a wide range of impact velocities. In fact, the experiments by Jonsson and Clemedson(13) suggested that as the velocity of impact increased, the tolerance to chest compression decreased, at least on the basis of lung injury.

Since impacts in the range of 5m/s to 20m/s are possible in high-speed automotive collisions, the sufficiency of a single maximum value for chest compression was studied by Lau and Viano(14) in a series of experiments. In these tests, the liver was the target organ, and the experiment was set up to attain a maximum level of 16 percent abdominal compression, which was well within the range of tolerable compression for a volunteer in a moderate duration loading. The rate of abdominal compression was varied from 5m/s to 20m/s to study the influence of the velocity of compression. The experiments confirmed an increasing risk of liver injury severity as the of abdominal compression increased (Figure 4). The experiments confirmed that the velocity of compression was an important factor in injury assessment.

Subsequent physiologic experiments by Kroell et al.(15) and Lau and Viano(16) involving blunt thoracic impact

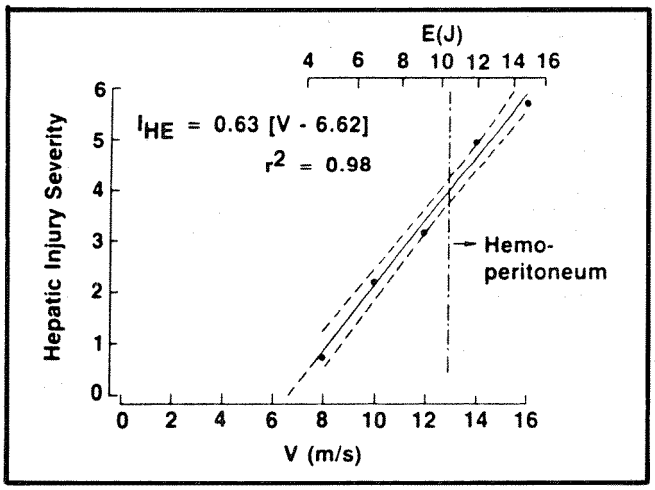

Figure 4. Hepatic injury severity and impact velocity for a fixed maximum compression. The maximum viscous response is the product of forced velocity of compression and 16% maximum compression (14). Impacts above 12m/s resulted in severe hemoperitoneum, bleeding in the abdomen

substantiated an interrelationship between chest compression and velocity of compression. These two responses were critical to the severity of skeletal or internal thoracic injury. Analysis of other physiologic experiments by Lau et al.(17) found that velocity of impact in the range of 13m/s to 24m/s was an important factor for nonpenetrating thoracic injury leading to ventricular fibrillation. Similar findings of the importance of the velocity of compression were identified in a series of open thoracic impacts of the heart by Stein et al.(18). The risk of fatal cardiac arrhythmias was found to increase with the velocity of cardiac compression.

Viscous Tolerance

The concept of a viscous tolerance (deformation velocity and compression sensitive tolerance) for soft tissues in the body was first proposed by Viano and Lau(19) who analyzed a large series of frontal thoracic impact experiments. The physiologic experiments included velocities of compression in the range of 5m/s to 22m/s and maximum thoracic compressions of 4 to 55 percent. On the basis of occurrence of critical-fatal injury, the experiments confirmed a velocity and compression sensitive tolerance to chest impact. Although the chest could withstand 50 percent compression for loadings of 5m/s velocity of deformation, the tolerance decreased significantly to 20 percent at velocities of 20m/s. Further analysis of the data showed that the maximum of the product of velocity of deformation and compression was an effective predictor of injury risk (Figure 5). The maximum viscous response was defined as VC max = [V(t) * C(t)] max and was shown to be a measure of the energy dissipated by viscous elements in the thorax. Probit analysis defined an effective maximum viscous

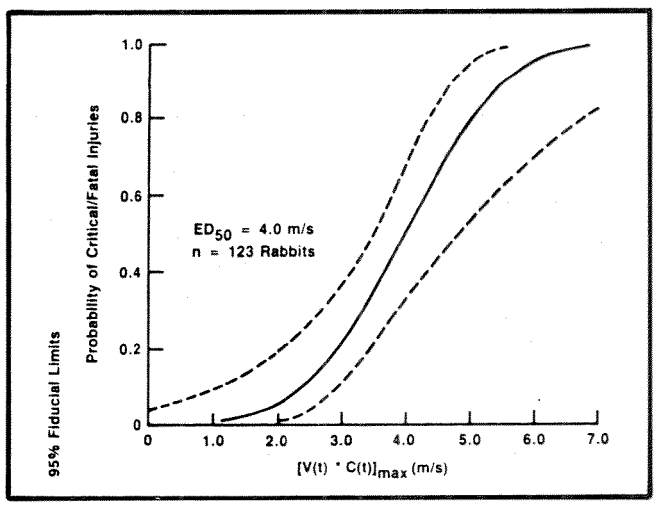

Figure 5. Probit analysis of critical-fatal injury risk and maximum viscous response for blunt frontal impact (19)

response for 50 percent occurrence of critical-fatal thoracic injury in the physiologic model at VC max = [V(t) * C(t)] = 4.0m/s.

Over the years of research on mechanisms of thoracic and soft-tissue injury, it has been increasingly evident that the body cannot be considered a rigid structure and that injury criteria based on whole-body acceleration are inadequate predictors of injury risk. It is now clear that the body is a deformable structure and at low speeds of impact (< 5m/s) the tolerance to rib cage damage and risk of crush injury can be evaluated by the maximum compression of the chest. This is primarily the case for belt-restrained occupants where tight coupling to the vehicle deceleration involves low speeds of chest compression. However, for high speeds of thoracic deformation (> 5m/s) typical of the unrestrained or those in high-speed side impacts, the quasi-static maximum compression tolerance does not adequately reflect the viscous properties of the chest and thus soft-tissue injury risks. For these types of impact, both the compression and velocity of deformation are important responses that relate to injury.

In more recent physiologic experiments by Horsch et al.(20) and Lau et al.(21) on upper-abdominal injury with steering wheel contact, the viscous response was found to be the superior predictor of severity and time of occurrence of liver injury. It also demonstrated more clearly the important biomechanical responses of the abdomen during steering wheel contact. These studies showed that liver injury by steering wheel contact occurred prior to maximum compression of the abdomen or maximum acceleration of the spine, but at the same time as the peak of the abdominal viscous response (see Lau et al.(21)). The viscous criterion has also been found by Rouhana et al.(22) to be the biomechanical response predictive of abdominal injury due to lateral impact.

In the following sections, the viscous response will be defined as the time-varying product of the velocity of deformation and compression and will further demonstrate that the maximum of this biomechanical response is an important predictor of injury. However, the viscous response and tolerance should be considered a supplement to the currently accepted maximum chest compression criterion that reflects the quasi-static or crush limit of the thorax.

Definitions

A lateral view of the thorax is shown in Figure 6, where coordinates y_1, y_2, and, y_3 represent the displacement of the skin covering the anterior chest wall, the sternum, and vertebral spine, respectively (Table 1). Chest compression (C) is defined as the difference in the displacement of the anterior skin and spine ($y = y_1 - y_3$) normalized by the initial exterior thickness of the thorax (D). The velocity

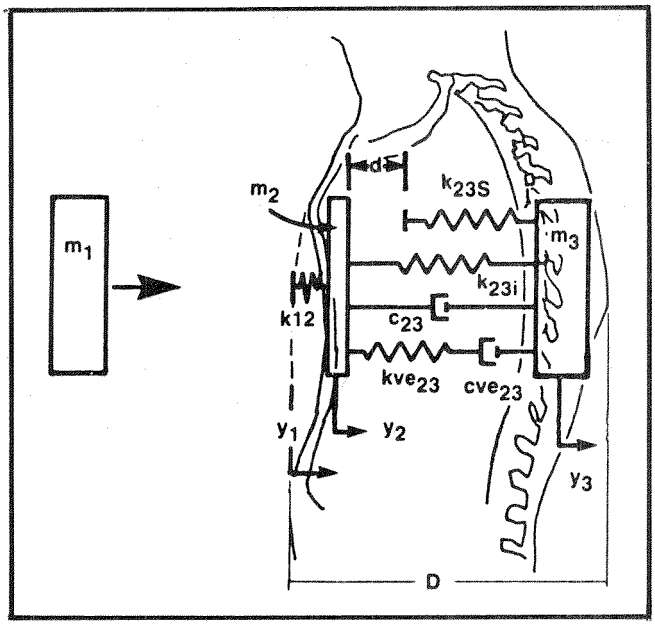

Figure 6. Lateral view of thorax with Lobdell's thoracic model(25) superimposed showing the sternal and spinal masses, and the spring and dashpot elements representing the thoracic compliance

of chest compression (V) is defined as the time rate of change of the relative displacement between the anterior skin and spine. The viscous response (VC) is defined as the time-varying product of the velocity of chest deformation and compression.

Energy Concepts for Injury Risk

Stored Energy

Simple mechanical analogs of the biomechanical response of the thorax can be used to discuss injury risks during frontal thoracic impact. A portion of the thorax can be represented by an elastic spring (see Figure 6). The spring response demonstrates how an increase in compression is associated with an increase in force, energy stored, and risk of reaching the elastic limit of the element.

When the elastic response of the thorax is represented by a spring, the energy stored (E_e) during compression is defined as the integral of the compressive force (F) during the deflection (y) it causes:

$$E_e(t) = \int_0^y F(t)\, dy \qquad \text{(Equation 1)}$$

Since force in a linear spring is proportional to the deflection of the endpoints (F(t)y(t)) and the incremental

Table 1. Definition of biomechanical responses

Variable	Response
$y_1(t)$	Skin Displacement
$y_2(t)$	Sternal Displacement
$y_3(t)$	Spinal Displacement
$\dot{y}_1(t)$	Skin Velocity
$\dot{y}_2(t)$	Sternal Velocity
$\dot{y}_3(t)$	Spinal Velocity
$\ddot{y}_1(t)$	Sternal Acceleration
$\ddot{y}_2(t)$	Spinal Acceleration
D	Chest Depth
$y(t) + y_1(t) - y_3(t)$	Chest Deflection
$C(t) + y(t)/D$	Chest Compression
$V(t) + \dot{y}(t)$	Velocity of Deformation
$\dot{C}(t) + V(t)/D$	Compression Rate
$V(t)C(t) + \dot{y}(t)y(t)/D$	Viscous Response

deflection is given by $dy = (dy/dt)dt = ydt$, Equation (1) reduces to:

$$E_e(t) = \int_o^t y(t)\ \dot{y}(t)\ dt \qquad \text{(Equation 2)}$$

Recognizing that the differential of y^2 is equal to the integrand of Equation (2) $(d/dt\ (y^2 = 2yy)$, Equation (2) reduces to:

$$E_e(t) = \tfrac{1}{2}\int_o^t d/dt\ (y^2(t))\ dt = \tfrac{1}{2}\int_o^t d\ (y^2 t)) \qquad \text{(Equation 3)}$$

However, Equation (3) is uniquely solved assuming a zero initial deflection or compression of the thorax, such that Equation (3) equals:

$$E_e(t) = \tfrac{1}{2}\ y^2(t)) \qquad \text{(Equation 4)}$$

Thus, the energy stored in compressing the elastic components of the thorax is directly proportional to the square of the time-varying deflection. Normalizing the deflection by the initial thickness of the chest implies that the stored elastic energy is proportional to the square of thoracic compression ($E_e \sim C^2$). Since compression derives this function, stored energy is determined by compression ($E_e \sim C$).

The maximum compression criterion essentially establishes a biomechanical response represented by compression of a spring. Load on the spring and stored energy in spring determine the risk of reaching the deformation limit or the energy capacity of the thorax, which is proportional to the compression of the spring. During impact, force applied to the chest accelerates body masses and compresses the spring elements. Since it is not possible to a priori separate the inertial and elastic components of force from the total load, compression is the measurable response and meaningful biomechanical parameter of injury risk.

Absorbed Energy

The viscous elements of the thorax can be represented by a mechanical dashpot (see Figure 6), and the absorbed energy (E_v) associated with deformation of the element is proportional to the force (F) acting across it:

$$E_v(t) = \int_o^y F(t)\ dy \qquad \text{(Equation 5)}$$

In this case, the force developed by a viscous dashpot due to deformation of the endpoints is proportional to the velocity of deformation $(F(t)\ \dot{y}(t))$. Recognizing again that the differential deflection is given by $dy = (dy/dt)\ dt = \dot{y}dt$, Equation (5) reduces to:

$$E_v(t) = \int_o^t \dot{y}^2(t)\ dt \qquad \text{(Equation 6)}$$

In the case of Equation (6), it is not possible to find a unique solution. However, if we recognize that the differential of $y\dot{y}$ is $d/dt\ (y\dot{y}) = \dot{y}\dot{y} + y\ddot{y}$, it is possible to reduce Equation (6) to the form:

$$E_v(t) = \int_o^t d\ (y(t)\ \dot{y}(t)) - \int_o^t y(t)\ \ddot{y}(t)\ dt \qquad \text{(Equation 7)}$$

The first integral of Equation (7) can be solved by direct integration so that the energy absorbed by the viscous elements representing the thoracic response during dynamic compression takes on the form:

$$E_v(t) = y(t)\ \dot{y}(t) - R(y, \ddot{y}) \qquad \text{(Equation 8)}$$

where the residual function in Equation (8) is given by: $R(y, y) = \int^t y(t)\ddot{y}(t)\ dt$. The first term in Equation (8) for the absorbed energy is related to the product of velocity of deformation and compression when the deflection is normalized ($E_v \sim \dot{y}y \sim VC$). Thus, absorbed energy is related to the viscous response. Maximum elastic (stored energy) limit is proportional to the square of maximum compression, and the maximum viscous (dissipated energy) limit is proportional to the maximum product of the deformation velocity and compression.

Strain Energy Analogy for the Viscous Response

Impact of an elastic material can cause the propagation of a wave. The principles of impulse and momentum can be used to define the stress, strain, and energy in the material. The velocity of propagation of the elastic wave

is $c = (E/\rho)^{1/2}$ where E is Young's modulus and ρ is density. There is a relationship (see Hudson and Housner(23)) between the velocity of deformation (V) of the impacted surface and the stress (σ) developed, such that $\sigma = (E\rho)^{1/2}V$. Since the strain (ε) is proportional to the foreshortening of the external dimensions, it is equal to the compression of the material, and $\varepsilon = C$. The strain energy is given by: $E\varepsilon = \frac{1}{2}\sigma\varepsilon = \frac{1}{2}(\rho\tau 5\varepsilon = C$. In this case, the propagation of an elastic wave due to an instantaneous surface velocity of deformation causes strain energy in the material in proportion to the product of the velocity of deformation times compression ($E_e \sim VC$). Thus, there is another mechanical basis of VC as a measure of the intensity of the energy density in a material during dynamic loading.

Although neither of the previous analogies represent a rigorous theoretical demonstration of the fundamental basis for the viscous response, a mechanical basis has been shown for the product of the two biomechanical responses (VC) as a proportional measure of intensity of a material response to dynamic loads.

Response of a Viscoelastic Thoracic Model

Lobdell's viscoelastic model(24,25) of the human cadaver chest provides another means of demonstrating the biomechanical importance of the viscous response. Using the parameters and responses defined in (24), the following two cases were simulated: Case 1, Impact Mass 20kg and Impact Velocity 7m/s, and Case 2, 4kg Mass and Impact Velocity of 15m/s. These two cases have identical kinetic energy of the impacting mass. The results of the simulation are shown in Figures 7 and 8, and maximum response values are tabulated in Table 2. There is a dramatic difference in response maxima for the two cases, which provide insight into the dynamic response of the thorax. Both cases resulted in a maximum compression of 30 percent. However, the maximum in velocity of chest compression and viscous response were nearly double in the low-mass, high-velocity impact simulation. Interestingly, there was nearly a doubling in dissipated energy in

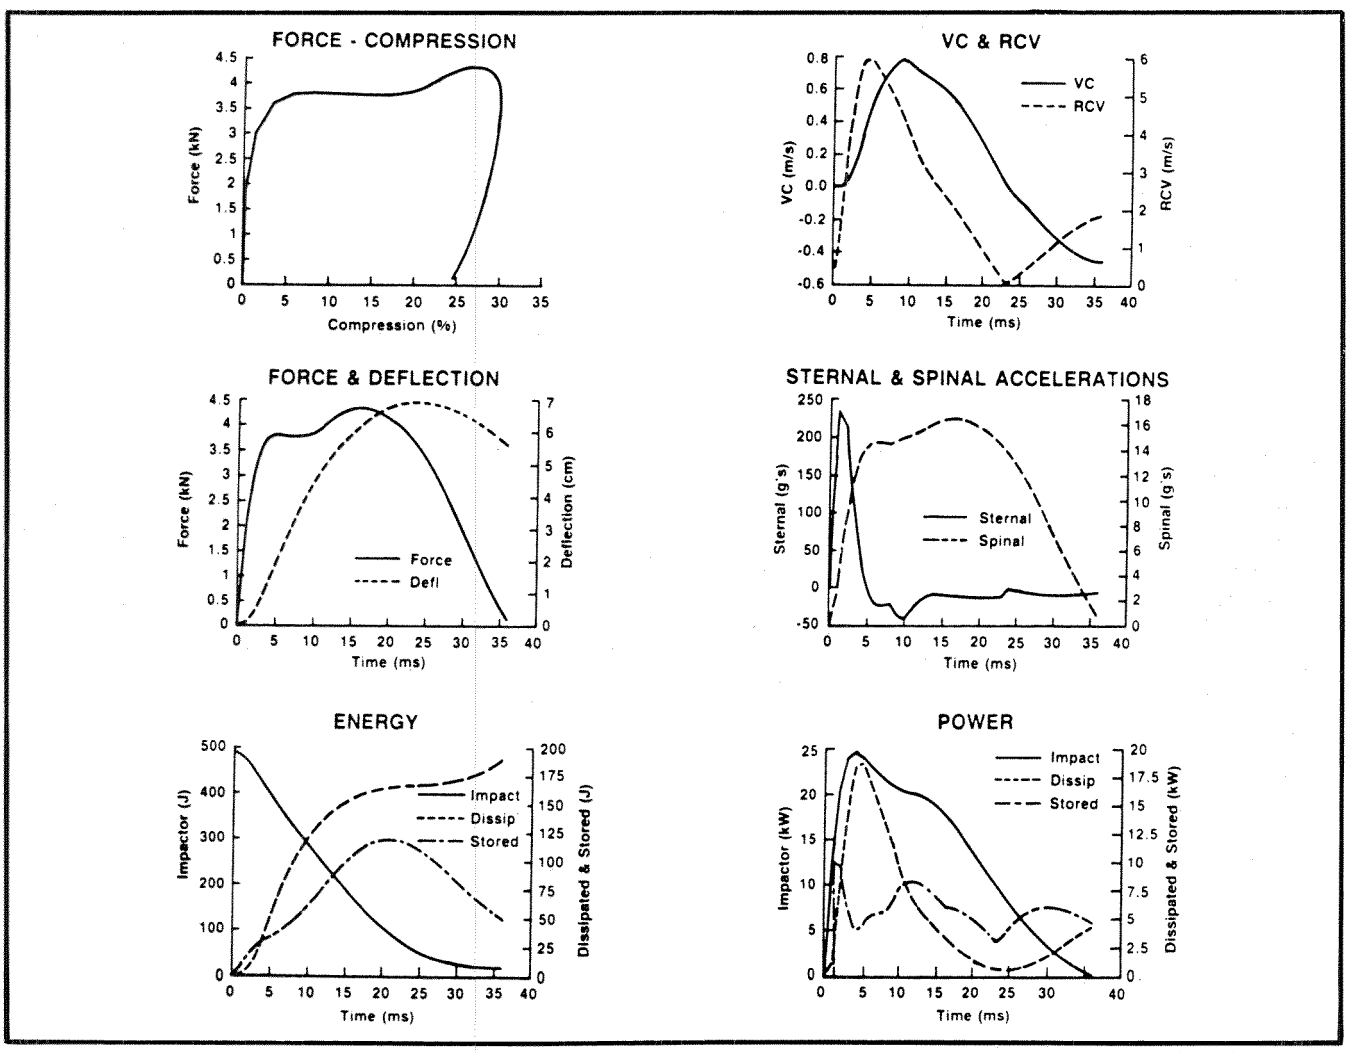

Figure 7. Thoracic impact responses for a 20kg impactor striking the chest at 7m/s

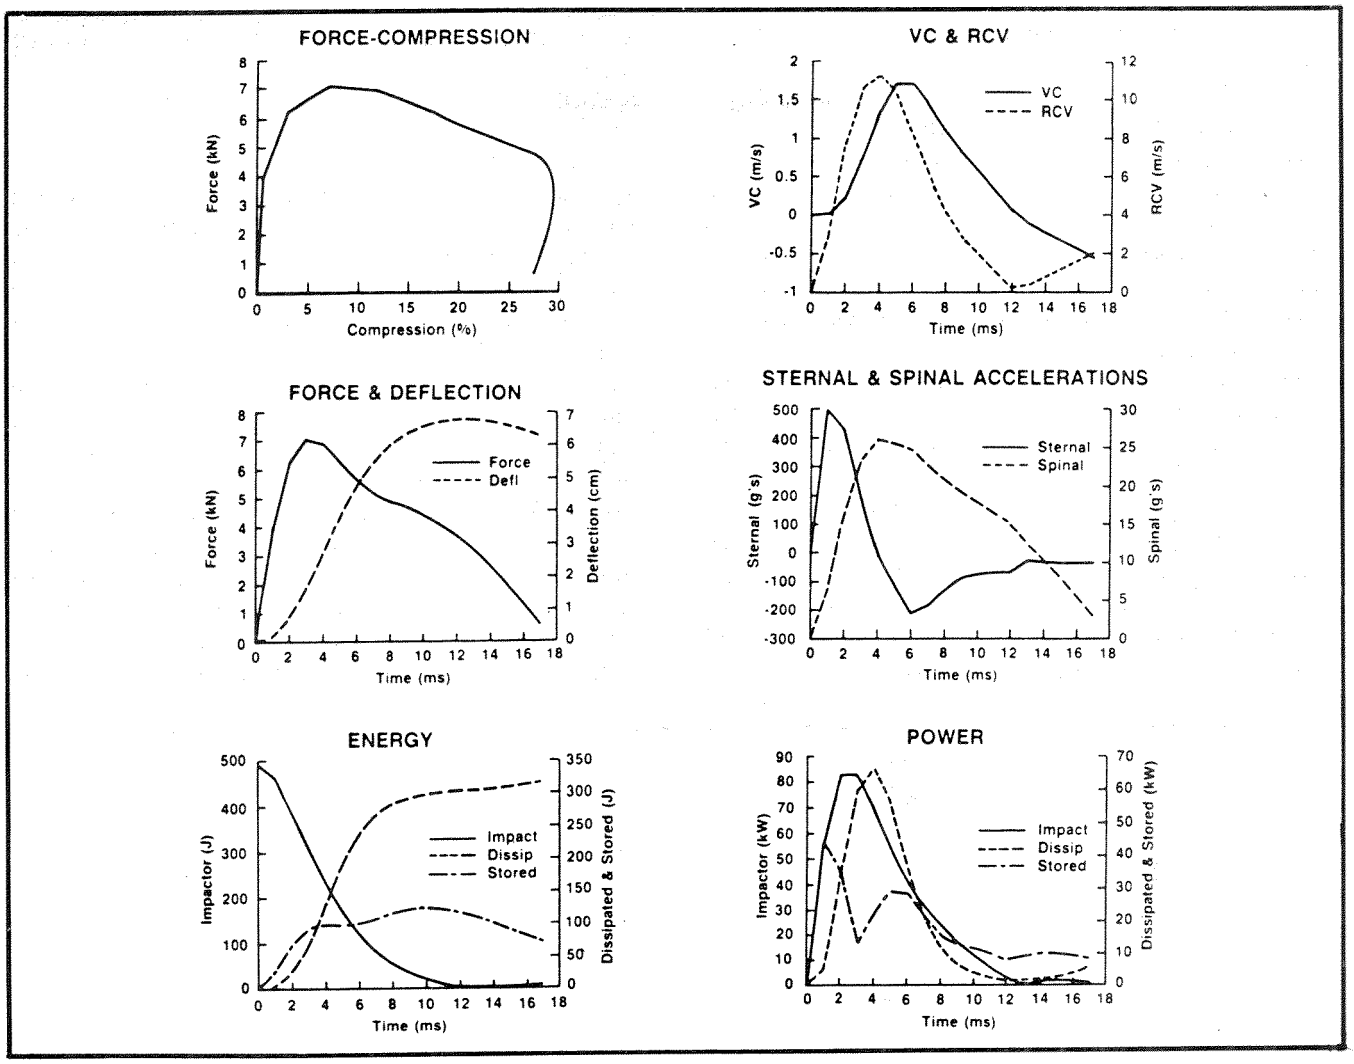

Figure 8. Thoracic impact responses for a 4kg impactor striking the chest at 15m/s

Table 2. Simulated response of a visco-elastic model of the thorax

Impact Parameters	Case 1	Case 2
Mass (kg)	20.	4.
Velocity (m/s)	7.	15.
Responses		
Force (kN)	4.2	7.0
Compression %	30.0	30.0
Rel. Chest Velocity (m/s)	5.8	11.0
Viscous (m/s)	0.8	1.7
Sternal Acc. (g)	230.0	500.0
Spinal Acc. (g)	16.0	28.0
Diss. Energy (J)	180.0	310.0
Stored Energy (J)	120.0	105.0
Diss. Power (kW)	18.0	65.0
Stored Power (kW)	7.5	58.0

the high-velocity impact with a reduction in energy stored in the elastic components. Sternal and spinal accelerations were greater in the high-velocity impact, as was the peak in load on the sternum.

In these two cases, the peaks in chest compression were arrived at by two substantially different deformation responses, one with nearly a doubling in the viscous response. The maximum viscous response occurred much earlier than the maximum in chest compression. On the basis of our previous experimental research(19,21), there would be a greater risk of soft-tissue injury in the low-mass, high-velocity impact even though the maximum compression is similar and within the tolerable level. Soft-tissue injury associated with a high viscous response would occur earlier than maximum chest compression. The two simulations demonstrate the variability in response associated with thoracic impact and show how the viscous response is a useful supplemental biomechanical response.

Analysis of Cadaver Data

The series of blunt frontal impact tests conducted at the University of California at San Diego (UCSD) under contract to the General Motors Research Laboratories represents one of the most comprehensive sets of data available. The response of the chest during blunt frontal impact was measured by transducers attached to the subject and by analysis of high-speed photographs of the impact event. Compression of the chest was determined by film analysis, and the time histories of the responses have been published and discussed in many papers (see, for example, Kroell(7) and (8-10)).

The viscous response of the cadavers was determined from the published chest deflection data, and examples of the viscous response are shown in Figure 9 for the tests used to develop response corridors for the human cadaver and to develop the Hybrid III dummy chests(7,10,11). Eight tests were conducted with a 23.4kg mass and impact velocity of 6.7m/s, and four tests were conducted with a 23.4kg mass and impact velocity of 4.27m/s. These data demonstrate that the peak viscous response occurs earlier (at 10ms) than the maximum compression (at 30ms) in the cadaver subject. Kroell(7) has shown that rib fractures occur progressively with compression, the first fracture occurring as early as 9.2ms and the second at 13.6ms in an event like this that takes 30ms to reach maximum compression. It is interesting that the maximum viscous response occurs at about the same time as the initiation of skeletal damage.

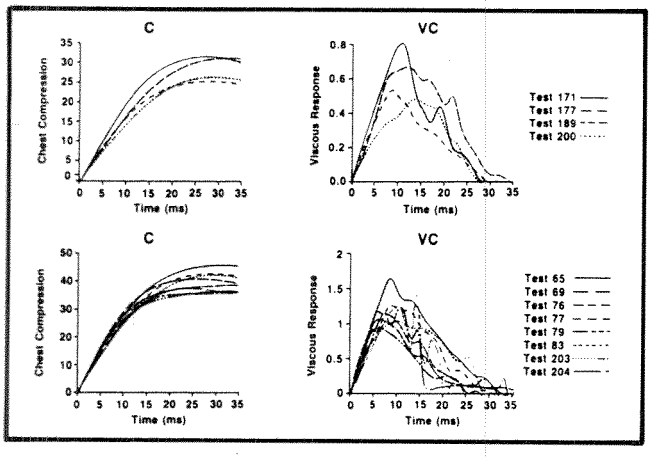

Figure 9. Compression and vicous response of University of California, San Diego, cadavers subjected to blunt frontal impact by a 23.1kg mass striking at 4.9m/s (top curves) of 7.2m/s (bottom curves)(7)

Determining the average maximum viscous response subjects exposed to a range of similar tests (see Viano(8) for groupings of tests) allowed the maximum viscous response to be correlated with the risk of critical injury (Figure 10). There is reasonable correlation between the

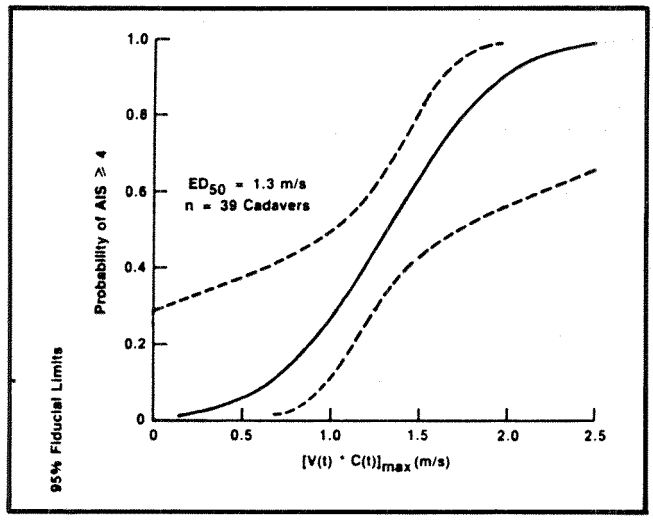

Figure 10. Analysis of critical injury risk (AIS 3) and maximum viscous response for blunt frontal impact of University of California, San Diego, unembalmed cadavers(7)

maximum viscous response and the risk of critical-fatal injury. The effective viscous dose for 50 percent critical injury is VC = 1.3m/s. The viscous response in the high-low-mass simulation of the previous section was VC max = 1.7. Based on the analysis of the UCSD data, there be a high probability (75 percent) of critical-fatal injury. In contrast, the low-velocity, high-mass impact would have a low probability (15 percent) of injury even though injury risk would be similar on the basis of compression.

Evaluation of the Viscous Response in the Hybrid III Dummy

One of the important instrumentation and response features of the Hyrid III dummy(11) is the biofidelity of the chest compression response and a transducer that measures the chest deflection. During a frontal impact, the Hybrid III chest deflects in a manner similar to the response of the human cadaver(10,11), and an analog signal of the deflection is produced. The computation of chest compression is done by normalizing the deflection data by chest depth. This is accomplished by analog to digital conversion of a deflection response and computer processing. Differentiation of the deflection response results in the velocity of deformation, and multiplication of the compression and the velocity of deformation results in the viscous response. A computer program was developed(27) to process Hybrid III and other test subject chest deflection data into the responses. Evaluation of the viscous response from the Hybrid III dummy is underway; however, a tolerance level for dummy testing has not been established.

Modelling the Lateral Impact of the Thorax in Car Side Impact Accidents

M.G. Langdon
Transport and Road Research Laboratory
Crowthorne, United Kingdom

Abstract

As part of the development of a simulation model for side impact accidents, it has been necessary to develop a model of the human thorax. This is required to provide both the correct dynamic interface with the simulation of the car structure and a reasonable criterion of injury probability. In terms of designing structures (such as additional padding) that will maximise occupant protection, it is important to have a good understanding of the dependence of injury on the time history of the impact forces.

It is only possible to develop a complete model of a system as complex as the thorax in terms of a step-by-step simulation. However, an analytical model has also been developed to describe the third order mass/spring/damper system that forms a major subsystem in the step-by-step simulation. This differs from the ordinary second order mass/spring/damper system by having an additional spring in series with the damper, which gives a softer response to a sudden impact. Detailed characteristics of the system have been derived, including an analysis of the dependence of peak deflection (probably a good measure of injury probability) on the duration of an applied impulse force.

Background

There is currently much interest in the problem of occupant protection in side impact accidents. Experimental data on the effects of such accidents are required, both to obtain a better understanding of the problem and be able to set safety standards to which production cars must conform. There are two practical methods by which such data can be obtained.

One is to examine the results of real accidents, in which occupant injuries and damage to the vehicles are easily measured. A major disadvantage of this approach is that the kinematic inputs are not controllable and are not always easy to deduce accurately from the evidence available.

The alternative is to crash vehicles deliberately under controlled conditions with instrumented dummies providing substitutes for human vehicle occupants. Because of constraints of cost and staff time, it is possible only to carry out a limited number of such experiments, and in the interpretation of the results there is some uncertainty about how well results obtained from dummies represent the likelihood that particular injuries, or fatalities, would have been sustained by human occupants.

To increase the number of "experiments" that can be carried out with limited resources, recourse is now made to mathematical modelling of various aspects of vehicle crashes. This is usually in the form of a numerical step-by-step simulation, though analytical models are sometimes useful for improving understanding of specific problems. The great advantage of mathematical models is that once a model has been developed, a large number of "experiments" can be carried out relatively quickly and cheaply. The development of the model can by itself frequently provide a useful insight into the fundamental processes occurring during an impact. However, the development of useful models is a skilled and time-consuming process, and great care has to be taken to insure that the final model provides an adequate representation of reality.

This paper describes the development of models to represent injury to the thorax suffered by the occupants of a car during side impact accidents.

Purpose of the Models

The long-term objective of the simulation programme is to produce a model of side impact that can investigate the relative usefulness of modifying various features of

vehicle design, such as the relative stiffness of various structural components and the provision of energy-absorbing padding to protect the occupants at points of impact. The starting point was a simulation model developed by British Leyland (now Austin-Rover) for the Morris Marina(1). The vehicle part of the model performed well and produced some useful and interesting results, but it rapidly became apparent that further progress would require a more sophisticated model of the dynamic behaviour and injury tolerance of the human thorax.

The accuracy with which the dynamic behaviour of the occupant is represented becomes important when the impacting part of the car structure is relatively light and soft, as for example with thin sheet metal or foam padding. In such cases, it is important to have a good model of the effect of the occupant on the car structure, as well as of the car structure on the occupant. In fact, the occupant and the car should be considered merely as distinguishable parts of an overall dynamic system. Current work is therefore concentrated on the development of models to represent the dynamics of the human thorax in lateral impact.

The initial design of a thorax simulation model was based on the mechanical design for the thorax of the EUROSID dummy(2). This consists of three relatively massive steel ribs, with an additional connection to the spine box provided by a spring/damper system. The model has proved very useful, and the current objectives of the research based on it are—

- To provide a suitable thorax submodel for eventual incorporation in an overall side impact model to investigate ways of improving vehicle design for safety
- To obtain a better understanding of the dynamic characteristics of the thorax substructure in the EUROSID dummy, leading eventually to design improvements in the dummy that can provide a closer match to the characteristics of a human thorax
- To develop a criterion for chest injury that takes full account of the time history of the imposed forces

Two basic models are being developed. One is a step-by-step simulation that attempts to model the human thorax in as much detail as is practicable and necessary. The other is an analytical model of the basic three degree of freedom mass/spring/damper system that represents the movement of the ribs relative to the spine (or alternatively the dynamics of the layer of skin covering the ribs). This has proved useful for providing a full understanding of the dynamic characteristics of parts of the more complex step-by-step model, and for deriving appropriate numerical values for some of the parameters in that model.

An Analytical Model of the Thorax

Description of the Model

The mechanical layout of the system represented by the analytical model is shown in Figure 1a. It consists of two masses, m and M, representing the ribs and torso, connected by a spring with spring constant k_1. This

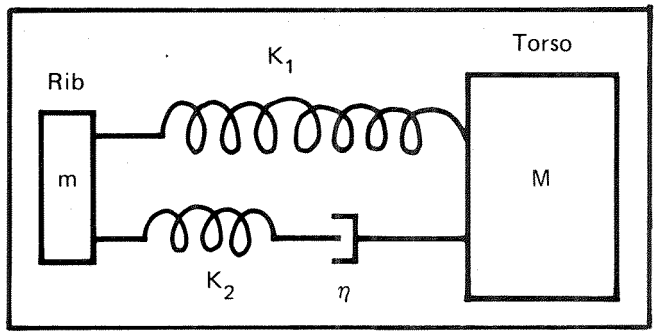

Figure 1a. Layout of system represented by the analytical model

system on its own would have no damping, which would be unrealistic, so damping is provided by a viscous damper, with damping coefficient η. If this damper were connected rigidly to the rib mass (m), it would give an instantaneous large force ($=\eta V$) if the rib were struck by an impactor to give an initial velocity V. This type of behaviour is not observed in actual impactor experiments on cadavers, where the rise in the restoring force exerted by the ribs is relatively slow, suggesting a "rubbery" type of structure. This type of characteristic can be obtained by putting an additional spring (spring constant k_2) in series with the viscous damper. This is the precise type of model used to develop a physical description of rubber elasticity.

In practice there will inevitably be a small mass at the connection between the spring k_2 and the damper. Simulation of the system with such a mass shows that provided the mass is small (e.g., less than 0.2 of the rib mass), it has little effect on the overall behaviour of the system. As its inclusion would seriously complicate the analytical model, such a mass has been omitted for the present.

The characteristics of the system are best evaluated in terms of the impulse response, which describes the behaviour of the system after the rib mass m has been given an initial velocity (e.g., by being struck by an impactor) and no further external forces are applied to the system. If y represents the distance between the rib mass m and the torso mass M, the characteristic equation for the system is:

$$\dddot{y} + k_2\ddot{y}/\eta + (k_1 + k_2)\,\dot{y}/M_0 + k_1k_2y/M_0\eta = 0 \qquad (1)$$

The Newtonian dot notation is used to indicate differentiation with respect to time.

M_o is the reduced mass: $M_o = Mm/M+m)$. If the torso is rigidly clamped so that effectively $M \to \infty$, then the reduced mass M_o becomes equal to the rib mass m.

This is a third order dynamic equation; the inclusion of the damper mass in the model would have led to a considerably more complex fourth order equation.

Following the method used in the well-known second order equation, it is convenient to express this equation in terms of an undamped natural frequency (which provides the dimensional scaling for systems with different frequencies) and two nondimensional parameters. The parameters chosen are:

Undamped (angular) natural frequency

$$\omega_o = \sqrt{k_1/M_o} \qquad (2a)$$

(The undamped natural fraguency $f_o = \omega_o / 2\pi$)

Nondimensional damping constant

$$\eta_s = \eta / M_o\omega_o \qquad (2b)$$

(Note: η_s differs by a factor of two from the corresponding nondimensional parameter normally used in the second order equation.)

Spring ratio $\quad r = k_2/k_1 \qquad (2c)$

This leads to the parametric equation:

$$\dddot{y} + R\omega_o\ddot{y}/\eta_s + (1+R)\omega_o^2\dot{y} + R\omega_o^3 y/\eta_s + 0 \qquad (3)$$

An alternative type of third order dynamic model that has been used to represent the thorax is shown in Figure 1b. This consists of a conventional second order spring/damper system, involving the spring K_1 and damper η, with an additional spring K_2 placed in series with this system. The characteristic equation for the overall system, with no external forces acting, is:

$$\dddot{y} + (k_1+K_2)\ddot{y}/\eta + K_2\dot{y}/M_o + K_1K_2y/M_o\eta + 0 \qquad (4)$$

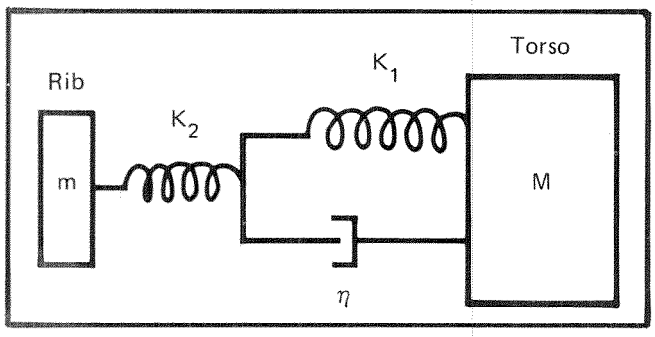

Figure 1b. Layout of alternative model

This can be expressed in terms of the undamped natural frequency ω_o and two nondimensional parameters by making the substitutions:

$$\omega_o^2 = [R/(1+R)]\ K_1/M_o \qquad (5a)$$

$$\eta_s = [R/(1+R)]^2\ \eta/M_o\omega_o \qquad (5b)$$

$$R = K_2/K_1 \qquad (5c)$$

The resultant parameterised equation is identical to the parameterised equation (3) for the system shown in Figure 1a, showing that with an appropriate choice of component values the two systems are dynamically identical.

Solution of the Model Equation—Impulse Response

The third order dynamic equation is solved by making the assumption that the solution is of the form:

$$y = Ae^{-\alpha t} \qquad (6)$$

(Since the equation is third order, there will be three pairs of values of α and A, and the general solution will be the sum of these three solutions.) Substituting this value of y, and its first, second, and third differential w.r.t. time in Equation 3, leads to the cubic equation:

$$\alpha^3 - R\omega_o\alpha^2/\eta_s + (1+R)\omega_o^2\alpha - R\omega_o^3/\eta_s = 0 \qquad (7)$$

This can be solved by the classical method, which involves a substitution of variable to eliminate the term in $a\alpha^2$. The solution is easy to program on a computer, but is not simply expressible in elementary terms. It can be shown that the solution has only three real roots when λ_s lies in the range:

$$(a - b) < \eta_s(a + b) \qquad (8)$$

where

$$a = R^2(R^2 + 20R-8)/8(1+R)^3$$

$$b = R^2\sqrt{R(R-8)^3}/8(1+R)^3$$

The expression for b in the above inequality is only real when $R>8$, so all solutions (for any value of λ_s) must include complex roots when $R<8$.

The complete solution for the case with complex roots is:

$$y = Ae^{-\alpha t} + e^{-\varepsilon t}(B\cos\omega t + C\sin\omega t) \qquad (9)$$

where A, B, and C are arbitrary constants that can be derived from the initial conditions. The parameters ε and ω are the real and imaginary parts of the complex roots of α.

$$\alpha_1 = \varepsilon - i\omega \qquad (10a)$$

$$\alpha_2 = \varepsilon + i\omega \qquad (10b)$$

When the system is excited by an (infinitesimally short) impulse of value I, the initial velocity of the rib mass is V = I/m, and the arbitrary constants have values:

$$A = 2\varepsilon I/m\,[(\varepsilon - \alpha)^2 + \omega^2] \qquad (11a)$$

$$B = -A$$

$$C = I(\alpha^2 - \varepsilon^2 + \omega^2)/m\omega\,[(\varepsilon - \alpha)^2 + \omega^2] \qquad (11b)$$

When all roots are real, the motion is nonoscillatory (over-damped), and the complete solution is:

$$y = Ae^{-\alpha_1 t} + Be^{-\alpha_2 t} + Ce^{-\alpha_3 t} \qquad (12)$$

The arbitrary constant A is given by:

$$A = I(\alpha_2 + \alpha_3)/m(\alpha_1 - \alpha_2)(\alpha_1 - \alpha_3) \qquad (13)$$

The values of B and C are found similarly by equations that are symmetrical with Equation 13.

Using the above equations, it is possible to calculate the impulse response characteristics of the system for any values of η_s and R. It is convenient to work with a "normalised" system for which the undamped (angular) natural frequency ω_o is unity, and to examine the response to an impulse giving unit velocity to the rib mass. The response for other conditions can then easily be calculated by simple scaling. If the real system has an undamped (angular) natural frequency of ω_o (calculated from Equation 2a or 5a), and suffers an impulse giving an initial velocity V, then actual values of time, displacement, or acceleration are found from the normalised values as follows:

Time: $$\text{actual} = T_{\text{normalised}}/\omega_o \qquad (14a)$$

Displacement: $$y_{\text{actual}} = y_{\text{normalised}} \times V/\omega_o \qquad (14b)$$

Acceleration: $$\ddot{y}_{\text{actual}} = \ddot{y}_{\text{normalised}} \times V \times \omega_o \qquad (14c)$$

The quantity y refers to the second differential of the distance between the rib mass and the torso mass, and only represents an absolute acceleration if the torso is clamped. If the torso is free to move, the absolute accelerations of the ribs and torso are found from:

Rib acceleration

$$a_{\text{rib}} = \frac{M_o\ddot{y}}{m} = \frac{M}{M+m}\ddot{y} \qquad (15a)$$

Torso acceleration

$$a_{\text{torso}} = \frac{-M_o\ddot{y}}{M} = \frac{m}{M+m}\ddot{y} \qquad (15b)$$

Figure 2 shows contours of specific values of maximum displacement, plotted as a function of the dimensionless parameters η_s and R. The region in which the solution of Equation 7 has all real roots (over-damping) is shown for interest. It will be noted that although the form of the solution changes at the boundaries of this region, there are no discontinuities in the contours. It will also be seen that when R is greater than 8, there are always two values of η_s that give critical damping (the boundary between over-damping and oscillatory solutions of Equation 3).

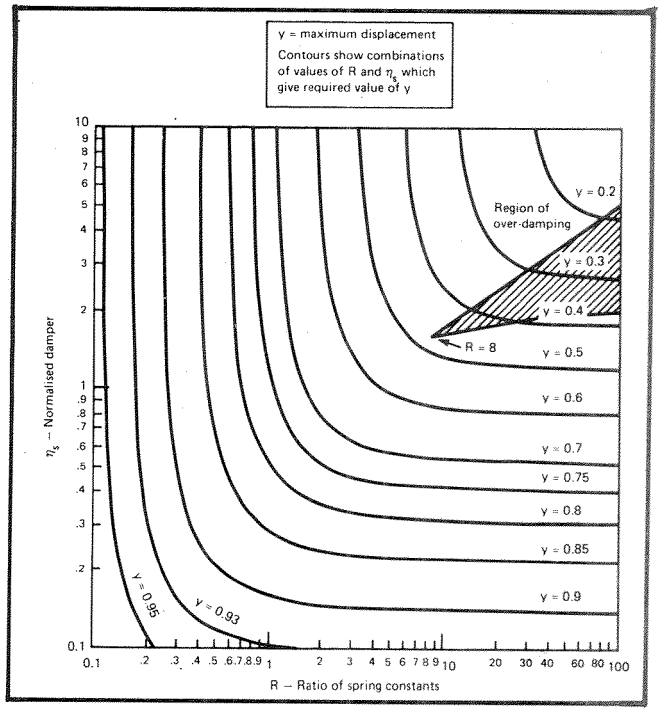

Figure 2. Analytical model—contours of maximum displacement after excitation by a unit impulse

Frequency Response

An alternative (but equivalent) method of representing the behaviour of the system is in terms of its long-term response to a constant amplitude sinusoidal input force. If the rib mass is subjected to a sustained sinusoidal force

F·sin ωt, then the relative rib displacement will also vary sinusoidally with angular frequency ω, after the initial transients have damped out. The displacement can be represented by the equation:

$$y = A \sin \omega t + B \cos \omega t \qquad (16)$$

This has an overall amplitude $\sqrt{A^2 + B^2}$, and a phase angle relative to the input force of ϕ, where tab = (B/A) (17)

The values of A and B are found by equating coefficients in the dynamic equation (3), modified to include the effect of the driving force. The values derived are:

$$A = \frac{F}{M} \cdot \frac{[\omega^2\eta_s^2[(1+R)\omega_o^2 - \omega^2] + R^2\omega_o^2(\omega_o^2 - \omega^2)]}{\{\omega^2\eta_s^2[(1+R)\omega_o^2 - \omega^2]^2 + R^2\omega_o^2(\omega_o^2 - \omega^2)^2\}} \qquad (18)$$

$$B = -\frac{F}{m} \cdot \frac{R^2\omega\omega_o^3\eta_2}{\{\omega^2\eta_2^2[(1+R)\omega_o^2 - \omega^2]^2 + R^2\omega_o^2(\omega_o^2 - \omega^2)^2\}}$$

Figure 3 shows the impulse response for a typical third order system (normalised with $\omega_o = 1$), and the corresponding frequency response plotted separately for the amplitude and phase characteristics. The impulse and frequency responses are mathematically related by the Fourier Integral transform. If the function y(t) represents the response at time (t) following an impulse at time t=0, and Y(f) represents the frequency response, then:

$$Y(f) = \int_o^\infty y(t) \cdot e^{-i2\pi ft}\, dt \qquad (19)$$

(the lower limit of integration should be $-\infty$, but as it is assumed that y = 0 for all time before the impulse, the lower limit can be set to zero.) i represents the imaginary number $\sqrt{-1}$

The function Y(f) derived from this equation is a complex number that contains both the amplitude and phase response. The relationship of Equation 19 is not in fact required to derive the frequency response listed in Equations 16 to 18 (though it is of course satisfied by these equations), but it is useful in further development of the theory of the system dynamics.

Response to Finite Length Pulses

Having evaluated the impulse response of the system, it is possible to calculate the response for any known input. Since the system is linear (i.e., the parameters m, M, k_1, k_2,η are assumed to remain constant for any finite displacements), the effects of a large number of infinitesimal impulses are strictly additive, provided that the effect of the different times of the impulses (i.e., phases)

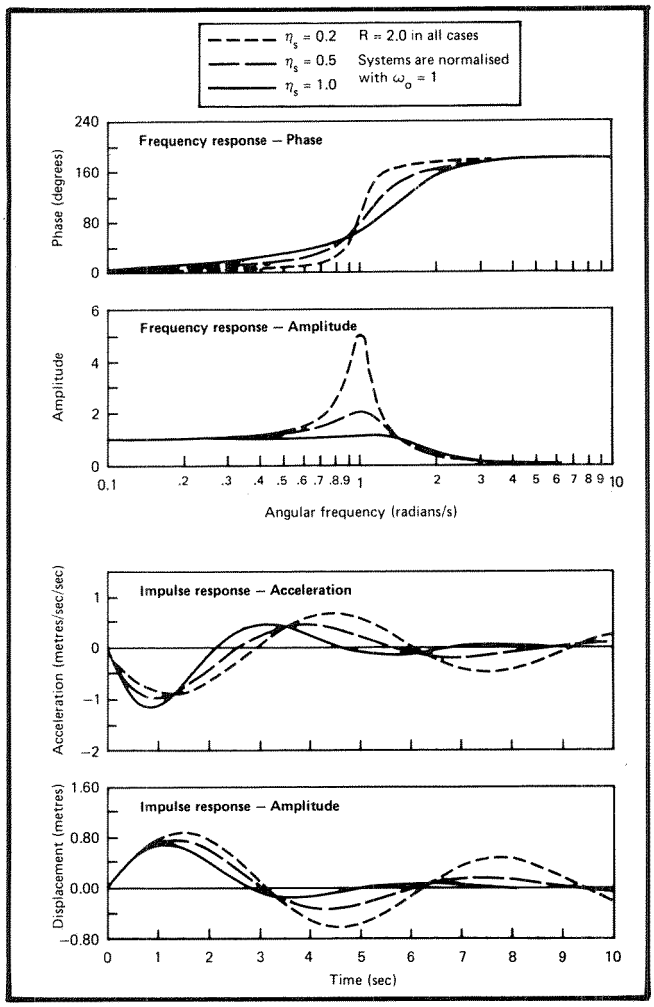

Figure 3. Impulse and frequency response of a third order dynamic system

are taken into consideration. If h(t) is the impulse response (i.e., y = h(t) at a time t after a unit impulse) and x(t) is the actual input at time t, then the response of the system at time t is given by the convolution integral:

$$y(t) = \int_o^t x(\tau)\, h(t - \tau) d\tau \qquad (20)$$

Response to Rectangular Impulses

If the input is a rectangular impulse of amplitude $x(\tau) = I/T_o$ for $0 < \tau < T_o$ and zero for all other time (i.e., it has a total impulse of I spread over a time T_o), then the response can be calculated directly from the impulse response (Equation 9 or 12, depending on whether the solution is oscillatory or not) and the convolution equation (20).

For the exponential terms in the impulse response having the form h(t) = A exp ($-\alpha t$), the overall response becomes:

$$y(t) + \frac{I}{m} \cdot \frac{A}{\alpha T_o} [1 - \exp(\alpha t)]$$

For $0<t<T_o$ (21a)

and

$$y(t) = \frac{I}{m} \frac{A}{\alpha T_o} \exp(-\alpha t) [\exp(\alpha T_o) - 1]$$ (21b)

for $t>T_o$

For the trigonometric terms in the impulse response (when an oscillatory solution is obtained) having the form $h(t) \exp(-\varepsilon t) [B \cos \omega t + C \sin \omega t]$, the overall response can be calculated either by direct integration of the convolution equation (20), or by rewriting the impulse response in terms of complex exponential functions (see Equation 10): the constants B and C also become complex in this case to give an overall real result and substituting the values in Equation 21a or 21b. The results for these trigonometric terms are:

$$y(t) = \frac{I}{m} \frac{1}{(\varepsilon^2 + \omega^2)T_o}$$

$$\{ [\varepsilon B + \omega C] [1 - \exp(-\varepsilon t) \cos \omega t] -$$

$$[\varepsilon C - \omega B] \exp(-\omega t) \sin \omega t\}$$

for $0<t<T_o$ (22a)

$$y(t) = \frac{I}{m} \frac{\exp(-\varepsilon t)}{(\varepsilon^2 + \omega^2)T_o}$$

$$\{[\varepsilon B + \omega C] [\exp(\varepsilon T_o) \cos \omega(t-T_o) - \cos \omega t]$$

$$+ [\varepsilon C - \omega B] [\exp(\varepsilon T_o) \sin \omega(t - T_o) - \sin \omega t]\}$$

for $t>T_o$ (22b)

These equations can be differentiated with respect to time t to find the velocity and acceleration responses to a rectangular impulse input.

Response to Half Sine Wave Impulses

A more realistic input is a half sine wave having the form:

$$x(\tau) = I \sin(\pi \tau / T_o) \text{ for } 0<\tau<T_o$$ (23)

and zero for all other time.

As for the rectangular pulse, this has a total impulse of I. It is again possible to calculate the response by direct integration of the convolution equation, but the result is rather more complicated.

For each exponential term, $h(t) = A \exp(-\alpha t)$, in the impulse response, the overall response is:

$$y(t) = \frac{I}{m} \frac{\pi T_o A}{2(\alpha^2 T_o + \pi^2)}$$

$$\{\alpha \sin \frac{\pi t}{T_o} - \frac{\pi}{T_o} \cos \frac{\pi t}{T_o} + \frac{\pi}{T_o} \exp(-\alpha t)\}$$

for $0<t<T_o$ (24a)

and

$$y(t) = \frac{I}{m} \frac{\pi^2 A \exp(-\alpha t)}{2(\alpha^2 T_o + \pi^2)}$$

$$[\exp(\alpha T_o) + 1]$$

for $t>T_o$ (24b)

These equations can be differentiated with respect to time (t) to find the velocity and acceleration responses to a half sine wave impulse input.

The expressions for the overall response from the trigonometric terms become very complicated, and numerical evaluation is best performed by complex arithmetic on a computer, using Equations 2a and 2b with the appropriate complex values substituted for A and α.

Figure 4 shows how the peak deflection of the rib mass varies as the duration of a half sine wave impulse is increased, keeping the overall impulse constant. Curves are shown for a range of values of η_s between 0.2 and 5.0, for a fixed value of spring ratio R = 2. (As before the system is normalised, with $\omega_o = 1$). The present EUROSID design is intended to have a value of η_s a little less than 2. Figure 4 also includes a dotted curve showing the displacement that would occur if a static force was applied equal to the peak force arising in the impulsive input. It will be seen that all the curves are asymptotic to this static deflection value for large values of the impulse duration.

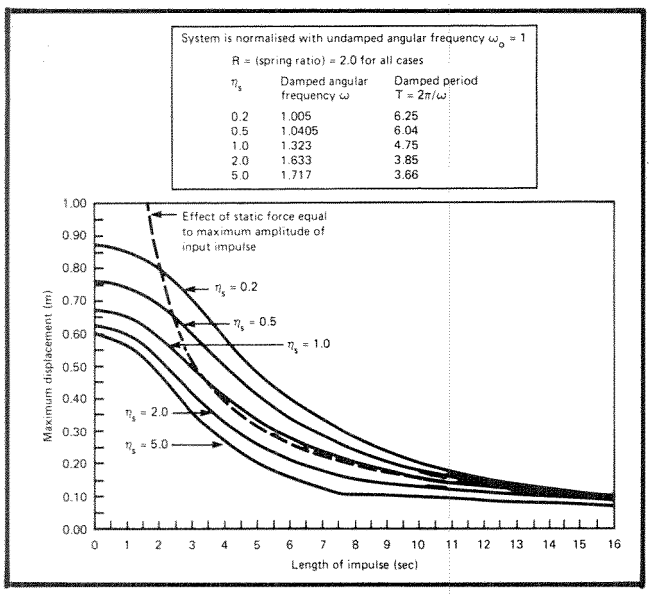

Figure 4. Responses of third order dynamic system to half-sine wave input impulses of different durations

The maximum displacements initially decrease rather slowly as the impulse length is increased, and it requires a pulse length approximately equal to the period of the system to reduce them to half value. (The period ω varies with η_s. See box in the figure.) The curves are at their steepest in this region. If padding is used to increase the length of the impulse, the increase in effectiveness for increasing thickness is obviously at its maximum here.

Similar curves are obtained with rectangular impulses, although the curves fall off rather more steeply. A pulse length of about 0.7 of the system period is required to reduce the peak displacement to half the value for a very short impulse. With a rectangular impulse, the discontinuity in slope of the curve for $\eta s = 5.0$ is much stronger; it occurs when the maximum value of displacement is at the second maximum of the displacement/time curve instead of the first.

Response to an Arbitrarily Complex Input

For input pulses with shapes more complex than the half sine wave, it does not appear worthwhile to attempt to calculate the output response by a purely analytic method. In principle it would be possible to use a direct numerical integration of the convolution equation (20), but the Fast Fourier Transform provides a much quicker method. Convolution in the time domain transforms into multiplication in the frequency domain. The impulse response h(t) and the input waveform x(t) are therefore transformed by means of Equation 19, and the product at each frequency of these transforms H(f).X(f) is then the transform of the output response Y(f). The output time response can then be recovered by the inverse transform.

$$y(t) = \int_{-\infty}^{\infty} Y(f)e^{i2\pi ft}df \qquad (25)$$

Computer programs to implement the Fast Fourier Transform are now widely available, and the methodology is well described in the literature(3).

However, if the impulse response is formed by the sum of a number of exponential terms (real or complex), as in the model under discussion, a much simpler numerical method can be used to find the output response. Consider the contribution to the total response contributed by the term $A \exp(-\alpha t)$, and suppose that the input waveform is sampled at a large number of times separated by intervals of Δt. Further, suppose that the total contribution from this term to the system output (e.g., rib displacement) after n intervals is S_n.

After a further period Δt, in the absence of any input, this displacement would have decayed to $S_n.\exp(-\alpha\Delta t)$. However, if the system is subjected to an average force F_n in the interval, it will have received an additional impulse $F_n\Delta t$, which will give a response $AF_n\Delta t/m$. The total response after n+1 intervals is therefore:

$$S_{n+1} = S_n \cdot \exp(-\alpha\Delta t) + AF_n\Delta t/m \qquad (26)$$

If t is very small, the exponential term can be approximated:

$$\exp(-\alpha\Delta t) \rightarrow 1 - \alpha\Delta t \quad \text{as } \alpha\Delta t \rightarrow 0 \qquad (27)$$

and Equation 26 can be simplified to:

$$S_{n+1} = S_n + (AF_n/m - \alpha S_n)\Delta t \qquad (28)$$

If the input is zero for all times before the time corresponding to n=0, and S_o is set to zero, this equation provides a simple iterative method of calculating the contribution by each term, and hence the overall system response, for all subsequent times.

When the overall solution is oscillatory and contains trigonometric terms, it is simplest to replace the trigonometric terms by the corresponding complex exponentials, and use these directly in complex versions of Equations 26 or 28. For example, the trigonometric form of the impulse function:

$$h(t) = A\exp(-\alpha t) + \exp(-\varepsilon t)[B\cos\omega t + C\sin\omega t] \qquad (9)$$

becomes

$$h(t) = A\exp(-\alpha_1 t) + B'\exp(-\alpha_2 t) + C'\exp(-\alpha_3 t) \qquad (29)$$

where

$$\alpha_1 = \alpha \text{ (the real term is unchanged)} \qquad (30a)$$

$$\alpha_2 = \varepsilon - i\omega \quad (30b)$$

$$\alpha_3 = \varepsilon + i\omega \quad (30c)$$

$$B' = 1/2(B-iC) \quad (30d)$$

$$C' = 1/2(B+iC) \quad (30e)$$

The complex exponentials $\exp(-\alpha_2 t)$ and $\exp(-\alpha_3 t)$ represent vectors rotating in the complex plane. The amplitude of the vector decreases at a rate controlled by the parameter ε, while the rate of rotation is controlled by the parameter ω.

When Equations 26 or 28 are evaluated and the results for all the terms are summed, it is found that the imaginary terms cancel out and vanish, leaving a result that is wholly real. The use of complex variables may therefore, if desired, be regarded solely as a mathematical device to simplify the calculations required, and need not concern the user of the results.

If the maximum rib displacement could be regarded as providing a measure of injury severity, the above method for calculating the response to any arbitrary input could be used as the basis for a new injury criterion. It would be much faster to calculate than exceedences or HICs, as well as appearing to be based on sounder physical principles.

Step-by-Step Simulation Model

The analytical model described above has proved useful for obtaining a better understanding of the operation of subsystems with up to three dynamic components (springs or dampers). However, a model of this type would become very complicated and difficult to use if extended to more complicated systems, and parts of the solution would require numerical methods of solution. (For example, solution of the equation to give the impulse function is only possible by numerical methods when the highest power of α exceeds four.) Furthermore it would be virtually impossible to include nonlinear components in the model, at least without losing most of the features that have made it so tractable.

The alternative type of model for solving more complicated problems is the step-by-step simulation. It takes more time to run than an analytic model and does not provide the same degree of insight in simple situations, but there are no fundamental limits to the complexity of the problem to which it can be applied, other than those set by the storage capacity and available running time of the computer. Programs have been written using the Advanced Computer Simulation Language (ACSL). With this the operator effectively has to write out a set of simultaneous equations that define the problem, provide initial values for all variables that are to be integrated, and set a step length. The ACSL system then automatically carries out a step-by-step integration of the set of equations and provides facilities for accessing any required variables at suitable time intervals. Outside the dynamic section of the program that performs the integrations, the operator may include ordinary Fortran coding, including access to Fortran subroutines, so the system is extremely flexible in use.

Systems Investigated

The basic model used in the step-by-step simulation is shown in Figure 5. The rib structure is identical to that investigated in the analytical model. Between the rib mass and the impacting mass, there is an additional spring/damper system to represent the skin. This could also be

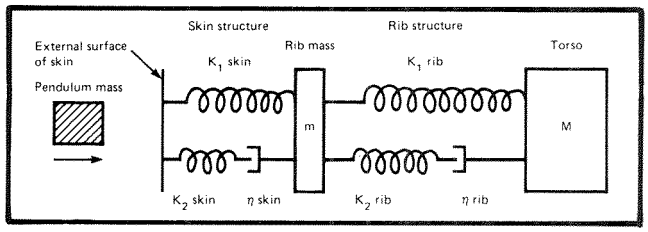

Figure 5.

used to represent the effect of padding, if required. This system is similar to the spring/damper used for the ribs, except that it is stiffer and the main spring (k_1-skin) is nonlinear. The force/compression characteristic is represented by the equation:

$$\text{Spring force} = k_{1\text{-skin}}.x.x_o/(x_o-x) \quad \text{for } x>0 \quad (31)$$

$$= 0 \quad \text{for } x<0$$

where x represents the compression of the skin, and x_o is a maximum compression, nearly equal to the initial skin thickness.

For small deflections, the skin behaves as a linear spring, with spring constant k_1-skin, but when the compression approaches a value x_o the spring becomes progressively stiffer so that the compression can never exceed x_o.

Typical values of the skin parameters used to simulate a foam covering used in tests on a dummy rib are:

$k_{1\text{-skin}}$ 200 kN/metre

$k_{2\text{-skin}}$ 4000 kN/metre

η-skin 250 Newtons/metre per second

x_o 10 mm

The spring parameters of the main rib system have been selected to conform approximately to some cadaver results, though more work is required to optimise the match of the simulation system to the experimental results. The rib mass is equated to the rib mass of the EUROSID dummy, and is rather large compared with the skeletal mass of human ribs. The parameters relating to one rib of the first prototype EUROSID dummy (one-third of a complete thorax) are:

$k_{1\text{-rib}}$ 15 kN/metre

$k_{2\text{-rib}}$ 33 kN/metre

η-rib 250 kN/metre per second

m-rib 1 Kg

i.e. ω_o = 122.5 radius/sec (19.5Hz)

R = 2.2

η_s =2.04

ω = 205 radius/sec (33Hz)

This basic thorax simulation has been built into a number of simulation programmes representing various possible test situations. These include:

i) Pendulum impact when the spine box (torso) is clamped

ii) Pendulum impact when the spine box is free to move

iii) Excitation by square wave or half sine wave impulses of varying pulse length (c.f., similar impulsive inputs to the analytical model)

iv) Impact of the whole thoracic system into a fixed wall; impact from horizontal motion corresponds to the "Heidelberg" test; impact from a vertical drop corresponds to the "Peugeot/Renault" tests

The dynamic outputs from the system can be filtered within the programme, if required, to produce results that are fully compatible with the results from experimental work. At present a second order Butterworth filter is incorporated, but more complex filters can easily be provided by the ACSL system if required.

The thoracic simulation has also been used as part of a complete vehicle side-impact simulation, but it is not intended to carry out further work on simulating vehicle impacts until a full comparison has been made between the simulation model and experiments with dummies and cadavers. At present the role of the model is seen as providing help in matching dummy and cadaver characteristics and obtaining a better understanding of the criteria for thoracic injury.

A number of problems or potential problems with the dummy thorax have been investigated by the simulation model.

Effects of Changing the Skin Characteristics

When a dummy rib is impacted by a pendulum, the measured accelerations on the rib or spine differ markedly from the smooth curve predicted by the simple analytical model (Figure 3), due to an additional higher frequency oscillation. This is caused by "bouncing" between the pendulum and rib, in the system formed by the pendulum and rib masses, and the skin elasticity. A similar acceleration waveform is shown by the simulation. The actual shape of the waveform can be altered significantly by changes in the skin characteristics. However, the displacement waveform, and particularly the peak displacement, are affected only slightly by such changes, provided that the "skin bounce" frequency is high compared with the fundamental response frequency of the rib structure. This would be expected from a consideration of the analytical model's response to impulses of different durations (Figure 4).

It is clear that if it is required to match the acceleration response of various parts of the dummy thorax with the responses recorded in cadaver experiments, then it is important to produce exactly the "right" characteristics for the skin covering the ribs. If, however, the injury effects on the dummy can reasonably be related to the peak displacement (compression) of the rib structure, then it may be much less important to "fine-tune" the skin characteristics to produce a dummy that can give a reliable measure of injury likelihood in crash experiments.

Effect of Rib Mass

An accelerometer attached to the pendulum used to provide the impact on a dummy will record an initial high-peak acceleration, followed by a series of oscillations due to "bounce" between the pendulum and rib mass. This initial peak is still apparent, though its amplitude is decreased, even if the output response is heavily filtered. The peak is reproduced on the simulation but is generally absent in cadaver experiments. The reason for this discrepancy is the high mass of the dummy rib, compared with the lower mass of the bony rib structure in a human cadaver. In the human, there is effectively a small concentrated mass in the bony rib, backed up by the distributed mass of various organs lying between the rib and the spine. This mass is set in motion gradually as the rib moves and will have quite a different effect on the acceleration of the pendulum.

The difference in mechanical layout clearly has implications on the degree to which the "lumped-mass" dummy can accurately reproduce the motion of a real human thorax. The important matter is whether this simplified model of the human chest incorporated in the dummy can still give a useful measure of the likelihood of injury under a wide range of crash conditions. This

problem will be investigated by the simulation model in the near future.

Effect of "Lateral Inertia" on Dummy Rib Mass

The values of spring constants and masses in a dummy rib system can easily be measured in quasi-static experiments. However, experiments on an instrumented dummy to determine the damper characteristics during the pendulum gave peculiar results, suggesting initially that the main spring k_1 has highly nonlinear characteristics in a dynamic (as opposed to quasi-static) situation. This seemed unlikely as the spring is a simple steel coil, but it now seems probable that the effect is due to a "lateral inertia" effect. (In this case, "lateral" is relative to the "left-right" direction of impact; in absolute terms, it is the "anterior-posterior" inertia.) When the rib is struck by a pendulum so that the springs are compressed (Figure 6), the steel strip forming the dummy rib deforms as well as being pushed away from the impulse, and part of it is accelerated in the a-r direction after a slight time delay.

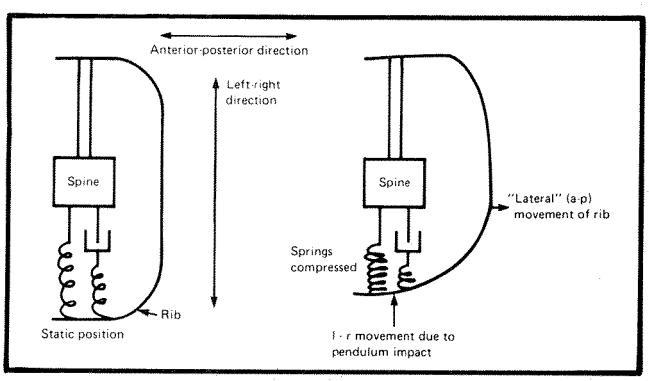

Figure 6.

Since the rib has a substantial distributed mass, a force is required to produce this acceleration, and this force is seen as an apparent increase in the mass of the rib at the attachment point of the springs. (The rib mass is represented by a single point mass at this location in the models.) In subsequent motion, the rib oscillates in the a-p direction with its own natural frequency (as well as any frequencies forced on it), and the effective mass at the spring attachment point varies widely.

The effect of this "lateral inertia" can be included in the (one dimensional) simulation by adding an additional mass attached only to the rib mass by an undamped (or very slightly damped) spring. The simulation has been used to check the correctness of the original hypothesis that a "lateral inertia" effect is the likely cause of the discrepancies in experimental results.

Preliminary results have suggested not only that the hypothesis is correct, but that the effect may improve the "fit" of the model to the results of cadaver tests. It seems likely that the additional mass can represent the effects in the human body of massive organs within the rib cage, which are only loosely coupled to the rib structure.

Discussion

A discrete element model can be built that appears to respond to a side impact in a similar way to the rib system of the human thorax. Two springs and a viscous damper are required to obtain a reasonable match of the dynamic response. There are two possible configurations for these elements (Figures 1a and 1b), but it can be shown that with an appropriate choice of parameters the two configurations can always be designed to give identical dynamic characteristics. A full analysis of this three-element model has been carried out by analytical methods, including its response to rectangular and half sine wave impulses of various durations.

The results have the following important implications for the design of padding. In most accidents in which there is no significant penetration of the vehicle structure, the total velocity change to which the occupant is subjected is largely unaffected by vehicle design. The importance of padding, or the inclusion of crushable or deformable elements in the vehicle structure, is to change the time over which the velocity change is applied. The analysis of the effect on rib crush of varying the impulse duration suggests that for thoracic injury, padding has little effect unless it can stretch the impulse out to a time that is at least half the natural frequency of the rib structure.

As well as providing a useful insight into the mechanics of the rib system and the probable effectiveness of padding in reducing injury, the analytical model also appears to provide a method for calculating an injury index based on sound physical principles, and would be much easier to calculate than the present method of exceedences.

To investigate the characteristics of more complicated systems such as a rib system covered by an elastic skin, a step-by-step simulation model has been developed. This is currently being used as an aid to the design of the thorax for the EUROSID dummy. It has thrown considerable light on the significance of the "skin" characteristics in modifying the acceleration response of the ribs in pendulum impact tests and has emphasised the importance of reducing the mass of the steel ribs near the point of impact. The simulation is currently being "tuned" to give the best possible fit to the results of cadaver tests. Because of the large number of variable parameters in the step-by-step model, a trial-and-error method of adjusting parameters would have been very time-consuming. The analytic model was therefore used to estimate probable

values of many of the parameters for the initial simulation runs.

The next stage of research will attempt to evaluate the performance of the human thorax in terms of a transfer function from input force (at the ribs) to rib deflection, rather than in terms of an equivalent mass/spring/damper system. It would then be possible to set up a simulation using this transfer function directly and compare the results (for a wide range of input impulses) with those of a dummy-equivalent simulation. This would provide information on the relative significance for injury estimation of remaining differences between the dummy and human characteristics.

Validity of Thoracic Injury Criteria Based on the Number of Rib Fractures

Jean-Pierre Verriest and
André Chapon
Organisme National de Sécurité Routière
Laboratoire des Chocs et de Biomécanique

Abstract

Most of the thoracic injury criteria proposed these past years are based mainly on the analysis of data obtained from experiments with human cadavers and are related principally to rib fractures. And yet, the actual threat to life incurred in real accidents results from lesions to intrathoracic viscerae that are not necessarily correlated with the number of rib fractures. Moreover, the injuries sustained by cadavers during experiments are mainly rib fractures. In these cases, visceral lesions are unusual and not necessarily identical with those sustained by real accident victims.

Preliminary results of measurements concerning rib strength and dynamic behavior of the cadaver thorax in frontal impacts show the rib cage offers a low resistance against compression and the vertebral column acts as a stop. The combination of these various data leads to questioning the validity of thoracic injury criteria based on the number of rib fractures observed on human cadavers.

Introduction

Thoracic injuries rank second, after head injuries, among the causes of fatalities or of severe impairment of vital ability in traffic accident victims. Injury criteria are needed to design protective devices and to evaluate their efficiency. In a recent review of biomechanical research, Aldman(1) defines such injury criteria as follows: they are a mechanical variable, or a group of mechanical variables, whose value enables an estimation of the injury risk for the considered body segment, for the road user submitted to an impulsive mechanical sollication similar to those found in traffic accidents. Numerous epidemiological and experimental studies have tried to better know the thoracic tolerance to impact and to define a corresponding injury criterion. The use of human cadavers as experimental subjects has spread these past years in the various laboratories involved in the research, maybe because of the problems resulting from the use of other substitutes, such as animals (involving scientific, ethical, and financial problems). This human substitute is thought to be reliable since it reproduces the anatomy of the living human accurately: therefore, there is practically no scaling problem. Besides, the human cadaver is considered to be more fragile than the living human from the point of view of resistance to injury; this means that protective devices defined from criteria based on the cadaver should

be all the more efficient for the living human. However, the reserves and recommendations made, among others, by some specialists in this field(3) and that are related to the limits of validity of cadaver data tend to be dropped. Everyone knows that a cadaver has no muscular activity, its blood does not flow, its heart does not beat, and its brain does not work. But the only corrective parameters that are presently included in data processing are age and weight.

In the discussion opposing the tenants of either deflection or force or acceleration as a physical variable to be measured to estimate the injury risk, there is a tendency to forget a main point which is the variety of injury mechanisms, to keep a sole lesion only which is the number of rib fractures. However, there are some arguments in the clinical and in the biomechanical fields as well to carry things further. The objective of this paper is to debate some of these from the analysis of accidentological data and preliminary results obtained from experiments performed in our laboratory.

Particularities of Thoracic Anatomy

The body segment concerned in this paper is thorax in the wide meaning of the word, i.e., the thoracic cage and its internal organs, including liver and spleen, which are sheltered behind the grid provided by ribs. The thoracic vertebral column is excluded from our discussion. The sketches of Figure 1 show how the various intra-thoracic organs are arranged in relation to the bony structure. It is important to notice the respective positions of the different organs and also the external and internal size of the thoracic cage. The space between the anterior face of dorsal vertebrae and the posterior face of sternum accounts for about 46 percent of the anterio-posterior diameter at the mid-sternum level. At the upper third, this space is only 39 percent; and at the lower third, it widens up to 48 percent. In other words, when the thorax sustains a frontal impact inducing a deflection of about 45 percent, the sternum comes into contact with the vertebral column. For an external diameter of 22cm, this deflection is about 10cm. It is also noted that the heart and major vessels are located in the median zone comprised between the sternum and the column, where the space is the most reduced.

Overview of General Injury-Producing Mechanism

During a traffic accident, since the trunk has a certain kinetic energy, it comes into contact with a more or less hard obstacle that applies on the thoracic wall a force that tends to crush the chest. This force opposes the inertia of masses in motion, fluid or solid, the elasticity of structures that are compressed, and their viscous resistance to rate of motion. Within the organs, this force induces various stresses (tensile, compressive, shearing, twisting) that can locally overrun the strength of tissues and hence produce injuries.

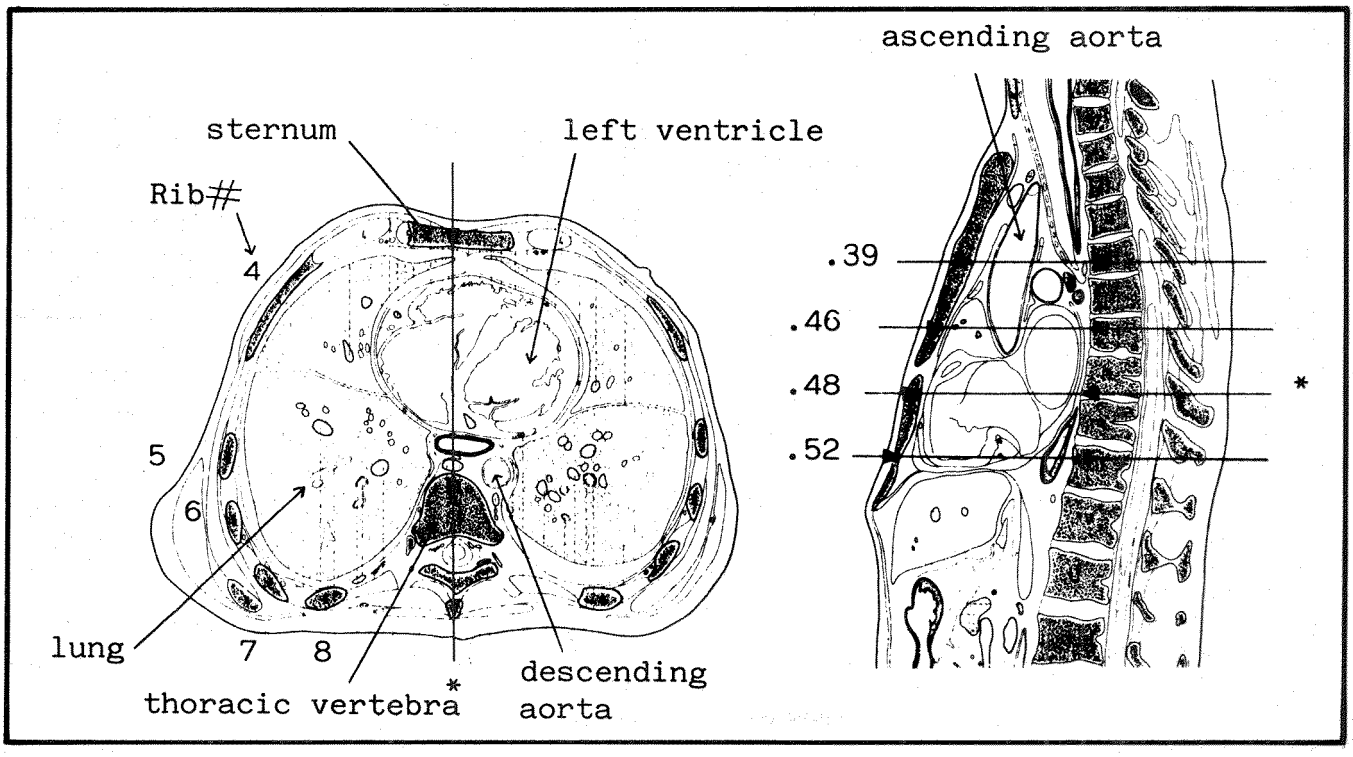

Figure 1. Transverse (left) and sagittal (right) sections of a human thorax

Schematically, during a frontal impact against the sternum, the first event is the initiation of the anterior wall motion. Then, once the speeds of both the thoracic wall and the impactor are equalized, the wall begins to deflect. This flexion mainly applies a bending stress to the ribs but also makes them rotate downwards about the axis of the costo-vertebral joint. The bending stresses can exceed the resistance of ribs, which break. According to the degree of crushing, intra-thoracic organs, especially the heart and the major vessels, are then compressed. The fluids inside them are flown out to other places, which opposes the compression through their inertia and the resistance of the vessels to the flow. Once the cavities are completely collapsed, the walls of organs are subsequently submitted to compression, which they resist by their elasticity and viscosity. But these organs may also be pushed aside in the adjacent cavities. Then they compress the adjoining organs and especially exert stretchings on their attachments up to rupture. The phenomenon is slightly different in the case of lateral impact since the viscerae are not jammed between two hard structures. The heart is perhaps better protected than in the case of frontal impact. Since not all organs have the same mechanical properties, the same mass, they behave differently. When observing inside motions through high speed x-rays(5,6), it can be seen that the heart behaves like a solid (few deformations and large motions), whereas the liver is more comparable with a fluid (large deformations, small motions). The intra-thoracic organs may also be submitted to stresses resulting from remote impacts, for example, at the abdominal level. In this case, the mechanism can be the intrusion of abdominal organs, which push thoracic organs up, and the propagation of a pressure wave.

Typology of Thoracic Injuries in Real Accidents

Injuries sustained by victims of a thoracic trauma in a traffic accident have largely been described in surgery and traumatology journals. Special synthesis reviews have been issued(7) and the case study from Huelke(8) gives a survey of possible injuries. Without entering into all the details, it seems necessary to underline some points of importance for the following discussion.

It is well established that rib fractures are found in nearly all cases. Their severity is related to their consequences on the respiratory function, which is altered if fractures are numerous and, above all, if they constitute an unstable flap preventing the normal expansion of the rib cage. When the fracture is open, it may result in organs being punctured subsequently to a very large local deformation. On the whole, however, the severity of rib fractures remains limited, thanks to techniques of respiratory aid now available.

The severity of the thoracic injury lies mainly in heart wounds and ruptures of major vessels. Among lesions resulting in an immediate death (before admission to the hospital), according to Gilroy(9), wounds to the heart and to main thoracic vessels are fatal in 57 out of 144 cases (34 aorta ruptures, 16 ruptures of the myocardium, and 7 of other vessels). Similar results are found in results of autopsies made by Sivard(10) of 100 road victims who died before admission to the hospital: 32 fatal lesions were of intra-thoracic origin. Liver and spleen lesions, such as laceration, tearing, or rupture, are severe because they produce hemorrhages— often profuse.

Other lesions, less impressive since they do not lead to large structural damages, may severely impair the functional ability. Disturbances of the heart electric conduction, such as fibrillation or block, are fatal if they are not attended very rapidly(11). Diffuse lesions of the lung parenchyma corresponding to ruptures of air-cells or pulmonary lobules are characterized by the parenchyma being flooded by a blood/air mixture. Depending on their size, these lesions prevent exchanges between blood and air and prove to be much more severe than macroscopic bronchial ruptures or lung lacerations, which are easier to detect and to treat(12). They often are only suspected when there is no indication for a surgical operation to treat a macroscopic lesion.

But the main point with respect to the present discussion is the association of visceral lesions with bone lesions, especially rib fractures. When an accident victim sustains a large number of rib fractures, there often is an underlying endo-thoracic lesion, either because broken pieces of ribs have perforated the tegument of an organ or, more simply, because the thoracic internal organs have been extensively compressed.

But this relationship is far from following an absolute rule: deep crushes of the costal grid without visible underlying lesion can be observed. On the contrary, the thoracic impact may produce very severe injuries to internal organs without any fracture or with a few. For example, among the 27 cases of immediate death reported by Sivard(10), which show 34 lesions of the heart and major vessels, 7 are mentioned without fracture. Out of 35 fatal wounds or ruptures of the liver, 19 are associated with fractures but 16 are not. Similarly, Chesneau(13) reports that out of 7 ruptures of the aorta, 3 are not associated with any fracture. Out of 10 nonfatal cases of rupture of the aorta isthmus reported by Caillard(14), 7 are without fracture.

What is true for vascular lesions applies also to lung parenchyma lesions. In a case report of 73 severe thoracic-injured admitted to the hospital with multiple rib fractures and/or a thoracic visceral lesion (AIS $\geq$ 3), Anselmet(15) notes that below 7 rib fractures, there are as many cases with visceral lesions (hemo and/or pneumothorax) as cases without lesion. As concerns the upper abdominal viscerae and depending on various authors,

only 10 to 30 percent of the lesions of the liver and spleen are associated with fractures of respectively right and left lower ribs(15,16).

Rib fractures, then, are neither a necessary nor a sufficient factor to involve severe intra-thoracic lesions. The absence of fracture is especially obvious in young subjects, whose ribs are much more flexible than older subjects.

Within the frame of using the number of rib fractures as an indicator of the severity of intra-thoracic and upper abdominal injuries, it would be necessary to establish relationships likely to exist between bone fractures and visceral lesions from the analysis of injury associations in real accident victims.

Topology of Injuries Produced Experimentally

Experimental works are necessary to evaluate human tolerance, and to establish injury criteria for accidentological surveys does not provide accurate characteristics of the input signal, and variation sources are too numerous. For obvious reasons, traumas can only be studied with substitutes of the living man. This is why many experimental studies have used human cadavers as a model. The injuries reported in most studies carried out with cadavers are rib fractures. In frontal impact and with a 3-point belt or in accident reconstruction, there is never or almost never intra-thoracic lesions(17,18, 19,20,21). On the other hand, the number of rib fractures is always higher in experimental subjects than in real accident victims as shown by accident reconstructions(22) or by the estimation of the input signal applied to real accident victims(23). This difference is due mainly to the age of the subjects available and also to their state of health before death. Impacts with a rigid striker result either in lesions to intra-thoracic viscerae(24,25) or in no lesion(26,27). In any case, a visceral lesion without a bone fracture is never reported. Moreover, when these lesions exist, they are not described accurately enough to allow a comparison with injuries sustained in real accidents. (Are lacerations of the aorta produced experimentally comparable with ruptures of the aorta sustained by real accident victims?) It is rarely a point of discussion to know whether injuries are of the same type; only injury severity levels are compared through injury codings (AIS, MAIS, etc.).

From all these attempts to evaluate thoracic tolerance, two main points can be drawn out:

- The injuries cadavers are likely to show are rib fractures. Visceral lesions are not frequent and do not necessarily correspond with those found in real accidents.
- Results are very different from one subject to another and the number of rib fractures depends mainly on the experimental subject's individual characteristics.

When these results are compared with real accident data, the validity of an injury criterion based on the number of rib fractures only, even with age compensation, may be questioned.

Static Mechanical Resistance of Thorax

A protective purpose is often implicitly devoted to the thoracic cage toward the organs it shelters. This is perhaps true when the released energy is low. In fact the statical force that can be opposed to a frontal compression is due mainly to the ability of inter-costal muscles to prevent the rotation of ribs around the costo-vertebral joint. In volunteers, this force is limited to a few hundreds of Newtons for a maximal deflection of 3 to 4cm(17,28,29). The stiffness calculated for these solicitations remains nearly constant and is of about 100 to 150N/cm.

In unembalmed cadavers, the first rib fracture occurs at about 1,500 to 1,800N for a deflection of 5 to 6cm(17). During this experiment, deflection values of 10 to 11cm (i.e., 38 to 49 percent) were reached for a force of 3,700 to 5,000N, resulting in multiple fractures (see Figure 2). Unfortunately these data are incomplete: the loading curve and also the deflection values at which fractures occurred (except the first one) are unreported as well as what happens if the force exceeds 5,000N. From the tests performed at our laboratory (full results to be issued later), the resistance of an isolated rib for a 53-year-old male varies from 35 to 95N, depending on the costal level, for a deflection of about 1.2 to 4.3cm (see Figure 3 and Table 1). These data are similar to those from Schmidt(19). Ultimate force values vary because of the different loading procedures used, but the bending moments are similar. Assuming that in a frontal compression 10 pairs of ribs are loaded at the same time, the maximum resistance provided by the rib cage alone cannot exceed 600N, with a stiffness of about 200N/cm, in a plane parallel with the ribs, i.e., in a direction of 45° relatively to the direction of compression. If inter-costal muscles oppose the rotation, as stated by Kroell(24), the total normal resistance settles at about 900N (see Figure 4), and it must decrease when fractures occur. The force of several thousands of Newtons that resists to the penetration of the impacting object, such as safety belt, steering column, or dashboard, does not come from the resistance of the rib cage but from the compression of intra-thoracic organs (elasticity, load losses in fluid motions, and inertia).

Dynamic Behavior of Thorax

When analyzing what occurs in a frontal impact with belt restraint, for example, the impact object, i.e., the

Table 1. Mechanical parameter values at failure for a single costal ring

Costal ring number	Ultimate force (N)	Desplacement at fracture (cm)	Average stiffness (N/cm)
2	64.9	1.6	40
4	34.6	3.7	9.3
6	56.5	4.3	13.1

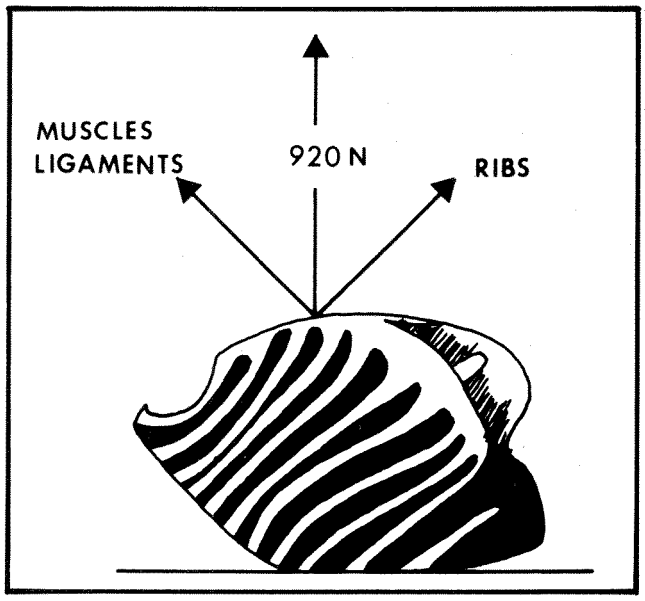

Figure 4. Maximal resistive force opposed by the ribcage (without internal organs) to a frontal static compression

belt, compresses the thoracic wall progressively. The ribs bend gradually and break depending on their specific deflection capabilities related to the costal level and the individual characteristics. Once the heart cavities and vessels are collapsed, the compression of walls and/or the forced displacement of these organs occur. It is most probably at this moment that the global thoracic stiffness increases. Force/deflection curves we established some time ago with pigs (see Figure 5) show this gradual stiffness increase(30).

For a cadaver in a similar situation (3-point belt, 45kph frontal impact, 20Gs mean deceleration), the compression force can reach 8kN whereas deflection is of 9cm (see Figure 6). Stiffness must tend toward an asymptote as the sternum comes into contact with the vertebral column, that is, for a 40 to 50 percent deflection. As soon as the sternum is stopped, there is no more deflection and hence no more rib fractures since these depend mainly on deflection. At this point, the extent of the damage to viscerae varies on the way the organs are either jammed between two hard bony structures or displaced into the

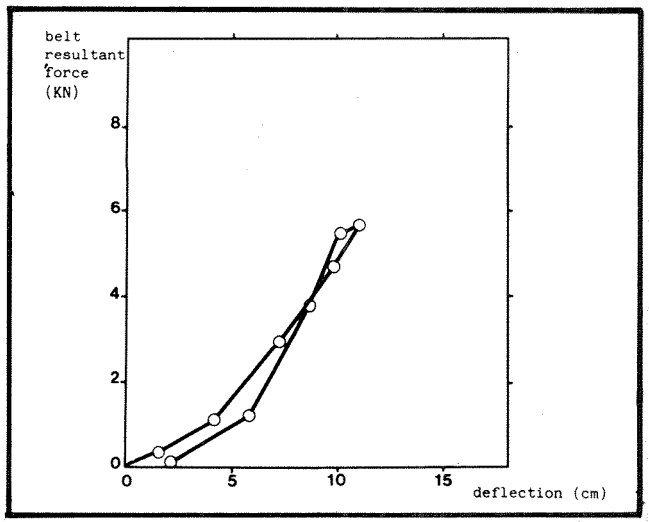

Figure 5. Load deflection curve of the thorax of a 35kg live pig submitted to a frontal impact with a 3-point belt at 45Kph. The stiffness progressively increases with deflection level(30)

side cavities. This explains why, over 40 percent penetration, a criterion based on sole deflection cannot accurately account for the severity of injuries—neither skeletal nor visceral.

In case of impact against a hard surface, the phenomena develop in a slightly different way, since, contrarily to the safety belt, there is a significant difference between the impactor speed and the thoracic wall speed. At the time of impact, an energy transfer occurs within a very short period considering the hardness of the contact. This transfer induces the wide peak of initial force(31) and injury mechanisms probably different from those induced by the safety belt. The fact is that the localization of rib fractures varies with the speed at which the thorax is compressed. But after the initial peak, if the remaining energy is still sufficient, the deflection goes on and shows a gradually increasing stiffness. The same phenomena as with the safety belt can then occur if the deflection is sufficient.

In lateral impact, mechanical phenomena are different since this stopping effect of the vertebral column does not take place. Possibilities of deflection are larger. Besides, force/deflection curves are different for frontal and lateral impacts.

Injury mechanisms are likely distinct, more related to large viscerae displacements. In this case, rib cage deflection, and hence rib fracture number, could account for tensile stress-related injuries; but the relationship between these two types of injury has to be established.

Besides, a series of studies conducted by Lau(32,33,34) on animals showed that visceral injury extent and severity are related to speed of compression, which, at first glance, does not apply to rib fractures.

So, to estimate the vital risk reliably, a thoracic injury criterion should not be limited to rib fracture number on

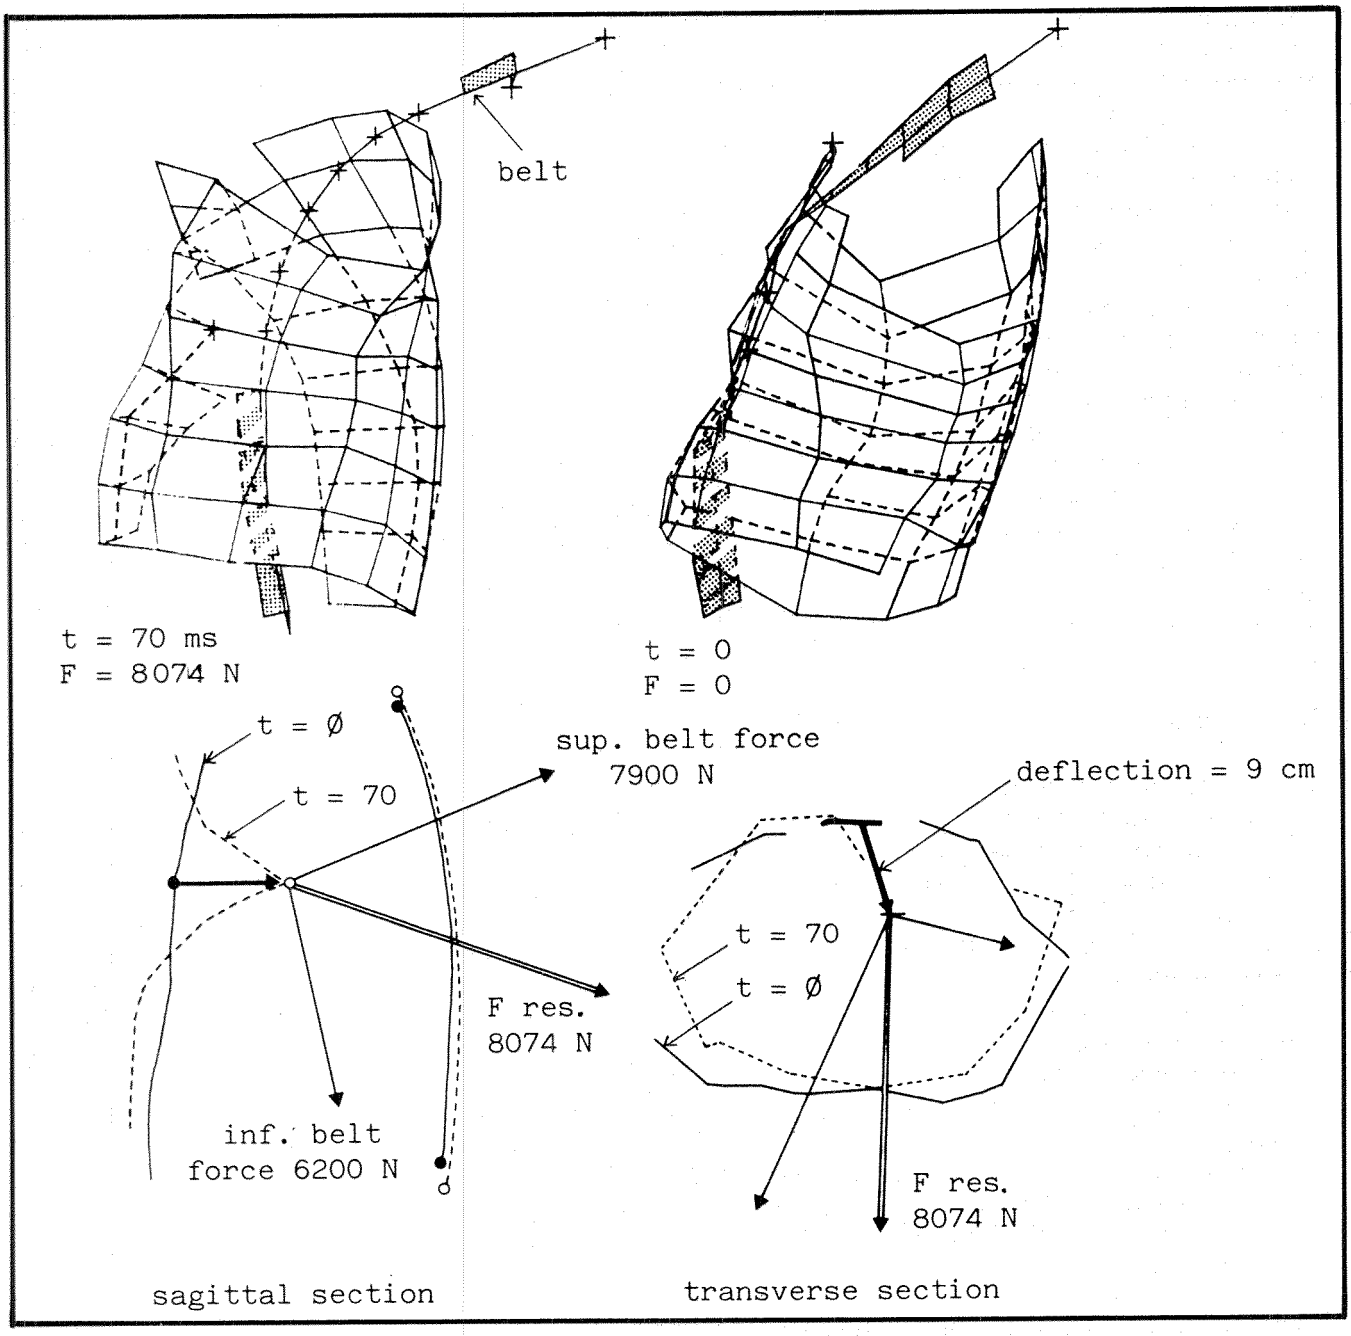

Figure 6. Frontal impact of a belted cadaver at 45kph

one hand, and should be based on more physical variables than the sole deflection level, such as speed of compression, force, and internal overpressure, for instance.

Conclusion

The injuries subsequent to an impact to the thoracic segment during a traffic accident affect the thoracic cage and the intra-thoracic and abdominal viscerae. Rib fractures are life-threatening only when they are very numerous and lead to a flailed chest or when they are open and perforate the walls of underlying organs. Lesions to the viscerae (heart, lungs, major vessels, liver, spleen), however, are nearly always severe and are responsible for a large number of fatalities. They represent the major threat to life.

A first analysis of accident logical data shows there is no relationship between the severity of visceral injuries and the number of rib fractures. This number is a factor neither necessary nor sufficient to involve a visceral lesion.

The experiments made with cadavers mainly produce bony lesions only. When visceral lesions occur, it is not clearly demonstrated that they are similar to injuries found in real accidents.

From a mechanical point of view, the resistance to compression offered by the rib cage is by far lower than the total thoracic resistance, which minimizes the protective purpose generally ascribed to the bony structure. What resists compression is elasticity, inertia, and viscosity of muscles, viscerae, and their contents. Moreover, in frontal compression, the deflection is limited to about 40 percent by the stop provided by the vertebral column. In these conditions, the number of rib fractures, which depends mainly on the bending stress these bones sustain, can only account for the injuries due to a similar mechanism, i.e., deflection.

Other lesions related to other physical variables are to be considered to estimate the vital risk.

The relevance of injury criteria based on the number of bony lesions observed on cadavers is then far from being valid.

Synthesis of Pelvic Fracture Criteria for Lateral Impact Loading

Mark Haffner
U.S. Department of Transportation, National Highway Traffic Safety Administration

Abstract

Two candidate functions for the prediction of pelvic fracture probability are created using lateral pelvic acceleration and age data from 84 cadaver impact experiments. These functions include measures of bone stress, bone strain, age, and load concentration factor. Data are analyzed using the maximum likelihood approach, and it is found that representation of the data by a Weibull distribution yields higher maximum likelihood than does the assumption of an underlying normal distribution.

Additional data are presented documenting pelvic force and acceleration responses for both cadavers and the Side Impact Dummy (SID). Systematic differences are noted and discussed.

Introduction

Lateral impact to the pelvis can result in injuries to the pelvic bone, to the hip joint, and to the soft tissue contents of the pelvic cavity. Bone fractures can occur at numerous sites on the pelvic ring: at the acetabulum, the sacro-iliac junction, the pubic symphysis, the pubic rami, and in the wing of the ilium. Within the pelvic cavity, fractures of the pelvis are associated with potentially severe injuries to the bladder and urinary tract.

Given this wide range of potential injury sites on the pelvic bone and within the pelvic cavity, it is most unlikely that a single parameter can be identified that is predictive of specific pelvic injury site and type. A more realistic goal, adopted here, is the identification of a parameter that is predictive of the occurrence of pelvic bone fracture, irrespective of fracture location.

In searching for a parameter predictive of pelvic fracture, we proceed on the assumption that a pelvic bone protection criterion will confer a large measure of protection on the contents of the pelvic cavity as well. Confirmation of this working hypothesis, however, remains for further study.

Data Resources

This analysis has drawn upon cadaveric lateral pelvic impact data from numerous sources. Table 1 presents a summary of these data resources and characterizes them by degree of applied load concentration, age range,

average age of cadavers tested, and other variables of interest.

It is important for our purposes to note several significant ways in which the ONSER(A) data set differs from the balance of the data base:

1. The average age of ONSER(A) cadaveric specimens is higher than the average age for most other data sets included.
2. Loading in the ONSER(A) series was directed to the limited area of the greater trochanter via a hemispherical rigid impactor, as distinguished from the other test series in which both the iliac wing and trochanter could be loaded by larger impact surfaces.
3. The experimental design of the ONSER(A) test series differs from that of the other test series included. The ONSER(A) series sought to identify fracture threshold for each specimen, by repeatedly testing each specimen at increasing impact severity until fracture occurred. By contrast, the other test series in the data base tested each specimen once at known impact severity, with either fracture or nonfracture reported as outcome.

The fact that a markedly different experimental design was employed in the ONSER(A) series as compared to the other test series strongly suggests that these blocks of data be separated for analysis and that distinct methods of analysis be applied to the two resulting subsets.

With regard to transducer data available, it can be noted from Table 1 that input force data are available only for the ONSER(A) and the Heidelberg test series. Some observations will be made shortly with regard to the relationship of input force to measured pelvic accelerations for these two data sets; however, it is clear from Table 1 that the only common thread available in all data sets is pelvic acceleration and that only the y (lateral) component of pelvic acceleration is available in all data sets.

With regard to data processing procedures, digital data tapes were obtained for all test series so that uniform data processing procedures could be applied to them. Following a quality control process using the "raw" data, all remaining force and acceleration data were filtered, subsampled, and refiltered[1] before being entered into the project data base for further analysis.

Previously Proposed Injury Predictive Parameters

Previous investigators have proposed both maximum applied force and maximum pelvic acceleration fracture criteria for lateral pelvic impact. Cesari, et al.(2) have proposed a 10kN (3ms clip) limit on impact force for a 76kg male and 4kN (3ms) for a 5th percentile female. These values are based on the data obtained from their older subject population. Also, these limits are associated with the specific concentrated trochanter loading protocol of the ONSER(A) cadaver tests. Tarriere et al.(9) conducted a series of lateral drop tests using cadaver subjects and reported pelvic fractures associated with resultant peak pelvic accelerations of 62 to 120g. Peak resultant pelvic accelerations associated with nonfracture ranged up to 135g. Harris(10) discussed the potential interaction during impact of lateral loadings acting on

1 Raw digital data were filtered with a 300Hz antialiasing Butterworth filter whose roll-off characteristics satisfied SAE J 211B. The data were then subsampled at 1,600SPS, and finally operated on with a finite impulse response filter with passband frequency = 100Hz, stopband frequency = 189Hz, passband ripple = 0225db, and stopband gain = 100db.

Table 1. Summary of data resources utilized in project data base

Organization	Description of Test Environment	Degree of Load Concentration on Pelvis	Number of Tests (Number of Fractures) male	female	Age Range male	female	Average Age male	female	Transducer Data Reported	References

the iliac crest and on the hip joint. A tolerance value of 6kN for the sum of both the iliac crest and trochanter forces was proposed for specific use with the TRRL side impact dummy.

The EUROSID dummy now under development(3) employs three force transducers in the pelvic segment: one at the anatomical location of the pubic symphysis, and upper and lower transducers at the anatomical location of the junction between the iliac wing and the sacrum. Selection of one or a combination of outputs from these transducers for injury predictive purposes has not been finalized. The pelvis is also designed to accommodate a triaxial accelerometer for use with acceleration-based pelvic injury criteria.

Formulation of New Predictive Parameters

As has been pointed out by Nuscholtz, et al.(11), the interactions of the femur, pelvis, and associated soft tissue during lateral pelvic impact are complex. A fundamental source of variability appears to exist in the anatomy of the hip joint because rotation of the femoral head in the acetabulum during impact is a relatively unpredictable function of (a) initial femur and pelvic bone geometry, (b) degree of entrapment of the proximal femur by the impacting surface, and (c) variations in soft tissue thickness and distribution. Nuscholtz et al. properly caution that a generalized injury predictive parameter may be difficult to identify. Notwithstanding the variability inherent in pelvic response and injury patterns, however, we have attempted to isolate some of the confounding factors and quantify the extent of variability remaining in the data.

In formulating new fracture predictive parameters, we have elected to pursue two parallel analysis approaches. The first approach (denoted Approach 1) utilizes maximum bone stress as a primary explanatory variable, and also considers specimen age, specimen sex, and degree of applied load concentration for inclusion in analysis. The second approach (denoted Approach 2) substitutes maximum bone strain for maximum stress in the predictive function.

A brief discussion of the rationale for consideration of these variables follows

1. Maximum Stress

Numerous solid material failure theories (e.g., maximum stress, maximum strain, maximum strain energy, maximum distortion energy, etc.) are available for application. For brittle materials, the maximum stress failure theory is generally favored. The maximum stress theory predicts failure when the largest principal stress reaches the uniaxial tensile or compressive failure stress. The efficacy of using a stress-related variable instead of raw applied force was suggested by Cesari(2). He hypothesized that many lateral pelvic fractures were linked to excessive bending stress in the frequently fractured pubic rami. In pursuing this hypothesis, he computed area moments of inertia of ilio-pubic ramus cross-sections (I_x) from undamaged portions of tested pelvic specimens, and successfully correlated fracture force (F) and (I_x) for fractured specimens (r = .96). The governing equation for simple bending is:

$$(1) \quad \sigma + \frac{M}{(I_x/y)}$$

σ = ultimate tensile stress induced by bending of ramus

M = applied moment

I_x/y = area moment of inertia of ramus divided by offset from neutral axis

The moment applied to each specimen M = (F)(d), where d is a characteristic moment arm. Therefore, the above expression can be written:

$$(2) \quad \frac{\sigma}{d} = \frac{F}{(I_x/y)}$$

The high linear correlation and near zero intercept reported by Cesari between F and (I_x/y) implies that:

$$(3) \quad \frac{\sigma}{d} \cong \text{constant}$$

If d is a weak function of subject size and sex, the hypothesis advanced is upheld.

In the present effort, we have found it useful to invoke the equal stress-equal velocity scaling law to treat the experimental data (hereafter called subject data). The equal stress-equal velocity scaling law for geometrically similar models assumes that both density and modulus of elasticity are invariant and that the following relationships follow between subject data and data scaled for a specimen of standard size and mass. If we define:

$$(4) \quad \frac{\ell_{sub}}{\ell_{std}} = \lambda$$

ℓ_{sub} = characteristic length of subject

ℓ_{std} = characteristic length of standard specimen

(5) then:

$$F_{std} = \frac{F_{sub}}{\lambda^2} \qquad \text{for force}$$

(6) $a_{std} = \lambda a_{sub}$ for acceleration

(7) $M_{std} = \frac{M_{sub}}{\lambda^3}$ for mass

Using (4) and (5):

(8) $$\frac{F_{std}}{(\ell_{std})^2} = \frac{F_{sub}}{(\ell_{sub})^2} \equiv S$$

Note in Equation (8) that the terms have units of force per unit area or stress, and thus that stress induced in the standard specimen and subject specimen are equal for the same test velocity (stress scales 1 to 1).

If, for convenience, we write equation (8) as:

(9) $$F_{std} = (S)(\ell_{std})^2$$

we can observe that F_{std} is a measure of subject stress, adjusted only by a constant $(\ell_{std})^2$

Thus we would propose $F_{std} = F_{sub}/\lambda^2$ as a measure of pelvic bone stress magnitude, which might have potential for fracture prediction.

For an isotropic specimen as assumed here:

λ is simply $\left(\frac{M_{sub}}{M_{std}}\right)^{1/3}$ from equation 7 and:

(10)

$$F_{std} + F_{sub} / \left(\frac{M_{sub}}{76}\right)^{2/3} \quad \begin{cases} M_{sub} \text{ in Kg} \\ M_{std} = 76 \text{ Kg} \end{cases}$$

In analogous fashion, using (6) and (7):

(11) $$a_{std} = \left(\frac{M_{sub}}{M_{std}}\right)^{1/3} (a_{sub})$$

Multiplying the right hand side of (11) by the quantity we obtain:

$$\frac{M_{sub}}{M_{sub}} = \text{unity}$$

(12) $$a_{std} = \left(\frac{1}{M_{std}}\right)^{1/3} \frac{(M_{sub}\ a_{sub})}{(M_{sub})^{2/3}}$$

The quanity $M_{sub}\ a_{sub}$ has units of force, and $M_{sub}^{2/3}$ can be expressed as:

$$[\rho_{sub}\ \ell_{c_{sub}}^3]^{2/3} = (\rho_{sub})^{2/3}\ \ell_{c_{sub}}^2$$

where ρ_{sub} is subject density and $\ell_{c_{sub}}$ is a characteristic subject length.

Thus:

$$a_{std} \approx \frac{1}{M_{std}^{1/3}\ \rho_{sub}^{2/3}} \left(\frac{F_{sub}}{\ell_{c_{sub}}^2}\right) \quad (13)$$

Since M_{std} is a constant and ρ_{sub} is also invariant, equation (13) is of the form:

$$a_{std} = (\text{constant})(\text{stress}) \quad (14)$$

We thus propose $a_{std} = \lambda a_{sub}$ as an alternative measure of pelvic bone stress. For an assumed isotropic specimen, Equation (11) may be used with $M_{std} = 76$kg to yield:

$$a_{std} = a_{sub} \left(\frac{M_{sub}}{76}\right)^{1/3} \quad \{M_{sub} \text{ in Kg} \quad (15)$$

The above approach to the determination of λ does not, however, take into account variation in subject build; i.e., a short, stocky specimen and a tall, thin specimen each of equal mass would each yield the same λ. The following method is proposed to improve the estimation of λ when subject height and mass are known.

The body is considered as a cylinder of mass M, density ρ, height H, and diameter D. The diameter of a subject may be estimated as:

$$D_{sub} = 2 \left(\frac{M_{sub}}{\pi \rho_{std} H_{sub}}\right)^{1/2} \quad (16)$$

Similarly, the diameter of the standard specimen is:

$$D_{std} = 2 \left(\frac{M_{std}}{\pi \rho_{std} H_{std}}\right)^{1/2} \quad (17)$$

Then since $\rho_{sub} = \rho_{std}$

$$\lambda = \frac{D_{sub}}{D_{std}} \left[\left(\frac{M_{sub}}{M_{std}}\right)\left(\frac{H_{std}}{H_{sub}}\right)\right]^{1/2} \quad (18)$$

For $M_{std} = 76$ Kg and $H_{std} = 1.75$ m:

$$\lambda = \left[\left(\frac{M_{sub}}{76}\right)\left(\frac{1.75}{H_{sub}}\right)\right]^{1/2} \quad \begin{cases} M_{sub} \text{ in Kg} \\ H_{sub} \text{ in m} \end{cases} \quad (19)$$

and using (5):

$$F_{std} = \frac{F_{sub}}{(M_{sub} / 76)(1.75 / H_{sub})} \quad (20)$$

In analogus fashion, using (19) and (6):

$$a_{std} = \left[\left(\frac{M_{sub}}{76}\right)\left(\frac{1.75}{H_{sub}}\right)\right]^{1/2} (a_{sub}) \quad \begin{matrix} M_{sub} \text{ in Kg} \\ H_{sub} \text{ in m} \end{matrix} \quad (21)$$

Implementation of Equations (10) and (15) is denoted scaling method A. Implementation of Equations (20) and (21) is denoted scaling method B. Both methods have been used for processing subject data; results will be presented below in the Analysis section.

Since bone is a viscoelastic material, bone stress may be considered to be a function of both strain and strain rate. The strain rate dependence of bone has received considerable research attention. Evans(12) reports the experiments of McElhaney and Byars (1965) and McElhaney (1966). The experiments conducted were constant velocity compression tests on cattle and human femoral bone. At strain rates exceeding 1cm/cm/s, the investigators found that ultimate compressive stress and modulus of elasticity increased while strain at fracture decreased. (Ultimate compressive stress at 1cm/cm/s was 22 percent greater than at .01cm/cm/s; ultimate strain decreased 31 percent.

A lateral pelvic deflection of .5cm (.2in) in 20ms would correspond to a strain of approximately 2 percent and a strain rate of approximately 1.1cm/cm/s. Thus, it appears likely that the pelvic bone exhibits significant rate sensitivity in the automotive crash environment. The inclusion of strain rate sensitivity in a pelvic fracture model is, therefore, desirable.

2. Maximum Strain

A maximum strain failure criterion is also a likely candidate for consideration. In the present application, maximum strain will be calculated via a lumped parameter pelvic model as discussed under Approach 2 below.

3. Age Effects

Evans(12) reports the data of Messerer (1880), who investigated the static bending strength of fresh cortical bone specimens from the tibia, femur, and humerus of male and female subjects. Ultimate bending stress increased to a maximum in the range of 20 to 30 years of age and declined steadily thereafter. The ratio of male femur ultimate bending stress at 75 years of age to that at 24 years of age is approximately .81; the corresponding ratio for females tested was .85. Yamada(13) cites data for static bending of fresh cortical bone and reports maximum ultimate bending stress occurring for specimens in the range 20 to 40 years of age, with strength declining thereafter. The ratio of ultimate bending stress reported at 70 to 79 years of age to that at 20 to 29 years is .80.

Thus, it is concluded that age effects upon probability of pelvic bone fracture are significant and should be incorporated into our pelvic fracture model.

4. Sexual Differences

In the bending data of Messerer reported above, sexual differences in ultimate bending stress can be assessed. The ratio of female ultimate bending stress to male ultimate stress for a given age range is approximately .90 for the femur and 1.0 for the tibia. Yamada reports no significant sexual differences in compressive strength or bending strength in samples of cortical bone.

The absence of significant sexual difference in ultimate bending stress suggests strongly that the lower pelvic fracture forces reported by Cesari(2) for females as compared to males is largely due to smaller female pelvic bone cross-sectional areas. As was discussed earlier, when Cesari normalized the male and female fracture forces in terms of a measure of stress, the male and female data were observed to overplot.

Therefore, it is tentatively concluded that the use of a stress-related variable should permit male and female data to be merged for analysis.

The possibility exists, however, that the scaling laws we are proposing will not fully accommodate the differing pelvic geometries of male and female specimens. (The scaling law requires geometric similarity.) It is therefore proposed that the extent to which male and female data does overplot be observed before reaching a conclusion on the suitability of this scaling approach.

5. Degree of Load Concentration

The pelvic load concentration factor has been mentioned as an important potential influence upon fracture potential.

It may be recalled that two main load paths exist into the laterally impacted pelvis, through the acetabulum via the trochanter and through the iliac wing. The ONSER(A) data can be considered as defining the pelvic fracture tolerance for the trochanter load path. However, in the balance of the experimental data (and presumably in the vehicle environment), load is transmitted in some proportion through both paths. A pelvic accelerometer cannot distinguish which load path or paths are active but responds to net applied force. Thus, pelvic accelerations as measured from the ONSER(A) experiments should not be interpreted in the same way as pelvic accelerations measured in distributed load experiments.

A simplified schematic drawing illustrating this point is shown in Figure 1. The pelvis is shown assumed as a rigid body of mass M with crushable elements at the trochanter and iliac wing locations. Let us say that we know the "trochanter" will fail at force F_1, and that the "iliac wing" will fail at some force F_2. For argument, we will assume that these failures are independent. In case (a) similar to the ONSER(A) configuration, we would associate acceleration F_A/M with pelvic fracture. In case (b), where the iliac wing carries external load, we would associate pelvic acceleration $(F_A+F_B)/M$ with the same fracture. Clearly, the nature of load distribution is a significant input to the interpretation of an acceleration-based pelvic fracture criterion.

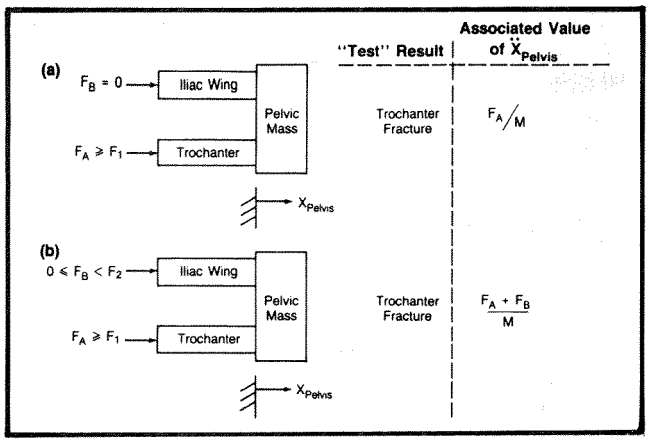

Figure 1. Schematic illustration of concentrated and distributed lateral pelvic loading

Summarizing our discussions relative to candidate parameters for inclusion in our fracture predictive function, it is postulated that probability of pelvic fracture is a function of the following variables:

1. A stress measure as quantified by a standardized (scaled) peak applied force or standardized (scaled) peak pelvic acceleration (Approach 1)
2. A strain measure as quantified by the output of a lumped parameter model (Approach 2)
3 Age of specimen
4. Degree of applied load distribution (concentrated or distributed)

Data Analysis and Results

Before proceeding with the analysis, it is of interest to look at the relationship between recorded force and acceleration for the limited number of ONSER(A) and Heidelberg tests in which both were recorded. (Only the lateral component of force F_y was measured. Also, only the y component of acceleration was utilized in analysis because (a) a_y is the only measurement available in all of the data, and (b) incorporation of resultant acceleration into the analysis was investigated and shown to yield no significant improvement in predictive capability.)

Typical overplots of force and acceleration traces from the ONSER(A) series are shown in Figures 2 and 3. (Note that the peaks of the force traces have been artificially scaled to match the peaks of the acceleration traces so that trace shapes can readily be compared.) As may be observed, there is lag in acceleration response initially, but force and acceleration peaks tend to coincide in time. Substantial differences exist, however, in the shapes of force and acceleration traces during the unloading phase.

Figure 4 shows the relationship between peak force and peak acceleration (scaled according to method A) for the 11 ONSER(A) tests in the data base for which both signals are available. The good correlation observed (r = .89) suggests that if (as has been proposed by Cesari) an injury criterion can be developed using peak applied force, then it should be possible to use pelvic acceleration to construct a similar predictive function.

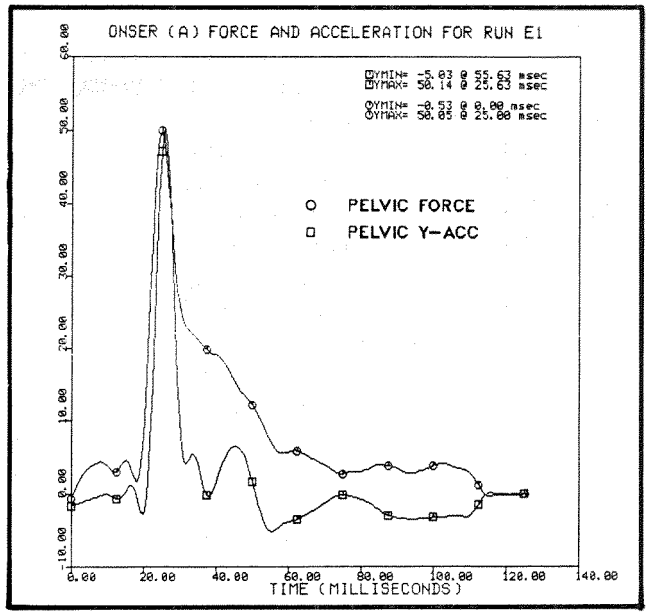

Figure 2. Pelvic force and pelvic Y-acceleration overlay for ONSER (A) test E1

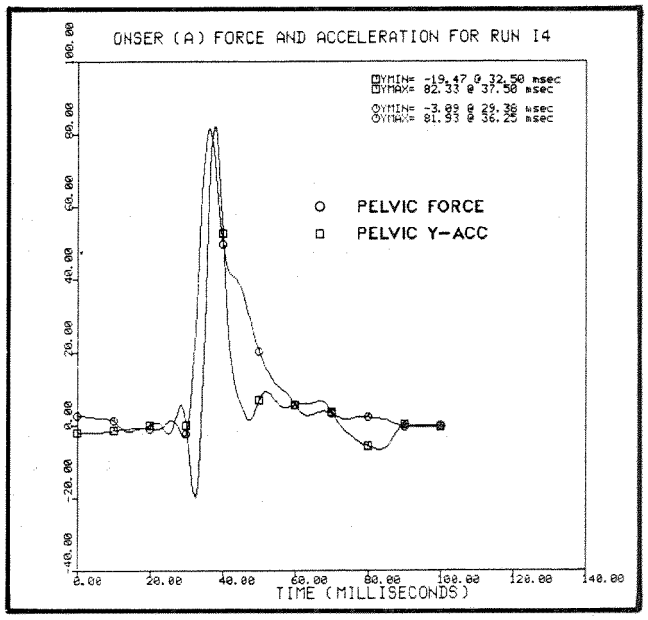

Figure 3. Pelvic force and pelvic Y-acceleration overlay for ONSER (A) test I4

Figures 5 and 6 present analogous overplots of force and acceleration for two Heidelberg tests—one rigid and one padded. The interesting and typical differences observed between these two tests will be discussed further in Appendix B, but for the moment we can observe that peak force and peak acceleration again tend to coincide in time. Figure 7 presents peak-scaled force vs. peak-

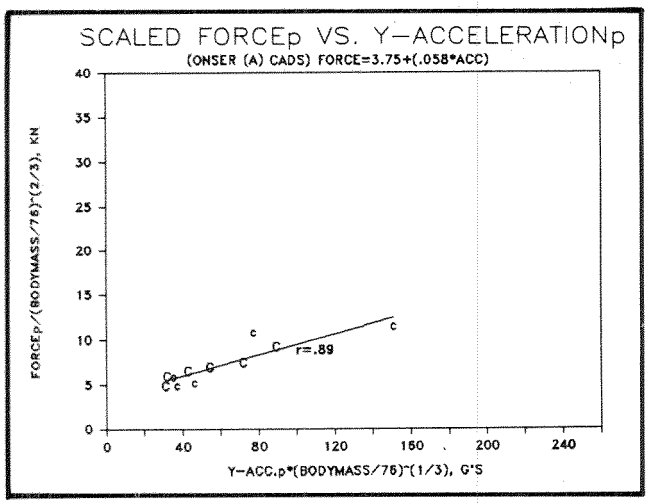

Figure 4. Scaled peak pelvic force versus scaled peak pelvic Y-acceleration for ONSER (A) tests

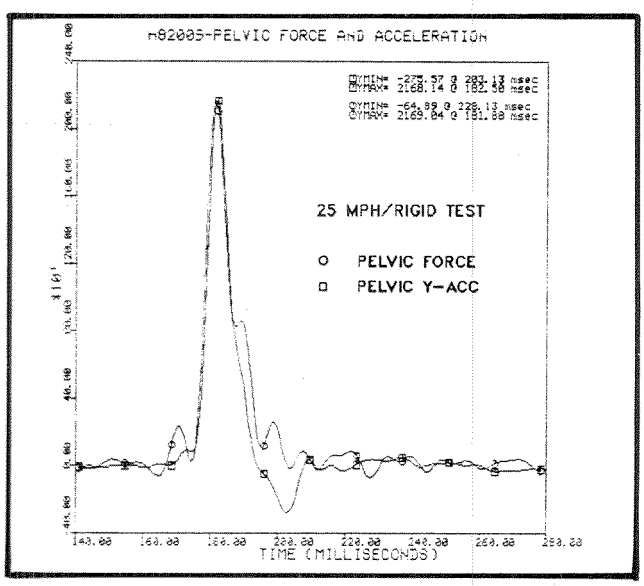

Figure 5. Pelvic force and pelvic Y-acceleration for Heidelberg test H82009

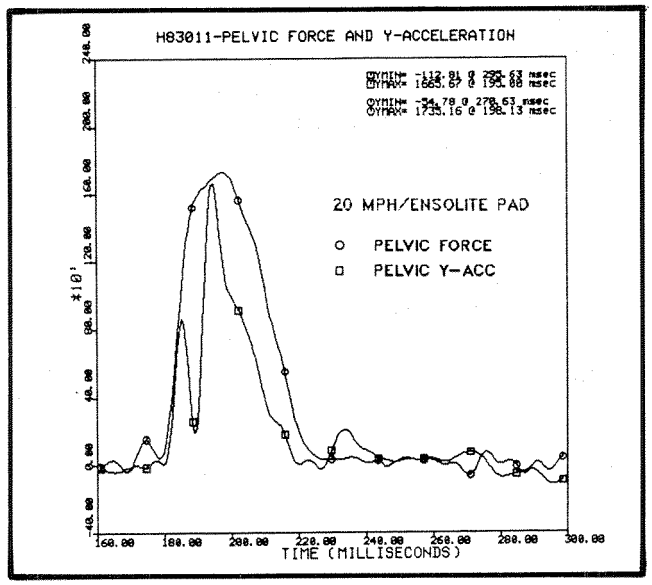

Figure 6. Pelvic force and pelvic Y-acceleration for Heidelberg test H83011

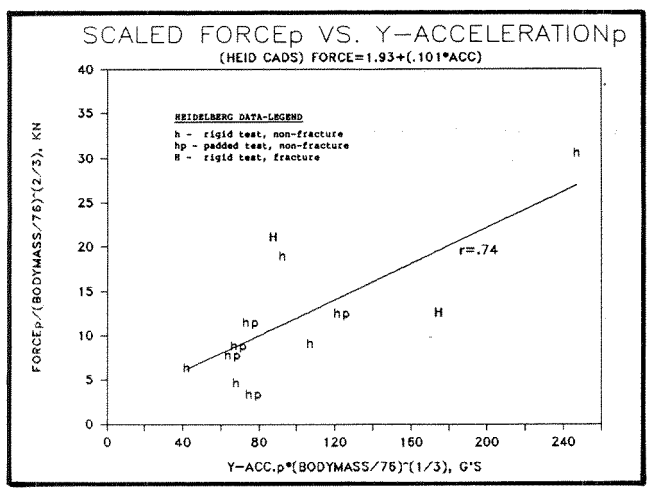

Figure 7. Scaled peak pelbic force vs. scaled peak pelvic y-acceleration for heidelberg tests.

scaled acceleration for available Heidelberg data. Correlation between them is not as high (r = .74) as the correlation found for the ONSER(A) data.

In general, it has not been possible to utilize force data to construct a predictive function from the non-ONSER(A) data. This is because excluding the ONSER(A) data, the number of cases of fracture for which force data is available is very small (0 male, 2 female). In any case, the force data as measured from the Heidelberg tests would not be comparable to the ONSER(A) force data, since the measured Heidelberg forces were applied via a large contact plate that spanned the pelvis and thigh.

As has been discussed, the ONSER(A) data have been separated from the other available data (see Table 1) for purposes of analysis. Analysis thus concentrated on the use of acceleration data as obtained from the Heidelberg, FAT, ONSER(B), and HSRI data sets.

Heidelberg, FAT, ONSER(B), and HSRI Data—Approach 1

The stress variable $a_{std} = (a_{subp})(\lambda)$ is plotted in Figure 8 against age, where we recall from Equation (19) that:

$$\lambda = \left[\left(\frac{M_{sub}}{76}\right)\left(\frac{1.75}{H_{sub}}\right)\right]^{1/2} \quad \begin{cases} M_{sub} \text{ in Kg} \\ H_{sub} \text{ in m} \end{cases}$$

and where a_{subp}, M_{sub} and H_{sub} are the peak y pelvis acceleration, body mass, and height for each test.

In Figure 8, each nonfracture test is plotted as a dot, while each fracture test carries the initial of its source according to the following code:

H—Heidelberg
B—ONSER(B)
F—FAT
S—HSRI

Based on the known decrease of ultimate bone strength with age presented earlier, a series of lines are drawn on Figure 8 with slope m = $-0.5g/_{yr}$ corresponding to a 20 percent reduction in ultimate stress between the ages of 24 and 75 years. It is then postulated that the zone between each pair of lines represents a region of nearly constant fracture probability. Since the equation of each line is of the form:

(22) $(a_{subp})(\lambda) + (.5)(age) = constant$

we further postulate that:

Probability of Pelvic Fracture
$= f[a_{subp} * \lambda + (.5)(age)]$

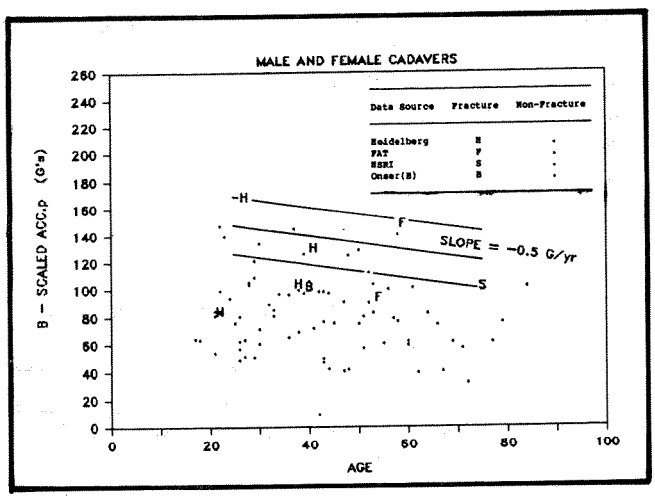

Figure 8. B-scaled acceleration versus specimen age—distributed load data

Since the data being considered are quantal or "censored," as defined by Ran et al.(14), we have applied the maximum likelihood approach discussed there, and have adopted a Weibull distribution as representative of the data. Figure 9 represents the result of analysis of the available distributed load data. For any selected fracture probability and age, a "tolerable" value of peak B-scaled acceleration = $a_{std} = \lambda a_{subp}$ can be read from the figure. For example, for a selected 20 percent probability of pelvic fracture at 40 years of age, we may find a_{std} = 143g. Similarly, for 10 percent fracture probability and 40 years of age, a_{std} = 103g. These "standard" values, we may

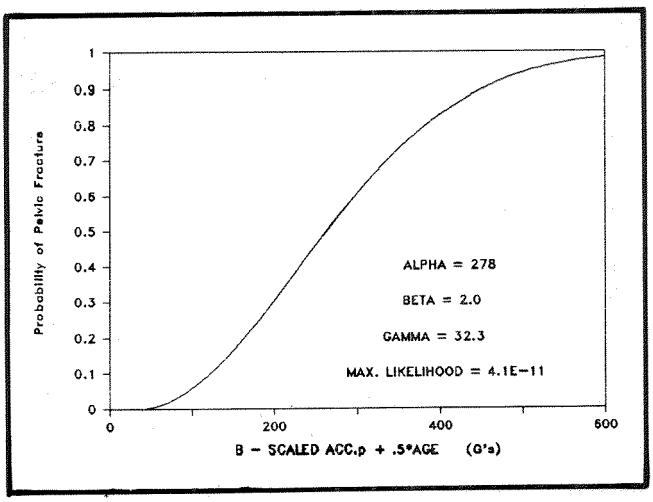

Figure 9. Probability of pelvic fracture from Weibull analysis of distributed load data—approach 1

recall, are for a specimen of mass = 76kg and height = 1.75m.

We may also note on Figure 9 the values of α, β, and γ as computed by the Weibull program for best fit to the data, and the maximum likelihood number of 4.1×10^{-11} associated with this computation. Figure 10 presents the computed probability density function. The fact that this function is not symmetrical confirms that the underlying distribution is not normal. However, we found it of interest to impose normality upon the data, observe the results, and compare them to the Weibull computations. (A probit analysis program was used for normal distribution computations.)

This comparison is presented in Figures 11 and 12, where it may be clearly seen that the Weibull distribution is right-shifted as compared to the normal distribution. Also of interest is the fact that the maximum likelihood number calculated for the imposed normal distribution

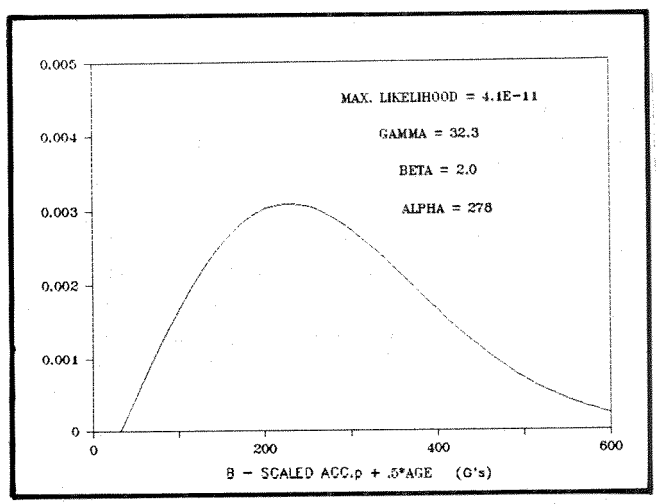

Figure 10. Weibull probability density function associated with Figure 9

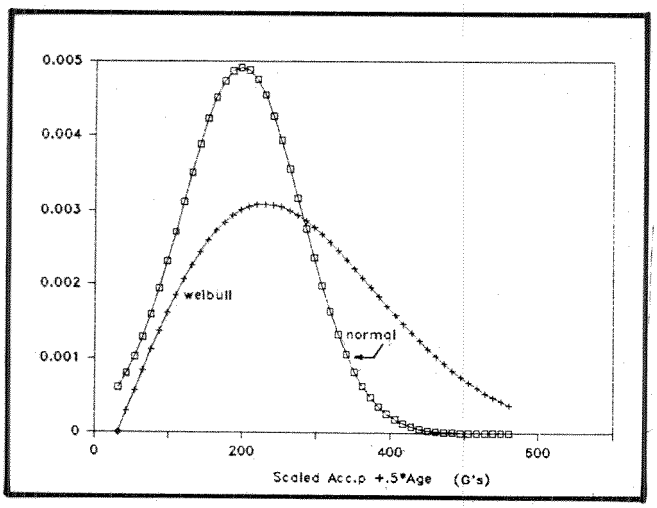

Figure 11. Comparison of Weibull and normal probability density functions calculated

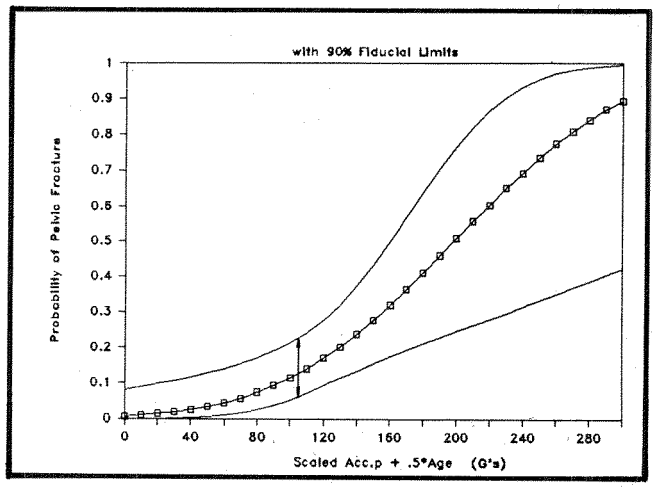

Figure 13. Fiducial limits on probability of pelvic fracture as computed from imposed normal distribution

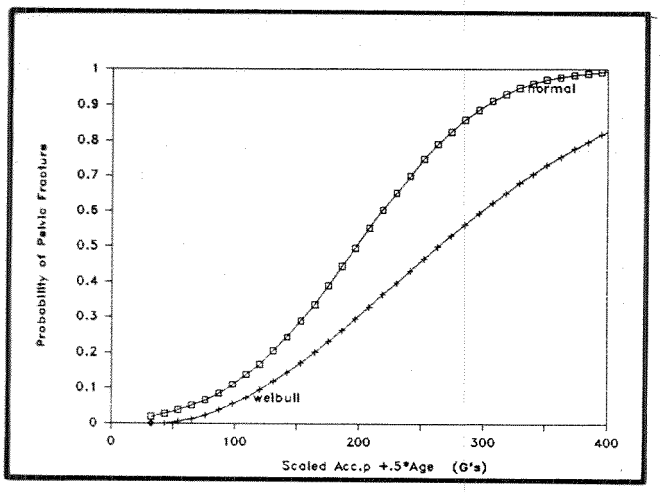

Figure 12. Comparison of pelvic fracture probabilities computed from Weibull and normal distributions—distributed load data—approach 1

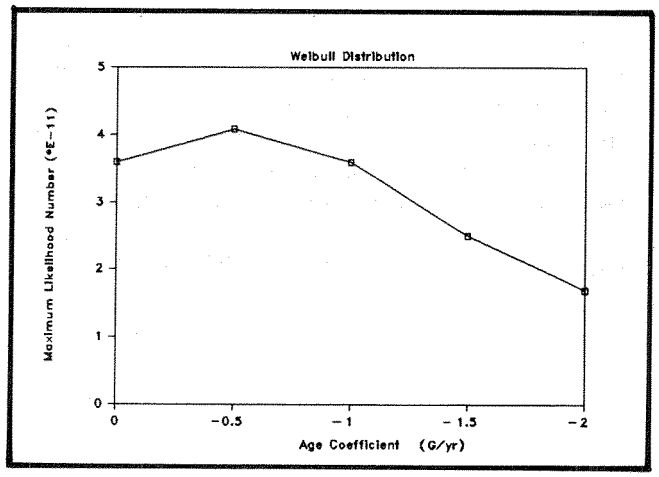

Figure 14. Maximum likelihood number versus age coefficient—Weibull analysis—approach 1

was 6.0 x 10^{-16}, lower than that for the Weibull computation, indicating that the Weibull function provides a better fit to our data.

With regard to confidence intervals, the algorithm for their computation is not presently available for the Weibull distribution. However, 90 percent fiducial limits have been computed for reference for the normal distribution assumption and are provided in Figure 13.

Further, as a check that the value of the coefficient on age m was correctly deduced as -0.5, a series of Weibull fits to the data were run for m = 0, -0.5, -1.0, -1.5, and -2.0. As indicated by Figure 14, maximum likelihood did indeed occur for m = -0.5, thus providing support for our selection process for m.

Heidelberg, FAT, ONSER(B), and HSRI Data—Approach 2

Approach 1 above operates on maximum pelvic acceleration as a measure of maximum stress. The utility of this approach tends to be limited, however, by the variability inherent in the measurement of a peak quantity. In Approach 2, a straightforward scheme was sought that would minimize dependence on this peak measurement. Toward this end, a lumped parameter one dimensional linear model was constructed as shown in Figure 15. Mass M_1 is associated with struck side upper leg mass, and M_2 is associated with the "pelvic mass" upon which the pelvic accelerometer is attached.

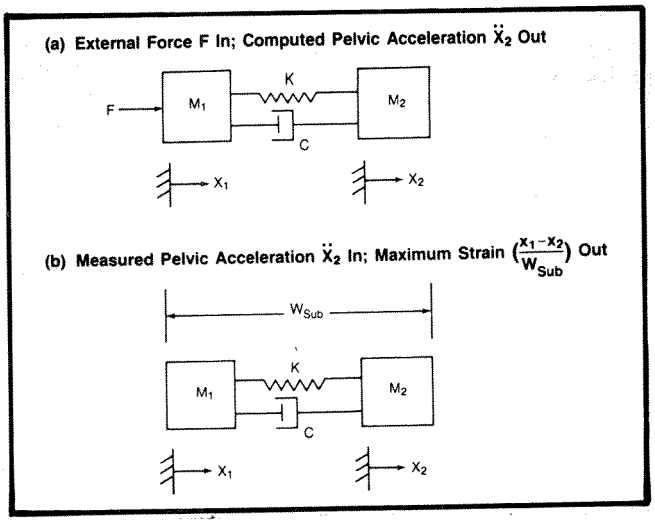

Figure 15. Model construct for pelvic injury assessment

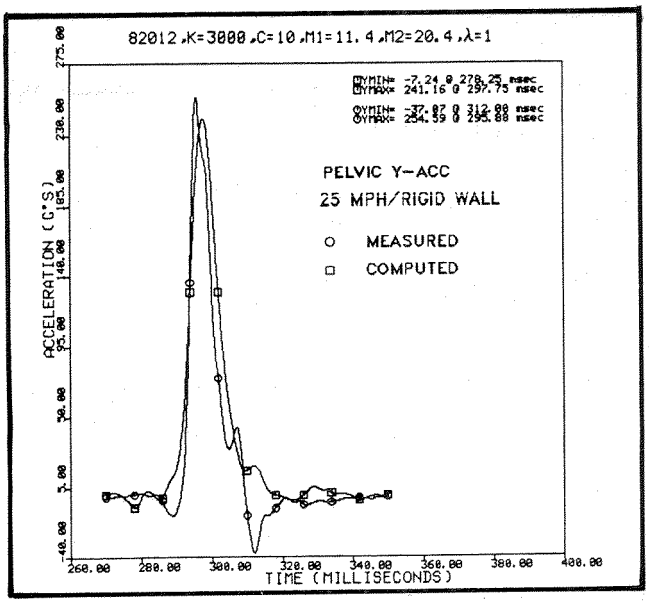

Figure 16. Comparison of measured pelvic Y-acceleration to that computed using two-mass model of Figure 15(a)—Heidelberg test H82012

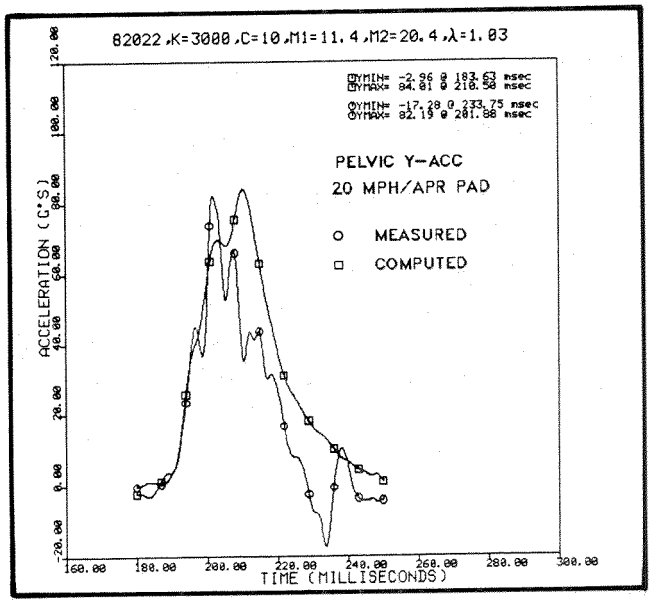

Figure 17. Comparison of measured pelvic Y-acceleration to that computed using two-mass model of Figure 15(a)

There is a basis for the formulation of a model in this configuration in the work of (11), wherein impedance plots for the laterally impacted pelves of three cadavers are reported. This simple construct should not be thought of as a literal model of the laterally impacted pelvis, but rather as a useful device for injury predictive purposes along the lines of the Brinn and Staffeld Effective Displacement Index(15) or the HSRI Maximum Strain Criterion(16).

Our operating premise is that if the model is "run backwards," i.e., if measured pelvic acceleration is provided as input to the model at M_2 (see Figure 15b), that a function of resulting maximum "pelvic" strain $(X_1\text{-}X_2)_{max}/W_{sub}$ can be utilized in a fracture predictive function (W_{sub} is subject pelvic width). Specifically, if we denote the quantity $(X_1\text{-}X_2)_{max}/W_{sub}$ as MPS or Maximum Pelvic Strain, we postulate that:

Probability of Pelvic Fracture = f[MPS+(n)(age)]

where n is an age coefficient relative to reduction of ultimate strain with age.

To select reasonable values for parameters M_1, M_2, K, and C, the model was first exercised in the "forward" direction (see Figure 15a), using the 12 Heidelberg cadaver runs for which both force and acceleration data were available. (Parameters were scaled according to the mass and height of each specimen using scaling method B.) Initial parameter estimates were deduced from the impedance plots of (11); adjustment by trial and error then resulted in the determination of a parameter set for which observed and computed pelvic accelerations were reasonably matched for both a rigid case (H82012) and an APR padded case (H82022), as shown in Figures 16 and 17, respectively. The parameter set selected was as follows:

M_1 = 11.4 lb, M_2 = 20.4 lb, K = 3,000 lb/in, and C = 10 lb-s/in.

Because this model exercise showed output pelvic acceleration to be more sensitive to change in total mass than to change in K or C, and since the influence of strain on fracture predictive capability was being investigated, three sets of standard parameters were selected for further use, with three possible values for C, as shown in Table 2.

As a final preparatory step before exercising the model, the standard parameters of Table 2 were B-scaled

Table 2. Standard parameter sets chosen for exercise of MPS model

Set No.	M_1(lb)	M_2(lb)	K(lb/in)	C(lb-sec/in)
1	11.4	20.4	3000	5
2	11.4	20.4	3000	10
3	11.4	20.4	3000	20

for each subject in the data base to create a file of subject specific parameters using the following relationships:

$$M_{1\ sub} = \lambda^3 M_{1\ std} \quad (23)$$

$$M_{2\ sub} = \lambda^3 M_{2\ std} \quad (24)$$

$$K_{sub} = \lambda K_{std} \quad (25)$$

$$C_{sub} = \lambda^2 C_{std} \quad (26)$$

where the value of λ for each subject was obtained from Equation (19).

A listing of the calculated subject specific model parameters may be found in Appendix A.

As shown in Figure 15(b), and using actual subject pelvic acceleration data as input to mass M_2, the model was exercised three times for each qualifying subject in the data base, once for each of the three parameter sets of Table 2. For each model run, the quantities $V_{max} = (\dot{X}_1 - \dot{X}_2)_{max}$ and maximum strain were calculated (see listings in Appendix A). The maximum strain (MPS) for each subject was calculated as follows:

$$MPS_{sub} = \frac{(X_1 - X_2)_{max}}{\lambda W_{std}} \quad (27)$$

where W_{std} is the pelvic bispinous breadth for a standard specimen = 22.5cm (8.84in) and λW_{std} is therefore equal to W_{sub}, or subject pelvic width.

Using a method analogous to that employed in Approach 1, the MPS values calculated for each subject using the model were then plotted versus corresponding subject age data. Three plots were thus created corresponding to the three parameter sets of Table 2. Figure 18 presents the plot for parameter set 3. Again, using methods analogous to those employed earlier, three candidate fracture probability functions were created for the three parameter sets as follows:

For Set 1: Probability of Pelvic Fracture
= f (MPS + .035 * age)

For Set 2: Probability of Pelvic Fracture
= f (MPS + .030 * age)

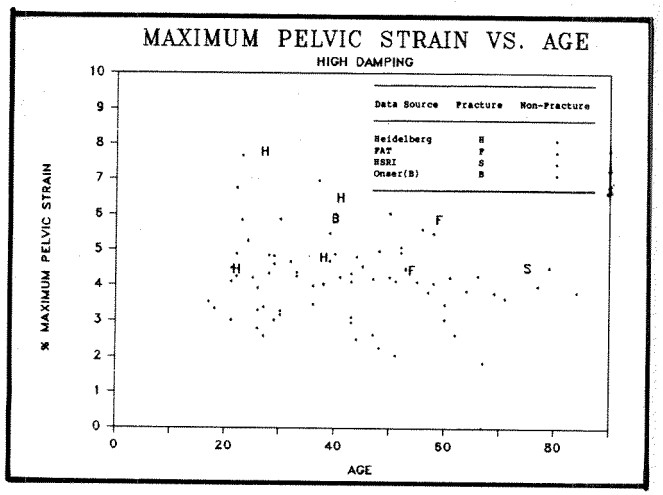

Figure 18. Computed maximum pelvic strain versus specimen age—parameter set #3—distributed load data

For Set 3: Probability of Pelvic Fracture
= f (MPS + .025 * age)

All three sets were submitted for Weibull analysis and computation of maximum likelihood numbers. The highest maximum likelihood, computed for parameter set 3, was 1.1×10^{-9}.

Figures 19 and 20 present the Weibull probability function and distribution, respectively, for parameter set 3 computations. We may note using Figure 19 that the value of MPS corresponding to 20 percent fracture probability at 40 years of age is approximately 6.1 percent, and that the corresponding value of MPS for 10 percent fracture probability and 40 years of age is approximately 4.8 percent

It is also of interest to compare the best maximum likelihood number arising from Approach 2 to that computed from Approach 1. These are shown in Table 3.

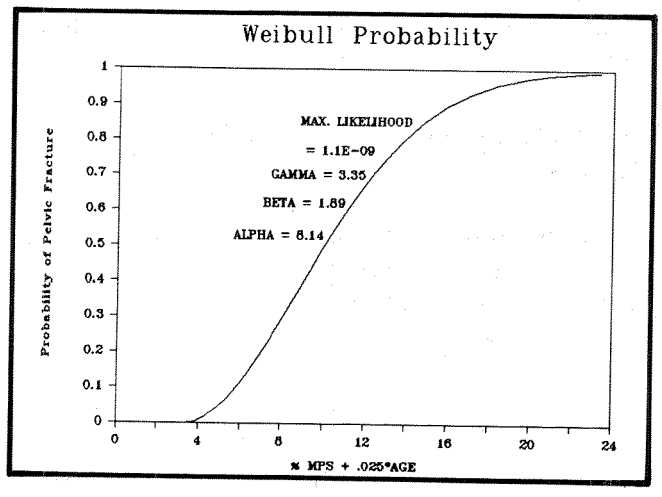

Figure 19. Probability of pelvic fracture from Weibull analysis of distributed load data, approach 2, parameter set #3 (M_1 = 11.4 lb, M_2 = 20.4 lb, k = 3,000 lb/in, C = 20 lb-sec/in).

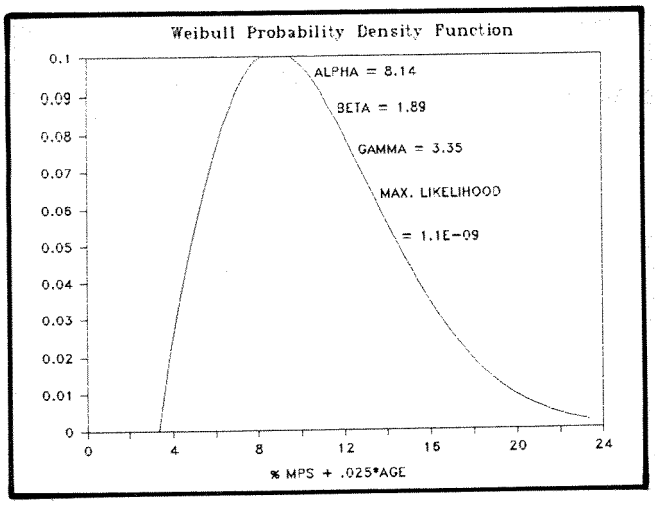

Figure 20. Weibull probability density function associated with Figure 19

Table 3. Comparison of maximum likelihood numbers

Approach No.	Maximum Likelihood Number
1	4.1×10^{-11}
2	1.1×10^{-9}

It is concluded, based on the higher maximum likelihood number achieved for the MPS approach, that the incorporation of additional information from the acceleration pulse into the predictive function increases its predictive power.

Finally, we have cross-plotted the values of the predictive functions for the two approaches (Weibull computations) for all qualifying subjects and present the results in Figure 21. We may observe that differences do exist in the relative ordering of the data by the two approaches; however, these differences are not large.

Incorporation of ONSER(A) Data Into the Analysis

As has been previously discussed, the ONSER(A) data have been separated from the balance of the data for purposes of analysis because—

- Unlike the other data sets, it is not quantal (or censored) in nature.
- Unlike the other data sets, concentrated loads were applied to the pelvis.

In subjecting each specimen to increasing impact severity until fracture occurred, Cesari sought to define the fracture tolerance of each specimen. For each specimen, we may presume that the severity of the last nonfracture test underestimates specimen tolerance, while

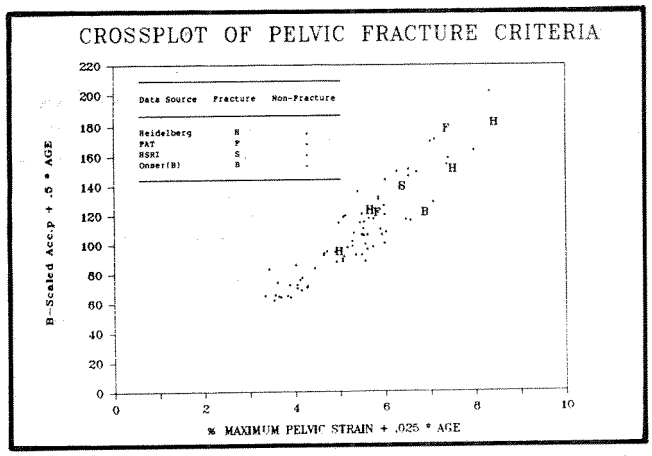

Figure 21. Crossplot of two candidate lateral pelvic fracture criteria

the severity of the fracture-inducing test overestimates specimen tolerance to some degree. Therefore, we take as the best estimate of fracture tolerance for each specimen the average response of the last nonfracture test and the fracture test. Four test pairs are available for examination. Scaled acceleration data for specimens D, E, I, and J are presented on Figure 22 (results for E are anomalous in that last nonfracture response is higher than fracture response; the higher value is thus taken as the fracture response estimate). The range of estimates for scaled acceleration associated with fractures thus ranges from 41g (D) to 79g (I). Since all of these tests are narrowly grouped in age, we plot the above scaled acceleration range on Figure 8 at age = 69 years and present the result as Figure 23. It is immediately apparent that ONSER(A) fracture estimates plot very low in the distribution of other available data.

A similar presentation using MPS as the response variable is presented in Figure 24, and the corresponding fracture estimate range is plotted on Figure 18 as Figure 25. Again, the fracture range estimate plots very low in the distribution of the other data.

It is concluded that ONSER(A) fractures occurred at significantly lower measured pelvic accelerations than in the other data sets. In fact, the highest fracture estimate in the ONSER(A) set corresponds to about a 5 percent fracture probability level in the main data set.

Discussion

It is believed that a probable explanation for the result found in the previous section may be found in Figure 1. That is, for concentrated loading to the trochanter as schematically shown in 1(a), acceleration associated with fracture is minimized.

The fact, however, that the fracture distributions for the ONSER(A) data are so different compared to the balance of the data base points to the conclusion that the

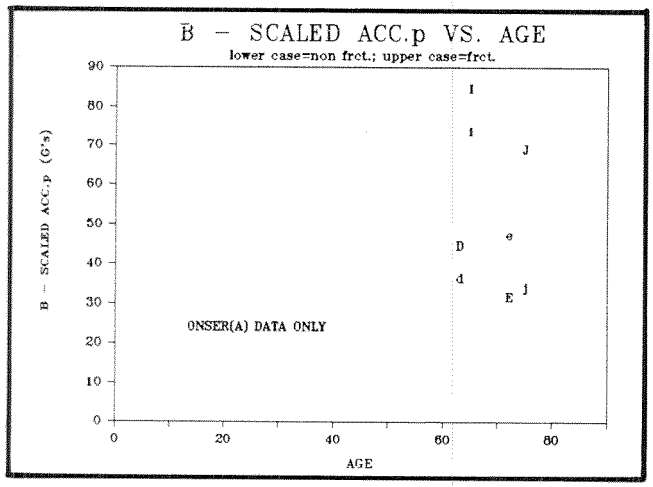

Figure 22. Nonfracture/fracture data pairs from ONSER (A) test series

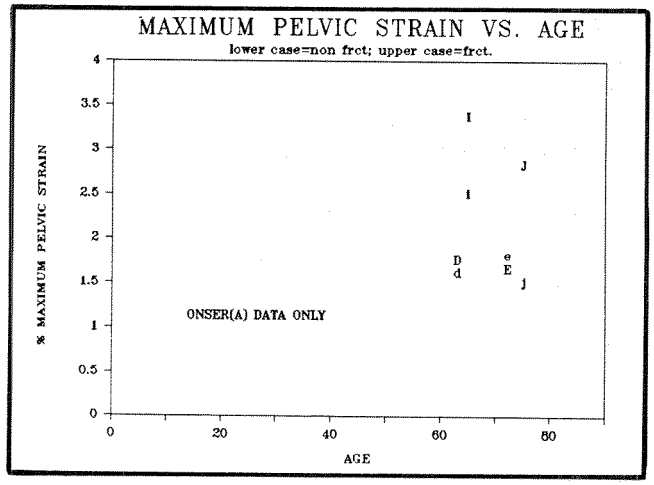

Figure 24. Nonfracture/fracture data pairs from ONSER (A) test series

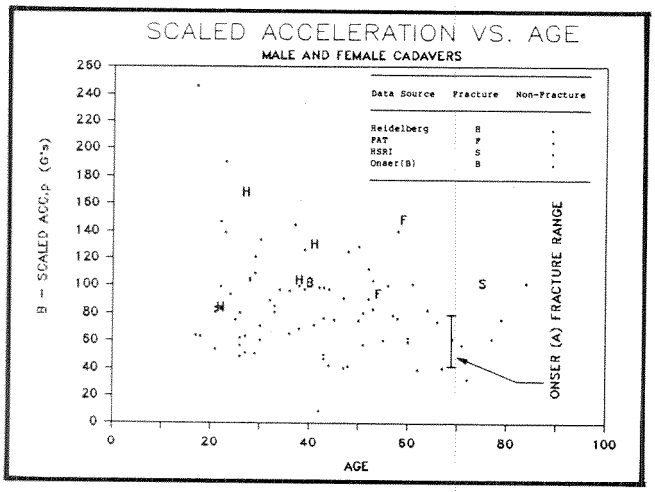

Figure 23. Superposition of ONSER (A) fracture range estimate on distributed load data—approach 1

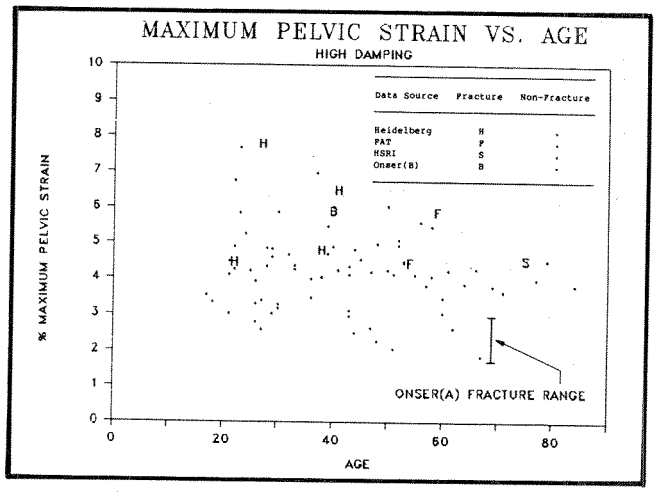

Figure 25. Superposition of ONSER (A) fracture range estimate on distributed load data—approach 2

ONSER(A) impact tests involved a degree of load concentration significantly higher than that realized in the vehicle environment. It will be recalled the tests used in our analysis involved rigid walls and three types of vehicle interiors (Opel, Rabbit, and Volvo). Yet in no case did a pelvic fracture occur at a response level as low as the estimated ONSER(A) fracture range.

The ONSER(A) data are, of course, most valuable in that the data define the load tolerance of one of the two major pelvic load paths. Investigation would also appear to be warranted into the load tolerance of the "other" load path through the iliac wing and into the effects of superposition of distributed loads as typically found in the vehicle environment.

It is recognized that any acceleration measure reflects the net force acting on the measured body. Thus, a pelvic acceleration measurement would be expected to be influenced to some degree by other forces acting on the pelvis during the impact event (e.g., horizontal seat interface force and horizontal shear force between the abdomen and pelvis). Some insight into the magnitude of this potential source of variability can be obtained by reference to Figure 4. Despite the presumed existence of seat and internal shear forces, a high correlation is obtained between peak applied force and peak pelvic acceleration. This result implies, for the ONSER(A) test condition at least, that the vector sum of the seat and shear forces is a predictable function of impact severity level. However, the extent of variability introduced into pelvic acceleration measurement in other environments more typical of the vehicle interior deserves further study before this observation can be generalized.

The data base is heavily biased toward nonfracture outcome. There is a need for additional fracture data to improve confidence in our fracture probability estimates, especially at higher fracture probabilities.

Male and female data have been merged for analysis, as have data from rigid and padded test conditions. The availability of further fracture data would permit a more detailed examination of the validity of this approach.

There is no doubt that a force-based approach to pelvic injury prediction exists as a strong alternative or adjunct to the acceleration-based proposals advanced here. The lack of a substantial body of comparable sets of force data have precluded our investigation of this alternative. When such data become available, a maximum likelihood analysis could provide a rational basis for ranking the effectiveness of the two approaches.

Summary and Conclusion

Two functions predictive of pelvic fracture due to distributed lateral impact have been synthesized from available data. The functions utilize the lateral component of pelvic acceleration as measured on 84 male and female cadaveric subjects from four major test series.

The second function, which incorporates the time history of measured acceleration, has been found to offer higher predictive power than does the first, which operates on peak acceleration magnitude alone. Age has been included as an explanatory variable in both approaches, and the value of its inclusion has been confirmed by the analysis.

All data have been analyzed using maximum likelihood methods. It has been confirmed that representation of the data by a Weibull distribution yields higher maximum likelihood than does the assumption that the data are normally distributed.

The degree of load distribution on the impacted pelvis has been identified as an important variable controlling pelvic tolerance to fracture. Acquisition of additional data defining the force tolerance of the pelvic bone under distributed loading conditions appears to be desirable.

Acknowledgments

Several individuals have made important contributions to the work reported here.

Deserving special mention, Margaret Hayden of Chi Associates painstakingly assembled the data base (see Appendix A) and artfully conducted innumerable queries of the data in the process of creating the presentations found throughout this paper.

Ranga Rangarajan of the Automated Science Group, Inc. implemented the MPS model under difficult time constraints and assisted in interpretation of early results.

Dominique Cesari of ONSER graciously provided a data tape of his [ONSER(A)] experiments for analysis, and Nabih Alem of UMTRI processed these data into the NHTSA format for our use.

Jeffrey Marcus and Richard Morgan of NHTSA developed many of the software routines that were extensively used on this project and that contributed materially to its progress.

Rolf Eppinger of NHTSA provided the benefit of many discussions during the course of the work.

Last, but certainly not least, Beulah Evans of NHTSA expertly prepared the manuscript for publication.

Appendix B

Comparison of Cadaver and Dummy Lateral Impact Pelvic Data

1. Comparison of Peak Responses

A limited amount of data is available from the Heidelberg data set that permits comparison of cadaver and SID dummy force and acceleration responses. Figures B-1 and B-2 present peak force versus peak acceleration data for Heidelberg cadavers and Heidelberg SID dummies, respectively. It may be noted that the slope of the line fitting the dummy data (.196KN/g) is approximately twice the slope of the least squares fit to the cadaver data (.101KN/g). This result suggests that the dummy generates higher peak pelvic interface force for a given level of peak pelvic acceleration response.

To investigate this indication further, dummy and cadaver data were segregated by test speed and by impacting surface (rigid or padded), and the ratios of average dummy peak responses to average cadaver peak responses for each test condition were calculated and plotted. Figure B-3 presents these computed acceleration ratios. It may be noted that the ratio of peak dummy acceleration to peak cadaver acceleration ranges from 1.0 to 1.7 for rigid impacts and remains stable at a lower value of approximately .85 for padded impacts.

Figure B-4 presents corresponding computed force ratios. Although data are very limited and should be interpreted with caution, the dummy appears to generate

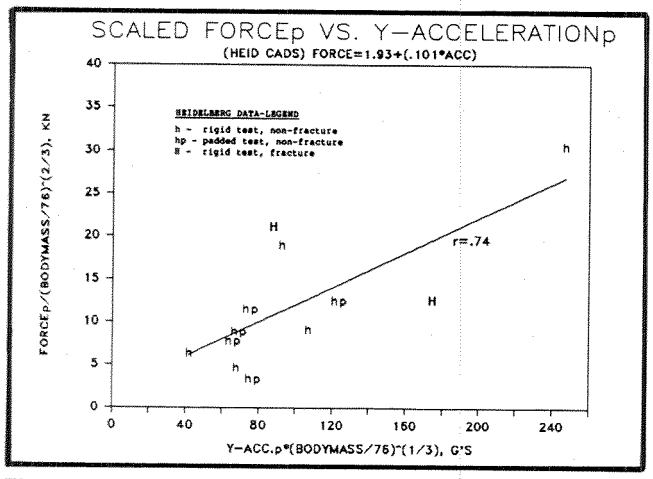

Figure B-1. Scaled peak pelvic forces versus scaled peak pelvic Y-acceleration for Heidelberg cadaver tests

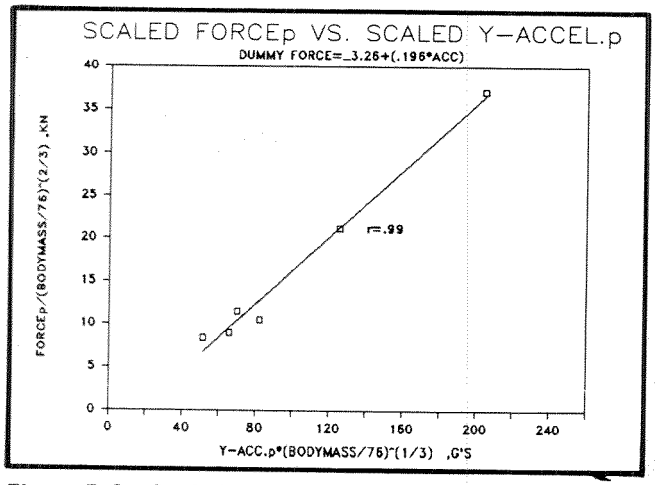

Figure B-2. Scaled peak pelvic force versus scaled peak pelvic Y-acceleration for Heidelberg SID dummy tests

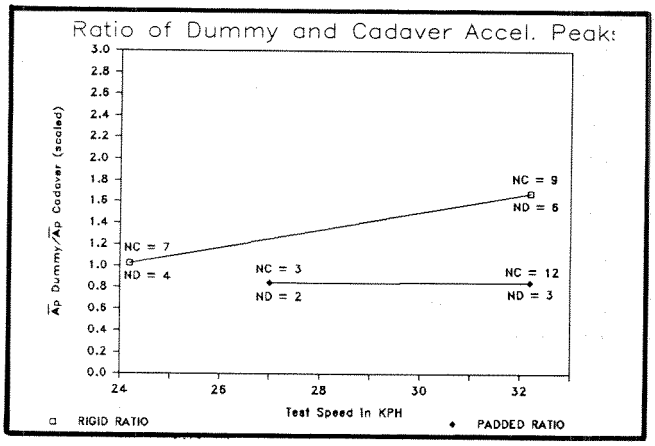

Figure B-3. Ratios of SID dummy and cadaver peak accelerations—Heidelberg data (NC and ND are number of cadaver tests and number dummy tests, respectively, included in ratio of determination at each data point)

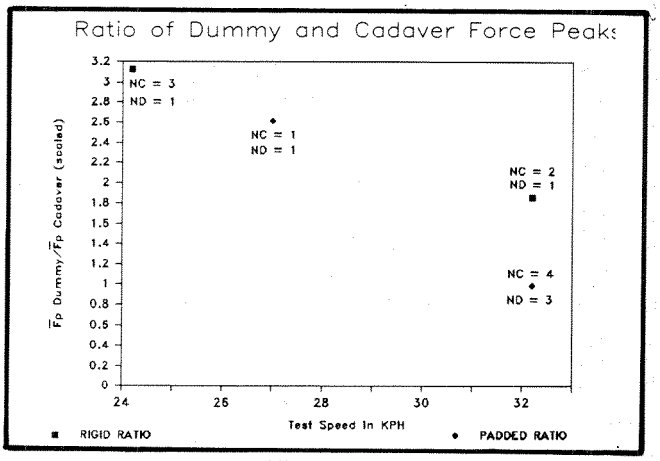

Figure B-4. Ratios of SID dummy and cadaver peak forces-Heidelberg data

higher interface force than does the cadaver at all test speeds. Also, the force ratio exhibits a trend toward reduction with increasing test speed. However, more data would be desirable to confirm these observations.

2. Comparison of Pulse Shape

Thus far, we have compared only the behavior of peak force and peak acceleration responses. It is also of interest to examine comparative pulse shapes for cadavers and dummies from the Heidelberg series, for both rigid and padded test conditions.

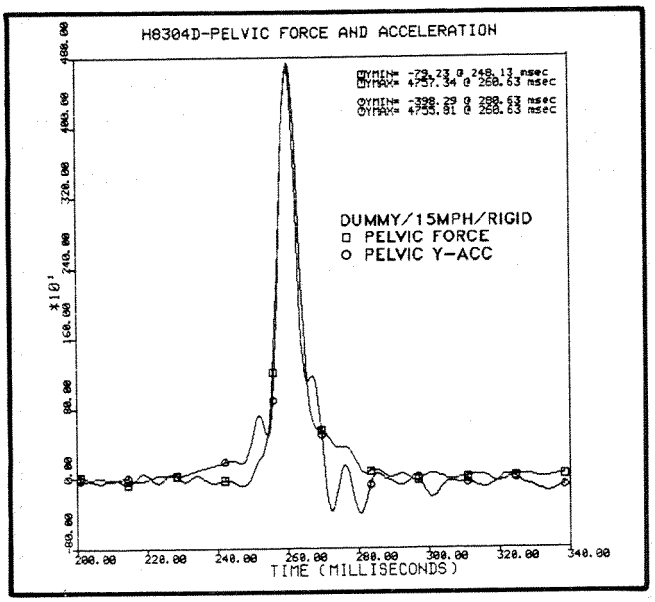

Figure B-5. Pelvic force and pelvic Y-acceleration overlay for Heidelberg SID dummy test H8304d

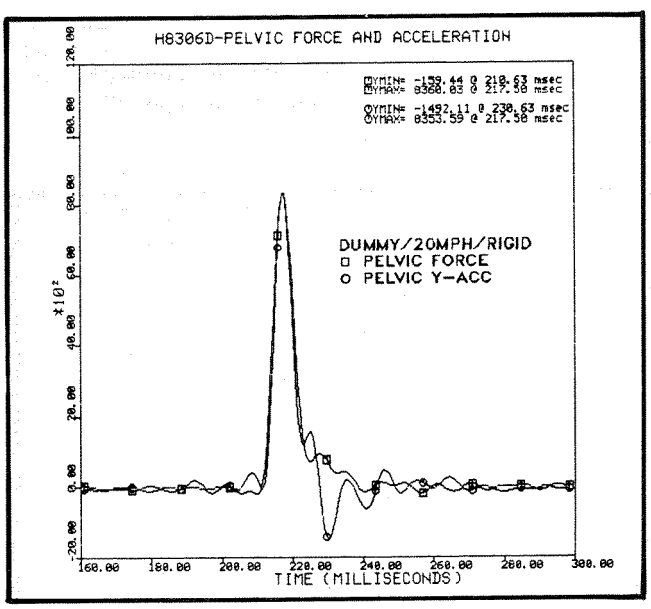

Figure B-6. Pelvic force and pelvic Y-acceleration overlay for Heidelberg SID dummy test H8306d.

A. Rigid Interface

Figures B-5 and B-6 present overplots of pelvic force and acceleration data for a 15mph dummy test and a 20mph dummy test, respectively. (Traces have been artificially scaled to equalize plotted peak amplitudes so that curve shapes can be better compared.) Figures B-7 and B-8 present comparable data for 20mph and 25mph cadaver exposures.

For all dummy and cadaver rigid tests, excellent agreement of force and acceleration curve shape is seen, and rigid body behavior is approached.

B. Padded Interface

Figures B-9 and B-10 present typical dummy tests, at 17 and 20mph, into ensolite padding. Figures B-11 and B-12 are corresponding plots for two cadavers at 20mph into ensolite.

Distinctly different characteristic acceleration pulse shapes are evidenced by the SID and by the cadavers in the padded environment. Whereas the dummy exhibits good tracking of force and acceleration up to peak force, the cadaver accelerations are seen to track force well initially, but then to dip and rise again to meet the force curve. In all cases, as was observed in the main body of the paper, peak force and peak acceleration are closely coincident in time.

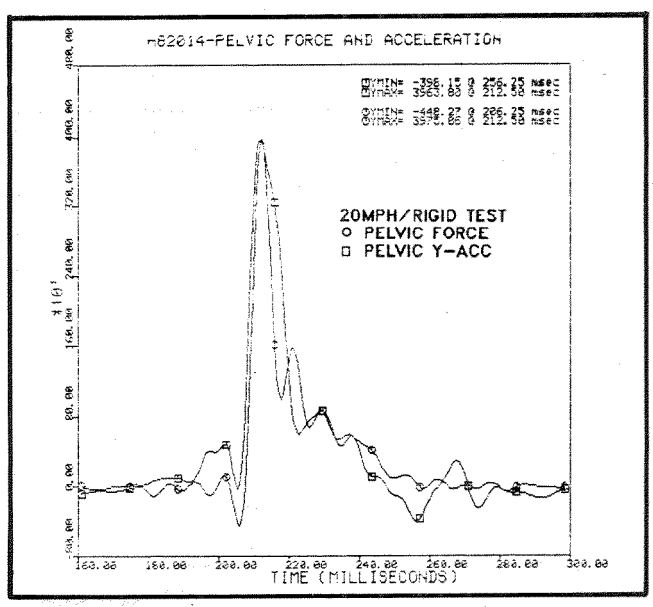

Figure B-7. Pelvic force and pelvic Y-acceleration overlay for Heidelberg cadaver test H82014

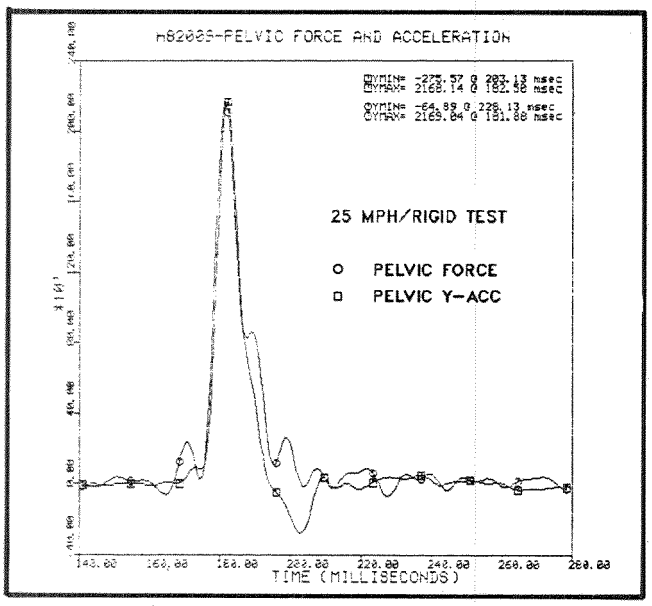

Figure B-8. Pelvic force and pelvic Y-acceleration overaly for Heidelberg cadaver test H82005

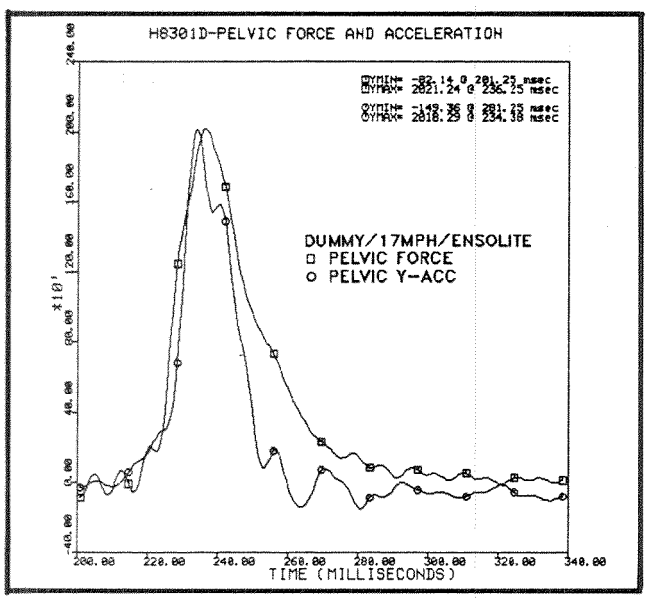

Figure B-9. Pelvic force and pelvic Y-acceleration overlay for Heidelberg SID dummy test H8301d

It is interesting to speculate as to why the differences noted above occur in the padded environment and not in the rigid environment. This difference could be related to additional compliance in the structure of the human hip joint or could be due to differences in phasing of horizontal shear forces acting between the abdomen and pelvis.

Although not pursued here, these observed differences should be better understood for input to the development of advanced side impact dummy concepts.

Abstract

EUROSID is the side impact dummy that has been designed and has now been almost completely developed by a group of European research laboratories working together under the auspices of the European Experimental Vehicles Committee (EEVC). It represents a bringing together of components and ideas from the three experimental side impact dummies sponsored by the EEC[1] as part of their Biomechanics Programme. These were produced by APR (Peugeot-Renault), ONSER, and MIRA. This paper describes the evolution of the EUROSID dummy and discusses the advances in biofidelity, the responses of its various components to impact, and the types of measurements it can record.

Introduction

When the EEVC first recommended a side impact test in its report to the Fifth ESV Conference(1), which included the use of dummies, there was no suitable dummy available. At that time, the only dummy designed for use in side impacts was the TRRL side impact dummy(2). This was regarded more as a dynamic load-measuring device than a dummy. While being built to 50th percentile male dimensions and weight, it made no pretense of being biomechanically correct in its response.

A symposium was organised by the EEC in 1975 to establish priorities for improving vehicle legislation. Following this the Biomechanics Programme was set up, with some help from EEVC members. It was partially funded by the EEC to expedite ongoing research, which was thought to be necessary as a basis for the safety aspects of this legislation(3). One of the recognised priorities included in the programme was the development of a suitable side impact dummy.

Projects undertaken within this programme included an accident investigation studying specifically side impacts, studies of biomechanical performance required for the design of dummies, and the development of three independent side impact dummies. The three side impact dummies are described in detail elsewhere(4,5,6), but their essential details are given below.

APROD (APR)

The head was a standard Hybrid III head. The neck was a modified version of Hybrid III. The chest was based on the rib cage of the Part 572 dummy but with the posterior ends of the ribs attached in two groups of three to the ends of pistons, which could traverse laterally inside cylinders attached to the spine. Chest compression was determined by measuring the movement of the pistons in their cylinders. The shoulders were modified forms of the Part 572 design to allow and encourage greater upwards and forwards rotation. Modified arms were used but the remainder was of the Part 572 design.

MIRA

The head, neck, legs, and arms were of the Part 572 design. The shoulder was a complex unit incorporating a sliding and rotating clavicle. The chest comprised six spring steel ribs, of which the force on each could be measured. The pelvis could measure acceleration and the force applied at the ilium, great trochanter, and the pubic symphysis.

ONSER

This was essentially a standard ONSER 50 frontal impact dummy with a new chest and shoulder design to adapt it for side impact use. The shoulder was a sprung sliding and pivoting unit and the chest was of moulded polyurethane foam on rigid spine. A transducer was incorporated for measuring lateral compression of the chest.

TNO Abdomen

TNO designed an abdomen based on cadaver tests performed by the Peugeot-Renault Association (APR)(7)

1. Financial support was also given by the governments of the participating countries (France, the Netherlands, and the United Kingdom).

that could in principle be used in any side impact dummy incorporating the standard Part 572 lumbar spine interface. In practice, the prototypes produced had the correct dimensions to fit the Part 572 pelvis and therefore could be used only with the APROD. The abdomen was designed to have the correct force-penetration characteristics at an appropriate impact velocity and incorporated switches to indicate when critical levels of penetration and force had been exceeded.

Side Impact Dummy Specification

During the final phase of the Biomechanics Programme, the three prototype dummies were evaluated and compared with each other, with the side impact dummy developed by HSRI for NHTSA(8), and with the available cadaver test findings. The results, being part of the Biomechanics Programme, were presented at the EEC Biomechanics Seminar in 1983(3,9).

At the same time, the EEVC Ad-Hoc Group on Dummies was drawing up an agreed specification for a side impact dummy, which evolved as the programme progressed(10).

A Unified European Side Impact Dummy

At the conclusion of the EEC Biomechanics Programme, the EEVC Ad-Hoc Group on Dummies coordinated the development of a single side impact dummy, which evolved by adopting the most successful principles of the three prototype dummies. The detailed side impact accident investigation(11) provided information on the location, cause, and type of injuries to car occupants in side impacts. This provided a guide to the requirements and priorities in the design of the side impact dummy. The distribution of injuries to struck-side occupants in side impacts is given in Table 1.

These results show that ideally the dummy should be capable of registering the likelihood of injury to the head, chest, abdomen, pelvis, and legs.

Table 1. Distribution of injuries to struck-side occupants in side impacts

Body region	Number of cases	
	AIS≥3	AIS≥4
Head and face	16	11
Neck	1	0
Chest	15	5
Abdomen	12	7
Pelvis	3	0
Legs	6	1

These results, the comparison testing of the three European prototypes(9), and the side impact dummy specification enabled the EEVC Ad-Hoc Group to coordinate the development of a unified side impact dummy. Various laboratories worked on the different body parts, which were combined into a European side impact dummy. This has come to be known as EUROSID. The sources of its component parts are now discussed briefly.

Head

The Hybrid III head was found to be closest in performance to the lateral drop tests performed with cadavers and was chosen for the dummy without further development.

Neck

The APROD 82 neck came closest in kinematics to the volunteer and cadaver results. The Peugeot-Renault Association was continuing its development of this neck, and therefore the developed version of the APROD neck was chosen for EUROSID.

Chest

Injuries to the chest are caused by excessive force or compression. On balance, the Ad-Hoc Group considered compression to be the parameter most closely related to injury risk in side impact. The APROD chest was considered to be the best at measuring deflection while being closest to the biomechanical performance references. However, the APROD design had some mechanical problems, at least in its earliest version, and it subdivided the chest into only two discrete areas. Accident studies showed that serious internal injuries can sometimes be associated with relatively few fractured ribs, three or four, suggesting that concentrated forces could cause injury whereas the same force over the whole rib cage would not. However, it is also desirable to keep to a minimum the number of instrumentation channels and the complexity of the chest design. It was decided that a new chest could be developed by TRRL in consultation with Peugeot-Renault and TNO based on the design principles of the APROD chest but with the chest divided into three discrete areas, and chest deflection would be measured in each area.

Shoulder

None of the shoulders from the prototype dummies were found to be satisfactory with regard to mechanical reliability or in reproducing the observed cadaver re-

sponses. The Ad-Hoc Group felt there was a need for arms on the side impact dummy and therefore a need for a fully articulating shoulder. This would help to achieve the correct inertial effect and the appropriate mass distribution and would enable correct engagement with the diagonal strap of a seatbelt. It was decided to have arms and shoulders if these proved practical to design. ONSER tests on cadavers in the Biomechanics Programme demonstrated that the chest is less liable to injury if the arm is trapped between the chest and an impactor(12). The "worst case" condition, which is the usual situation for legislative testing, is therefore with the chest exposed. For this reason, the specification calls for a shoulder that, when struck laterally, moves forward to expose the chest to a more direct impact. TRRL agreed to include the development of a new shoulder to meet the requirement of the specification as part of the thorax development.

Abdomen

The performance of the TNO abdomen was close to that specified from the tests on cadavers. No other abdomen has been or was being developed, and the Ad-Hoc Group agreed that TNO should develop the abdomen for EUROSID by small modifications to improve its performance and to adapt it to fit the EUROSID chest and pelvis.

Pelvis

None of the three prototype dummy pelves were satisfactory. When struck by a rigid impactor, they all produced a far higher force than the cadavers when similarly tested. The Ad-Hoc Group felt that force was the parameter most closely related to injury potential for the pelvis. Acceleration would only be related to force by a constant factor if the effective mass remained constant and the pelvis was not trapped by the seat or car structure. Only the MIRA pelvis could measure force but its instrumentation was complex and no further work was proposed to improve this pelvis. ONSER had planned to develop a force-measuring pelvis and agreed to produce the pelvis for EUROSID to the Ad-Hoc Group specification.

Legs

Although leg fractures feature regularly in side impacts, no suitable instrumented femur had been developed and this area was given a lower priority than the other four body areas. It was agreed that Part 572 legs would be used for EUROSID at this stage.

Arms

Arm injury was not considered to be sufficiently serious to warrant instrumentation. Part 572 arm dimensions would be used, modified only insofar as this affected the performance of the chest and shoulder.

Design and Performance of Specialised EUROSID Components

Neck

The first version of the APROD dummy neck (1982 version) was developed from a biomechanical data base derived from volunteers and from human subjects (cadavers).

Data from experiments with volunteers came from tests performed by Ewing(13). Their aim was to study the dynamic response of the head-neck system when the entire body was subjected to an acceleration of the +Gy type. Experiments involving cadavers, performed in the same test conditions as those used by Ewing, were performed in the Association Peugeot-Renault Laboratory. The tests selected for the design of this neck are shown in Table 2. They enable a direct comparison to be made between the cadaver and volunteers' responses.

The sled deceleration for the two types of tests met the conditions of HOLD (High rate of Onset, Long Duration).

Table 2. Test conditions for cadaver and volunteer tests

CADAVER TESTS		
Test	Average peak sled acceleration	Initial velocity of the sled
MS 234 MS 235 MS 239 MS 240	7.55g (74.06 m/s_2)	6.08 m/s
VOLUNTEER TESTS		
Test	Average peak sled acceleration	Initial velocity of the sled
1594 1921 1922 1926 1924	7.07g (69.4 m/s_2)	6.408 m/s

The characteristics of these tests are described in detail in (14) as is the description of the design of this 1982 version.

Technological problems arose at the time of tests performed with the neck, especially cable breakage, the separation and even the shearing of the buffers at the interface plates, and seizing-up of the half-spheres.

To remedy these problems and improve biofidelity of the neck for high impact severities, a second version was developed in the APR Laboratory, this being the version developed for EUROSID.

Development of APROD Neck for EUROSID

During cadaver tests, under the conditions defined above, it was observed that the subject sustained no injuries either to the cervical spine or to bone joints.

This led, therefore, to more violent experimental conditions than those of earlier tests ($74 m/s^2$ and 6.08m/s). These severities could not be obtained from volunteers but were necessary to improve the neck design up to injury level.

Three tests with cadavers were performed in 1983 in the following test conditions.

Table 3. Test conditions for 1983 cadaver tests

Test	Peak sled acceleration		Initial velocity of the sled
	g	m/s_2	m/s
249	12.02	117.91	6.11
297	14.02	137.53	6.22
298	13.06	128.11	6.11

Biomechanical Data Base

The following such data were used in the development of this EUROSID neck.

A { — Ewing data from volunteer tests
— APR data from cadaver tests

B { — APR data from cadaver tests described in table 3 above

The results of APR tests are published in a separate paper(15). A description of the EUROSID neck is given in the following section.

Description of EUROSID Neck

This version is composed of three parts:

- A neck/trunk interface piece
- A head/neck interface piece
- A central section made of rubber that links the two interfaces to one another

Figure 1 illustrates various neck sections, showing the components of each part.

Each interface is made up of two plates; an exterior one ((3) or (1) in Figure 1) and an intermediary one(2) bonded to the central part. Linking of the two plates is by means of a sphere, which, in fact, constitutes a point of rotation to replicate head neck kinematics.

Two types of buffers are interposed between the plates: the section CC (Figure 1) illustrates this. Those buffers that are triangular act as buffers at the end of travel.

The central component(5) and these buffers are all part of the same system. The circular buffers modulate the shearing or rotational movement in relation to the centre of the half-sphere.

Figure 2 shows the neck/trunk interface in its final position.

The central part of the neck, simulating the cervical vertebral column, allows flexion and extensions. The neck prototype, which has been developed, has the following stiffness characteristics:

- Central part and triangular section buffers: 70 shores
- Buffers(6) with a circular section: 70 shores

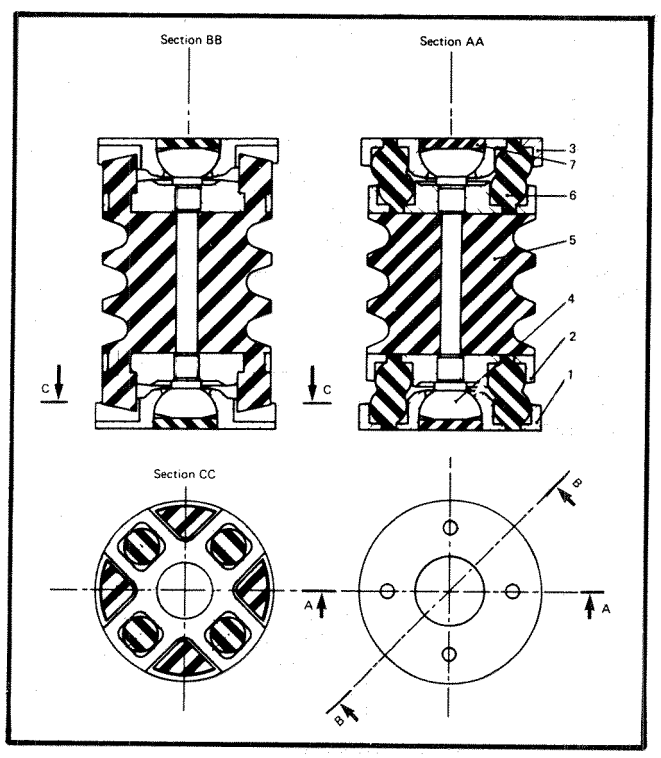

Figure 1. EUROSID neck

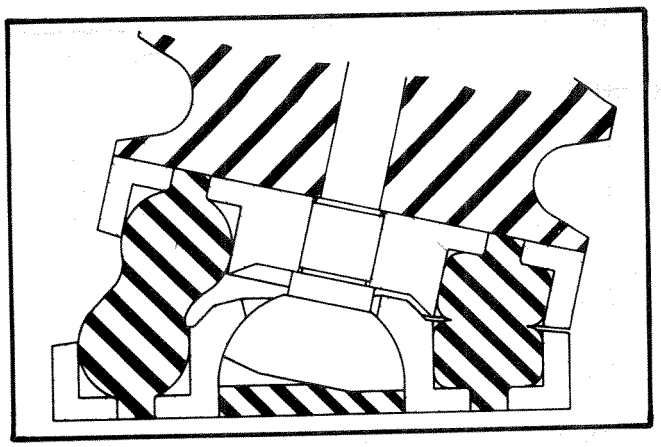

Figure 2. Neck-thorax interface

Figure 3 shows the various possibilities of simple movements of the different parts of the neck.

It can be said that this set-up represents a system having two pivots and three modes of deformation.

The two pivots are represented by the centre of the half-spheres.

The three modes of deformation possible for such a neck are:

- Simple lateral flexion (of the central part)
- Translation and rotation (relative movements of the interface plates)
- Extension of the central part

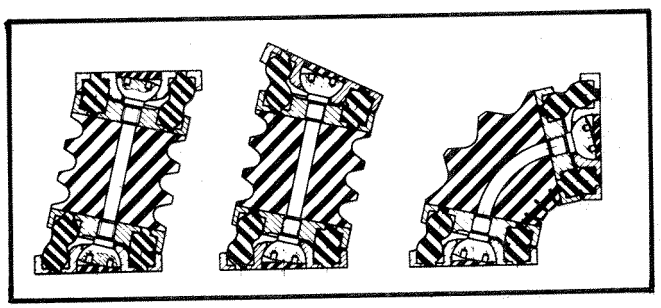

Figure 3. Possible neck deformation modes

The play that exists around the buffers and the compliance of these latter may give rise to torsion—a rotation around the neck's vertical axis. This matter will be discussed when the processing of available data is completed.

Mechanical Behaviour Tests

With a view to studying the whole system's mechanical behaviour (resistance to impact of the various neck components), particularly violent tests were performed with the neck attached to an APROD dummy.

The characteristics of these tests were as follows.

The dummy is decelerated laterally against a rigid wall (at 90° where it is subjected to an impact velocity (V_i) of approximately 20m/h. This is a high-violence impact, which is reflected in a lateral thoracic acceleration$_{\gamma T}$(3ms) of about 180g.

Table 4 summarizes the parameters of these tests.

The results of these tests show that—

(i) In the two tests, no deterioration was observed either in terms of welding of components or in terms of rubber parts of the neck.

(ii) From the point of view of kinematics, test 2346 C1, where the stiffnesses of the prototype were respectively 60 and 50 shores, shows that the displacements of the head/neck system are much greater than for test 2346 C2.

Validation Tests

Currently, side impact tests using cadavers and the APROD dummy equipped with the second version of the neck (stiffness of 70 shores) are in hand.

The principle of these tests is exactly the same as that of the preceding tests (study of the head/neck response when the body is subjected to an acceleration of the type +Gy).

Table 4. Characteristics of mechanical behaviour tests

Test	V_i to which the dummy was subjected		Stiffnesses used		Peak horizontal acceleration measured at APROD's thorax (γT)		γT (3ms)	
			Central part and triangular buffers	Buffers (6)				
	km/h	m/s			g	m/s^2	g	m/s^2
2346 C1	31,4	8,73	60 sh	50 sh	184	1805.04	132	1294.92
2346 C2	31,4	8,73	70 sh	70 sh	176	1726.56	120	1177.2

The method used, on the other hand, is slightly different:

- More appropriate instrumentation that is also more reliable (a different array of transducers in relation to the anatomical coordinate frame)
- More flexible conditions of studying head-neck kinematics (cameras fixed to the laboratory, more highly developed camera calibration methods)

The results of these tests, as well as a simple specification for the dummy neck, will be the subject of another paper presented at the 1985 ESV Conference(15).

Shoulder

The specification for the shoulder is given in detail in (10), but briefly it requires that the shoulder when struck laterally moves forward and possibly upward to expose the chest, under a relatively low force. It should include a representation of the clavicle and should return to a positive neutral position.

The dynamic behaviour of cadaver shoulders when impacted laterally is given from tests performed by Peugeot-Renault, and a force-deflection corridor has been proposed (Figure 6(9)). The quasi-static lateral compression of the shoulder with respect to the spine at a maximum force of 200N was found to be about 55mm with volunteers(16).

To encourage forward rotation of the shoulder when struck laterally, the centre of rotation must be posterior to the point of impact. However, there is no such position, using a fixed radius arm for the clavicle, that would allow the upper arm to clear the front of the chest and permit full rotation of the clavicle. It was also found that an initial transverse movement of the clavicle caused the inner flesh of the upper arm to bind on the chest flesh, inhibiting the subsequent forward rotation required. The solution found to these problems was to design the clavicle as a cam so that as the shoulder rotates forward, the instantaneous center of rotation moves forward allowing the arm to clear the chest (Figure 4). The shoulder is made from polypropylene and has survived rigid wall impacts of 9m/s (20m/h).

The maximum compression at the acromion with respect to the spine under 200N force was found to be 190mm. Lateral impact tests on the shoulder have been performed with a 23.4kg impactor, suspended on four wires, at 4.3m/s. The results are shown in Figure 5 together with the cadaver corridor. The dotted lines extend the corridor beyond the range of the cadaver tests.

New upper arms were built with the metal skeleton positioned towards the inner surface and with Sorbothane flesh, in order to reduce the inertia spike. It can be seen that for 90° impacts, the force-deceleration curves correspond to the cadaver corridor.

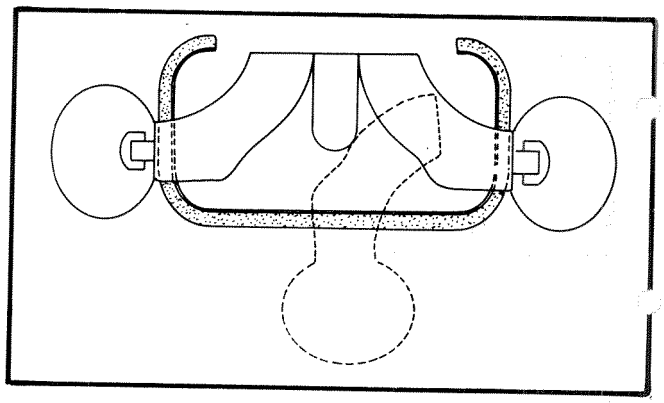

Figure 4. Diagram of shoulder cam (top view)

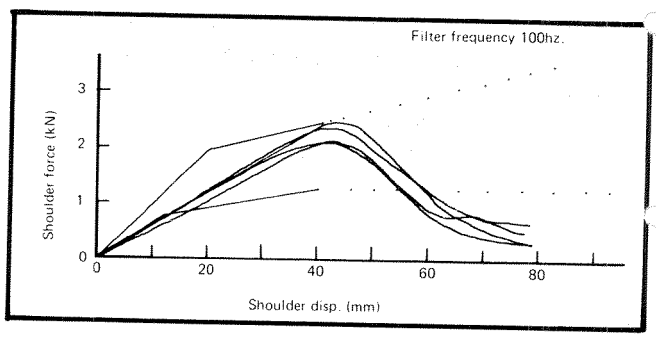

Figure 5. Force displacement results for lateral impacts to the shoulder with a 23.4kg pendulum at 4.3m/s

Table 5 shows the peak forces generated for non-impacts. It can be seen that the shoulder cam works well for perpendicular impacts and for impact directions aft of perpendicular. At impact directions of 10° or more of perpendicular, the peak force rises and the arm does not rotate forward.

Chest

The design requirements given(10) call for a chest divided into three separate regions or ribs, of which the deflection of each can be measured. There are three prime sources of cadaver reference tests that have been used as the performance basis for the chest. These are (i) the cadaver drop tests performed by the Peugeot-Renault Association(4) from which force-deflection and force-time corridors have been obtained(4,17,18), (ii) the impactor tests performed on cadaver tests by HSRI (now UMTRI)(8) from which impactor force and rib acceleration curves have been obtained, and (iii) the rigid and padded wall tests performed at Heidelberg for NHTSA(19), which give impact force, rib, and spine acceleration curves(20).

The APROD rib, piston, and cylinder concept for the chest mechanism has been adapted for the EUROSID chest. The pistons have been increased in length so the

Table 5. Peak shoulder force in pendulum impacts

Direction of impact	Perpendicular				Aft			Forward		
	90°	90°	90°	90°	100°	110°	120°	80°	70°	60°
Peak force (kN)	2.37	2.17	2.55	2.14	1.84	1.64	1.64	3.04	4.58	4.91

separation between the two bearings inside the cylinder is now much greater (Figure 6). This has eliminated the occasional occurrence of piston jamming seen with earlier designs. However, this has also meant that the chest can collapse from one side only. To make the dummy suitable for testing on both sides of a vehicle, the rib-piston assemblies are individual units that can be removed easily from the spine and inverted so the piston is now on the opposite side of the dummy. The three rib-piston assemblies are identical, which means they can be calibrated off the dummy and replaced individually if necessary.

A mathematical model of the thorax(21) was used to help with the development of the EUROSID chest. It became clear at an early stage that it was necessary to incorporate damping into the chest and also in the representation of the skin. The model used is shown in Figure 7.

The objective was to find appropriate values for the spring stiffnesses, damper coefficient, and rib mass that would match the model response to the three cadaver bases. Rib response was found to be critically dependent on the flesh characteristics and rib mass, but relatively unaffected by the rib spring and damper factors. Also thorax force-time curves were the only responses available for all three cadavar bases. Therefore, this was the response used primarily as the basis for selecting the chest spring and damper properties.

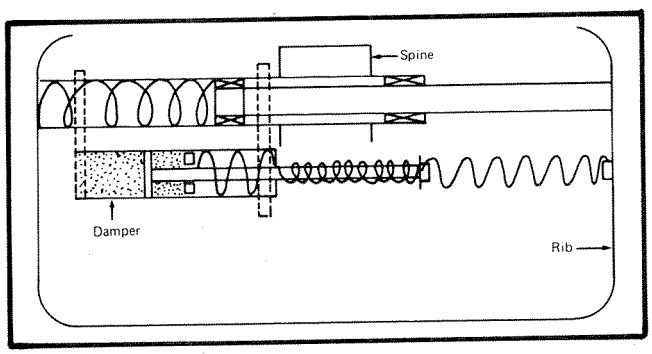

Figure 6. Diagram of rib—piston—damper module

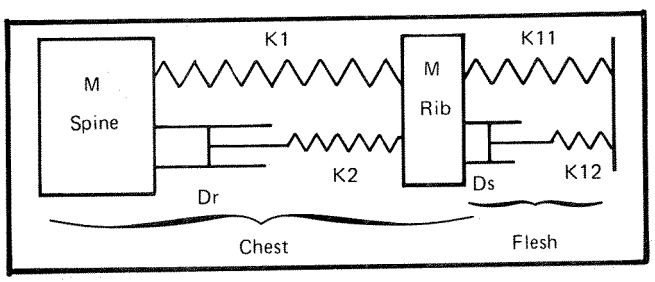

Figure 7. Mathematical model of thorax

Despite the incorporation of a damper into the model, no combination of springs and damper could be found that would give a good match to all three data bases. Either this representation of the thorax is too simple or the cadaver data bases are incompatible. Simulations using the model suggested that suitable initial values for these components would be K1 = 15kN/m, K2 = 30kN/m, and Dr = 250N/m/s.

Preliminary testing using a pendulum impactor showed that, mechanically, this design worked well. However, the provision of a pivot between the rib and piston made the thorax more sensitive to impact direction than if the link were solid. A supplementary leaf spring was provided behind the main rib to prevent plastic bending of the rib at this point.

Some difficulty was experienced in obtaining a suitable damper since most commercially available shock absorbers are carefully designed to produce a rising force coefficient with stroke. Armstrong Patents have developed a suitable adjustable damper by modifying a production model.

Simulations of the pendulum impact on the thorax suggested there would be a high inertia spike at the start of the impactor force curve, caused by the rapid acceleration required to raise the velocity of the rib over a very short period. This prediction was confirmed by the first pendulum impacts onto the thorax. The model showed this could only be reduced significantly by reducing the mass of the rib as much as practical or by the addition of an unrealistic amount of flesh to the side of the thorax. The effective mass of the ribs was reduced by replacing the solid steel pistons with hollow aluminum pistons. This inertia spike was further controlled by the use of 10mm sorbothane as flesh attached to each rib.

The deflection of each rib is measured by using a reflecting graticule attached to the piston and an optical transducer attached to the cylinder, following the method used on the APROD dummy.

The results of the HSRI cadaver tests using a 23.4kg impactor(8) have been normalised following the method

given by Mertz(17) adapted for a two-mass system. Performance corridors generated from these normalised curves, together with the impactor and spine accelerations measured in tests on the prototype thorax, are shown in Figures 8 and 9. As predicted by the simulation model for the spring and damper coefficients chosen, these values of thoracic acceleration rise above the maxima of the corridors. However, the pulse duration and general shape of the curves are in close agreement with the cadaver results.

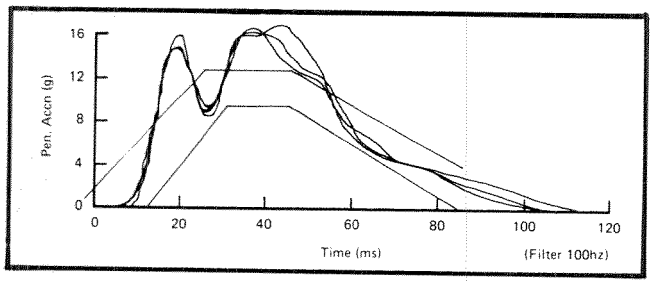

Figure 8. Acceleration of impactor striking prototype thorax at 4.3m/s compared with corridor derived from HSRI cadaver tests

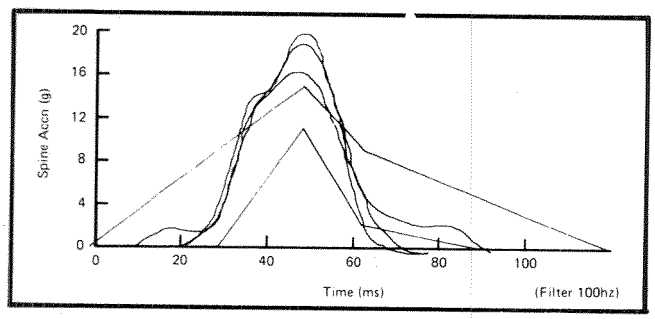

Figure 9. Spine acceleration for pendulum impacts to thorax at 4.3m/s compared with corridor derived from HSRI cadaver tests

Preliminary testing with the first prototype thorax attached to a Part 572 pelvis and legs, following the procedure used in the Heidelberg study(19,20), showed some anomalous results. The spine acceleration in the 15m/h (6.7m/s) and 20m/h (8.9m/s) rigid wall tests showed two distinct pulses. Close examination of the relative times of the spine acceleration and the rib acceleration and displacement showed that the first spine acceleration pulse occurred before the rib-piston springs had compressed (Figures 10 and 11), suggesting that the shoulder might be transmitting a significant force to the spine. A repeat of the test at 15mi/h (6.7m/s) with the shoulder held forward produced a spine acceleration duration that was much closer to cadaver results(20), although the amplitude was slightly too high compared to the cadavers (Figure 12).

It appears that, at impact speed of 15mi/h (6.7m/s) or greater, while the shoulder does rotate forward, it does

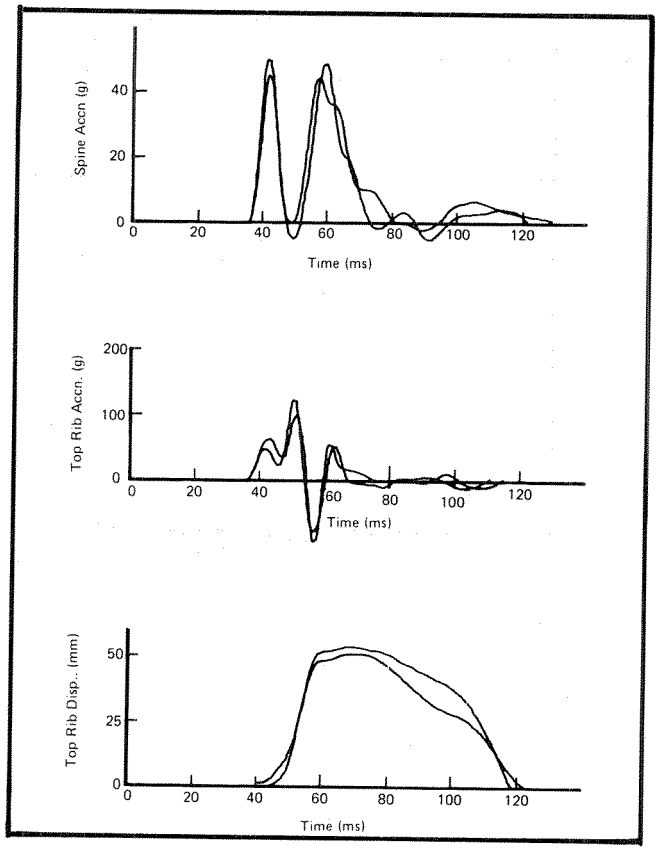

Figure 10. Rigid wall test on EUROSID thorax—15m/h

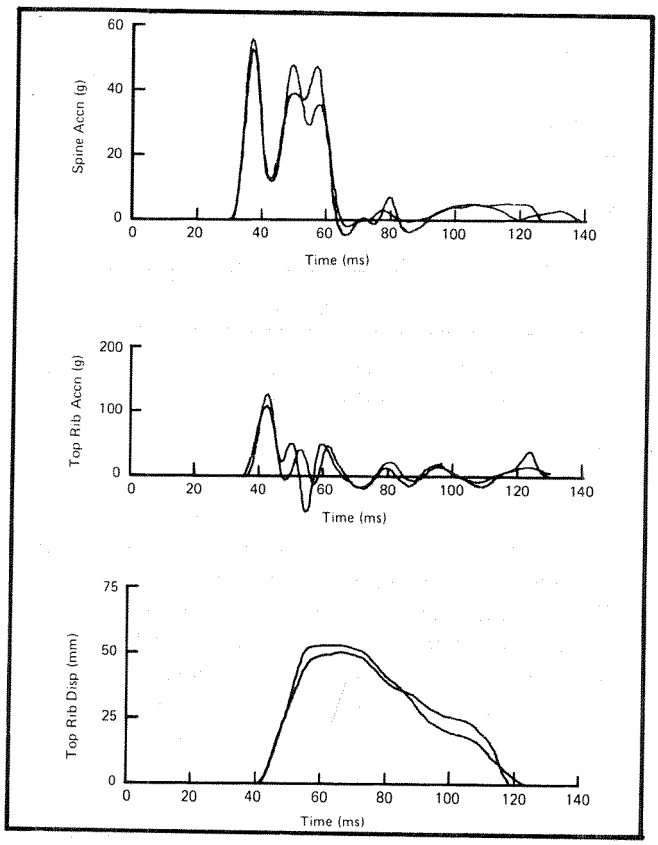

Figure 11. Rigid wall test on EUROSID thorax—20m/h

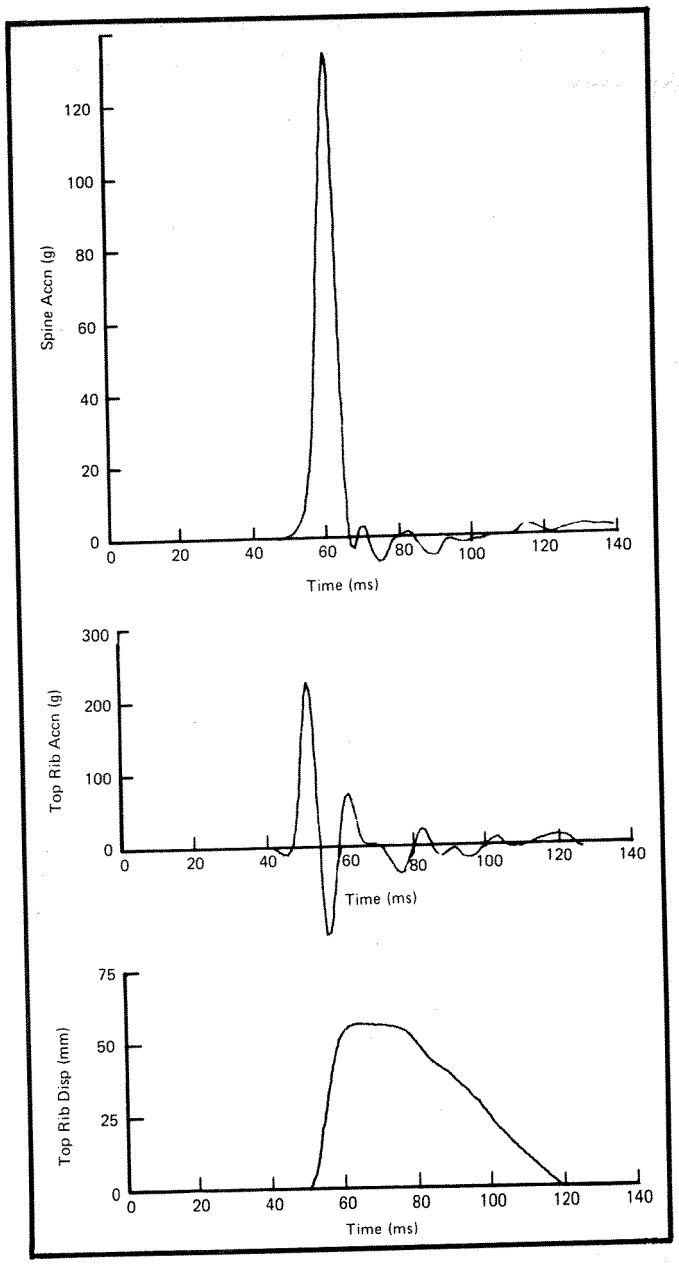

Figure 12. Rigid wall test on EUROSID thorax with shoulder rotated forward—15 mi/h

not do so sufficiently rapidly if the whole torso, including the shoulder, strikes a flat rigid plate.

This shoulder-induced spike was not observed in a 15m/h (6.7m/s) padded impact where the APR padding block top surface was below the shoulder. It should be noted, perhaps, that in most vehicles, the shoulder will be in the area of the side glazing and above the metal structure of the door.

A revised prototype thorax is under construction with more accurate dimensions and mass, and this will be tuned to the published cadaver data.

Remarks on the Thorax

A prototype thorax has been constructed whose shoulder can rotate forward, taking the arm clear of the side of the chest and with a rib cage that can measure deflection on three individual rib units. The chest is tuneable by means of replaceable springs and adjustable dampers, and can withstand repeated 20m/h (8.9m/s) rigid wall impacts without failure or jamming.

Abdomen

The abdomen section for the EUROSID side impact dummy should interact in a humanlike manner with any structural component of a tested car in a side impact to assure correct kinematics of the complete dummy (biofidelity). In addition, the abdomen section must measure the injury parameters or detect exceedance of the set human tolerance limits (measurement function)(10,22). The EUROSID abdomen has been designed by TNO on the basis of lateral drop tests of various cadavers impacting a rigid armrest, which were performed by the Association Peugeot-Renault(23,7).

Peugeot-Renault defined from the cadaver tests a force-deflection corridor that is valid for the mid-abdomen (120mm space between lower rib and iliac wing of pelvis) impacted by a 7cm-wide flat armrest at a velocity of 6.3mi/s. They also established tolerance values of a maximum force on the abdomen of 4,500N and a maximum allowed penetration of 40mm, both corresponding with an AIS 3 value(22). These formed the design requirements for the hardware (Figure 13).

The principle of the EUROSID abdomen section is a metal drum that is rigidly attached to the lumbar spine-thorax box interface of the dummy. This drum is covered by a flexible material up to the outside contour of the abdomen that allows a penetration of 40mm before "bottoming out". Between this flesh-simulating material

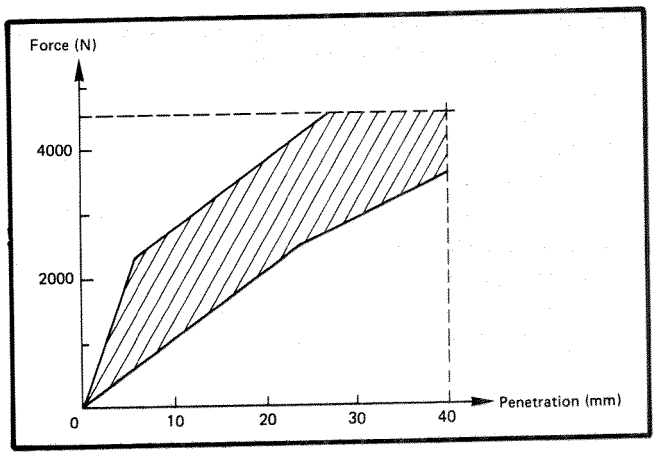

Figure 13. Force-deflection corridor for abdomen section, based on APR cadaver tests

and the rigid drum are located three vertical steel leaf-spring switch units. These switch units can be individually adjusted to trigger at an externally applied force level of 4,500N.

To obtain correct biofidelity up to the point at which the tolerance levels are exceeded, it was necessary to add to the flesh-simulating polyurethane foam a certain amount of mass. This mass is obtained by moulding a total of 1.5kg of small lead pellets in the outside contour at the impacted side (Figure 14). The resulting force-deflection response is then of a degressive form fitting into the design corridor. The first series of prototypes as described by Maltha(7) were tested by various laboratories in Europe and the United States. These tests showed some shortcomings with respect to the response and interference of the mass-carrying rubber/lead slab in side bending of the dummy.

For this reason and to obtain a better interfacing with the EUROSID pelvis and thorax sections, the abdomen has recently been completely redesigned. This redesigned abdomen has not yet been tested, but there is good confidence that the response will be in the design corridor and the switches can be easily calibrated to the correct force-trigger level.

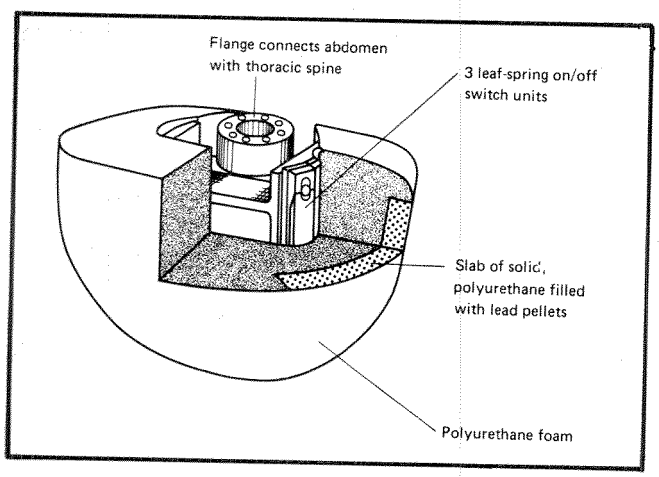

Figure 14. TNO abdomen section with lead pellets on impacted side

Pelvis

Main Specifications for the Pelvis of the EUROSID Dummy

The external shape of the pelvic bone should be realistic the legs of the Part 572 dummy at the level of the upper extremities of the femur force transducer and to the torso at the lower extremity of the Part 572 lumbar spine.

The external slope of the pelvic bone should be realistic and, especially, it must be representative of the shape of the human pelvis at the points directly involved in a side impact and at the interactions with the car seat as well as at the iliac crests where the seatbelt fits around the pelvis. Its design should consider the deformation capability of the pelvis bones as well as of the flesh.

The motion capability of the femurs relative to the pelvis is considered of great importance, and an abduction of 30° seems the value to be considered in the design of the hip joint.

The EUROSID should permit the measurement of pelvic acceleration, if possible, at the same locations as on the Part 572.

The flesh in the area at the side of the pelvis liable to be struck should be sufficient to comply with the likely requirements and sufficiently durable that it should not deteriorate significantly during many impacts.

Design of the EUROSID Pelvis

The geometry of the pelvic girdle was analyzed by Reynolds et al., and this study was followed by a plaster model of the 50th percentile male pelvis(24).

The shape of the EUROSID pelvic bones is based on this model: Figure 15 shows the EUROSID pelvic bone.

The external shape and the important points such as the pubic symphysis, the H point, and the center of L1 are in the same location on the EUROSID pelvis as on the human pelvic model. The hip articulation of the EUROSID pelvis is intentionally different from the human one: to minimize the effect of the leg position on the pelvic loading, the external forces are transmitted to the pelvis along an axle passing through the hip ball joint. To increase the energy absorption capability, the EUROSID pelvis has the part of the flesh that is directly compressed by the impact made from Sorbothane.

The EUROSID pelvis is designed to measure pelvic compressive forces as well as pelvic acceleration. The compressive force is measured in the pubic symphysis area with a force transducer and on the iliac wing with a strain gauge. The pelvic acceleration is measured at the same location as on the Part 572 dummy.

Results of Validation Tests

The new pelvis of EUROSID was tested in conditions similar to the cadavers used for pelvic tolerance study in side impacts(25).

A series of eight tests at four different speeds (25, 30, 35, and 40km/h) were conducted with the same impactor used for cadaver tests.

Test results show a great sensitivity of the pubic force to the increasing of the impactor speed. When the impactor speed increases from 25 to 40km/h, the maximum of the pubic force is increased by 260 percent. This is important because in side impacts the speed of the side

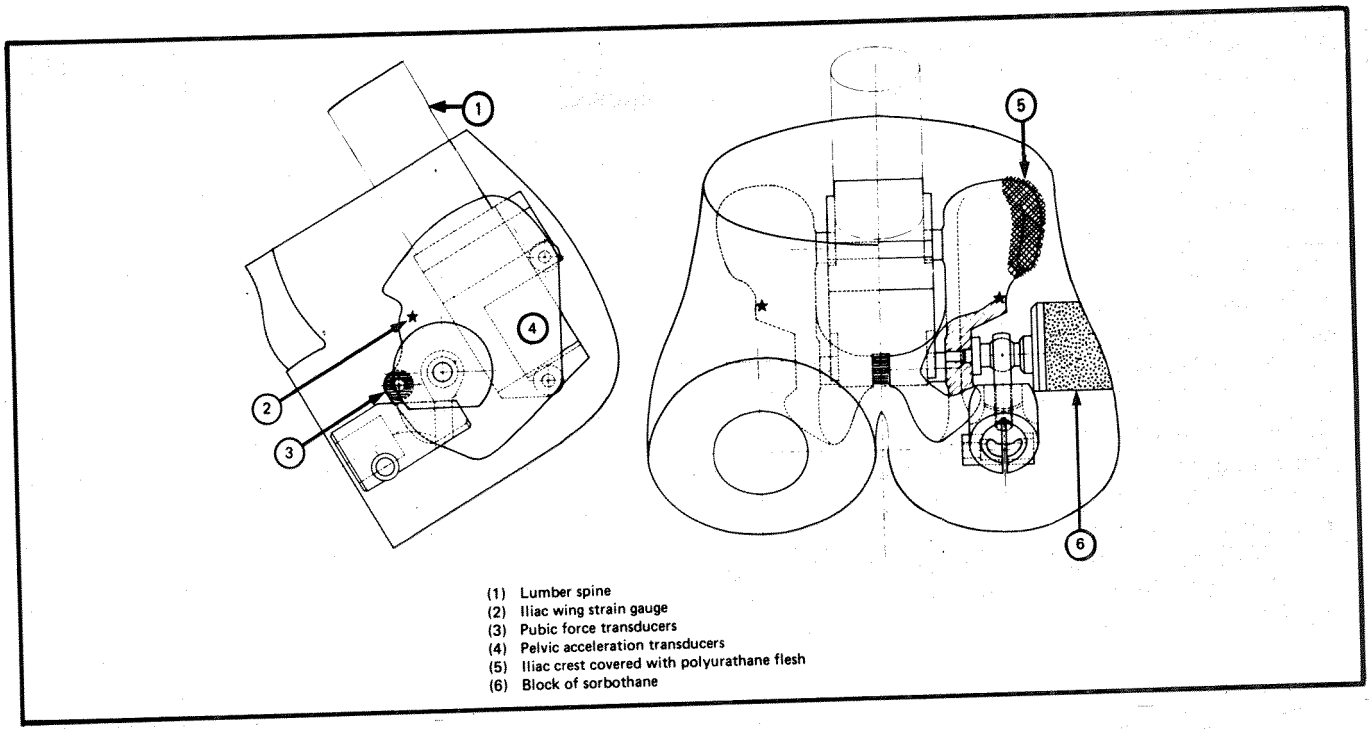

Figure 15. EUROSID pelvis diagram

panel at the time of contact with the occupant is the parameter that is considered related to the severity of the impact, and the motion of this side panel is simulated by the impactor.

The only parameter that was recorded on dummies and on cadavers in all the tests is the transverse pelvic acceleration. Figure 16 presents the maximum values of pelvic transverse acceleration of cadavers and side impact dummies relatively to impact speed. This figure shows clearly that the EUROSID pelvis sustained for the same impact speed a higher acceleration than the cadavers but lower than the other side impact dummies. Moreover, the repeatability of results seems better for the EUROSID: for the three tests conducted at 35km/h, the average of maximum pelvic acceleration is 149.37g and the corresponding standard deviation 4.96g (3.3 percent). For the other dummies, the values vary from 4.88 percent for the ONSER dummy to 9.93 percent for the DOT-SID.

The first tests performed with a dummy fitted with this pelvis show that—

1. The compressive force recorded on the pelvis is directly related to the impact speed.
2. Compared to cadavers, the EUROSID pelvis gives higher injury parameter values but clearly lower values than other side impact dummies.
3. Although the evaluation of durability and repeatability needs a larger number of tests, the pelvis sustained 25 impacts at a speed range of 25 to 40km/h without any damage either to the skeleton or to the flesh, and three tests performed at the same conditions gave very close results.

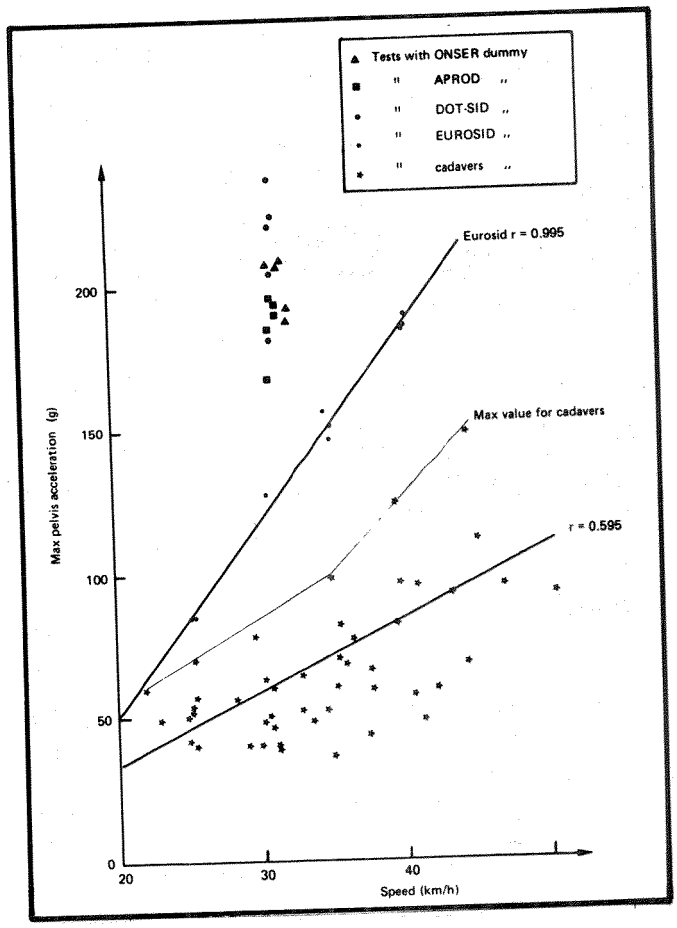

Figure 16. Pelvis acceleration versus impact speed tests with circular impactor

Conclusion

A prototype side impact dummy has been constructed from a basis of accident investigation, biomechanical studies, and the experience gained from the development and evaluation of three side impact dummies carried out in the EEC Biomechanics Programme 1978-1982. The EUROSID dummy is capable of measuring potential injury risk to the head, thorax, abdomen, and pelvis. Although test experience may suggest one or two final adjustments to the design, it may be agreed this has been a successful collaborative effort between laboratories within Europe coordinated by the EEVC Ad-Hoc Group on Dummies.

The prototype has been constructed from components produced in France, the Netherlands, and the United Kingdom, together with a head and legs purchased from the United States. This prototype will now be evaluated as a complete dummy and refined to a state where it will be usable in legislative tests, such as that proposed by ECE, and other side impact tests.

Advanced Anthropomorphic Test Device Concept Definition

John W. Melvin
The University of Michigan

Abstract

This paper summarizes the results of Phase 1, Concept Definition, of the AATD program and identifies the reasons such a new test device is needed. The following areas are addressed: (1) injury priority from accident data; (2) current dummy design, use, and potential improvements; and (3) technical characteristics and design concepts for a new AATD, its data processing, and its certification systems.

Overview

Phase 1 of the AATD program[1] has shown that there is a need to develop a new anthropomorphic test device that has humanlike response in frontal through lateral as well as rollover impact directions, interacts realistically with restraint systems and the vehicle interior, is capable of making numerous meaningful measurements of injury assessment, is durable and easily maintained, and can be certified without disassembly. Because of the necessary time lag between design and production, current dummies are not based on currently available data. A greatly improved and expanded biomechanical data base has been developed in Phase 1, and these data form the basis for defining impact response characteristics necessary to insure that the AATD will perform in a humanlike manner.

The new dummy will have significant advantages over current ATD's. First, its shape in the seated configuration will be based on actual mid-sized-male-seated anthropometry, which will contribute to more realistic interaction with the vehicle seat and other components. Second, it will have biofidelity in frontal, oblique, lateral, and vertical impacts, to be achieved through such features as a deformable face, a multidirectional neck and chest, and a flexible thoracic spine. Thus, only one dummy will be needed for crash-testing purposes, and it will give realistic trajectory, contact-point, and loading results. Its humanlike response will also allow many more meaningful engineering maesurements to be made, which will in turn greatly enhance injury assessment capability. Next, its materials will be durable, and its designs will be rugged and repeatable but cost-effective to manufacture. Materials will be selected to minimize the sensitivity of the AATD to temperature variations. Finally, the certification process will be more efficient and repeatable between laboratories, to be achieved through the use of a whole-body certification fixture with a dedicated data processing system.

[1] Primary participants in this program include N.M. Alem, O. Carsten, J. O'Day, D.H. Robbins, and K. Weber of the University of Michigan; P. Begeman, R. Cheng, A.I. King, and G.W. Nyquist of Wayne State University; R.H. Arendt, P.M. Miller, and D.J. Segal of MGA Research Corporation; J. Smrcka of Alderson Research Laboratories, Inc.; R.H. Eppinger and M. Haffner of the National Highway Traffic Safety Administration.

In the following sections, the results of various aspects of this program are summarized. First, we describe an analysis of accident data to determine the priority of injuries to be addressed, based on estimated cost to society. Then we present findings on the design and use of current ATD's along with suggestions for how dummies could be improved. Finally, we summarize the technical characteristics and design concepts proposed for the new AATD and for its data processing and certification systems.

Another major task in the AATD program, not summarized here, was a review of literature on biomechanical impact response and injury in the automotive environment. This review incorporates published research available through the end of 1984 and includes chapters on the head, spine, thorax, abdomen, pelvis, and lower extremities. Each chapter addresses the anatomy, clinical injury experience, and results of laboratory impact studies for the various regions. The experimental studies include information on biomechanical response to impact as well as injury mechanisms, tolerance, and criteria. For the full review, see Melvin and Weber(1).

Injury Priority Analysis

An analysis of the National Accident Sampling System (NASS) data for 1980 and 1981 places the cost of individual or aggregated groups of injuries in perspective relative to the cost of society for all AIS 2-6 injuries to automobile occupants. The NASS files were first augmented to incorporate an impairment factor that goes beyond the Abbreviated Injury Scale (AIS) by taking into account the consequences of an injury as determined by two panels of physicans as well as a percentage impairment based on American Medical Association guidelines(2). Then a factor was generated from an economic cost model to account for expected lifetime earnings had an individual person not been injured. The impairment factors for the actual NASS injuries were multiplied by the expected earnings factors for individual injured persons to create an Injury Priority Rating (IPR). These IPR's were then aggregated by body region, direction of force, and delta V and expressed in terms of a percentage of total IPR. Tables 1 through 3 show these distributions, which indicate the relative contribution of each grouping of injuries to the total societal cost of injuries to automobile occupants. It should be noted that the occupants sustaining these 2,262 injuries were nearly all unrestrained.

The primary conclusions from these and further bivariate analyses are as follows:

1. The combination of the head, face, and neck body regions accounts for 60 percent of the IPR to passenger car occupants.

Table 1. IPR distribution by body region

Body Region	Distribution (%)	Body Region	Distribution (%)
Head	44.6	Ankle/Foot	0.6
Face	10.5	Lower Limb	0.0
Neck	5.1	Upper Arm	1.3
Shoulder	0.3	Elbow	0.5
Chest	18.9	Forearm	1.3
Back	1.6	Wrist/Hand	0.4
Abdomen	7.5	Upper Limb	0.3
Pelvis	1.1	Whole Body	0.9
Thigh	2.1	Unknown	0.2
Knee	1.6		
Lower Leg	1.0	TOTAL	100.0

Table 2. IPR distribution by direction of force

Direction of Force	Distrubution (%)	Direction of Force	Distribution (%)
1 o'clock	4.8	9 o'clock	3.3
2 o'clock	9.8	10 o'clock	7.9
3 o'clock	3.5	11 o'clock	5.0
4 o'clock	0.0	12 o'clock	36.9
5 o'clock	0.1	Nonhorizontal	16.1
6 o'clock	0.7	Unknown	10.4
7 o'clock	0.3		
8 o'clock	1.2	TOTAL	100.0

Table 3. IPR distribution by delta V

Delta V	Distribution (%)	Delta V	Distribution (%)
1-5 mph	0.1	41-45 mph	1.5
6-10 mph	0.6	46-50 mph	0.0
11-15 mph	2.0	51-55 mph	2.7
16-20 mph	4.3	>55 mph	3.8
21-25 mph	7.0	Unknown	68.9
26-30 mph	4.9		
31-35 mph	2.6	TOTAL	100.0
36-40 mph	1.5		

2. The combination of the chest, back, and abdomen body regions accounts for 28 percent of the IPR to passenger car occupants.
3. Over one-third of driver IPR occur from collisions with a 12 o'clock direction of force. One-fifth result from collisions with nonhorizontal directions of force.
4. Oblique side collisions account for more IPR than direct side collisions. This applies both to drivers and to right-front passengers. Thus, 9 o'clock collisions account for 4.3 percent of

driver IPR but 10 and 11 o'clock collisions account for 11.9 percent. Similarly, 3 o'clock collisions account for 9.4 percent of IPR to right-front passengers; 1 and 2 o'clock collisions account for 19.2 percent.

5. Using only known values of delta V, 84 percent of the driver IPR with a 12 o'clock direction of force result from severe crashes, i.e., those with a delta V greater than 20mph. For right-front passengers, the figure is 97 percent. However, it should also be noted that, for cases with known delta V, 81 percent of driver IPR and 77 percent of right-front passenger IPR was attributable to crashes with a delta V of 45mph or less.
6. Again, using only cases with known delta V, 66 percent of driver IPR for injuries to the head, face, and neck result from severe crashes. For injuries to the chest, back, and abdomen, the comparable figure is 81 percent; for injuries to the upper extremities, 45 percent; and for injuries to the lower extremities, 93 percent. Thus, one might conclude that, for drivers, serious injuries to the upper extremities are the easiest to prevent because a higher proportion of them occur in less severe crashes. Next would come the combination of the head, face, and neck, followed by the combination of the chest, back, and abdomen, and last the lower extremities.
7. Comparison of IPR with the earlier Harm model(3) indicated that the two models were in complete agreement in assigning relative priority to the directions of force in the 1980 and 1981 NASS data. When ranking body regions, however, the IPR model gives higher priority to the head, face, and neck, and correspondingly less prominence to the chest, abdomen, and extremities. This is because of the relatively severe long-term consequences of injury to the head, face, or neck.

Because of limitations in the data, it was not always possible to depict, to the extent desired, the crash environment in which the IPR to the various body regions was incurred. In particular, the high rates of missing delta V meant that analysis of crash severity was often not possible. Another concern is with the comparatively small number of occupants in the NASS files that sustain serious injuries. The 1980 and 1981 NASS files combined have only some 2,262 injuries of severity AIS 2 or greater to passenger car occupants.[2] These injuries are sustained by 1,262 occupants. There are a total of 15,378 passenger car occupants in the combined 1980 and 1981 files. Thus, 92 percent of the occupants sustain no injuries, injuries of AIS 1, or injuries of unknown severity.

[2] This figure includes some injuries originally coded with an AIS of 7.

One solution to the shortage of cases for analysis is to incorporate additional years of NASS. It is hoped that the 1982 NASS data can be added to the existing data structure so the analyses reported here can be run with additional confidence and perhaps be extended to include such issues as contact point in more detail. Another solution would be to revise the threshold for the inclusion of cases in the NASS system or to sample at higher rates cases in which injuries greater than AIS 1 are sustained. Such a revised sampling scheme could be combined with reducing the amount of investigation carried out on cases with no injuries or minor injuries.

Finally, the reader should bear in mind that the model used here is not completely satisfactory. In particular, it does not take into account the fact that a single person may have sustained more than one injury. It is hoped to pursue the development of a multi-injury model in the future.

For further details on this analysis, see Carsten and O'Day(4).

Review of Dummy Design and Use

Dummy User Survey Results

A survey of users of the Part 572 and Hybrid III dummies was taken to determine the problems these users have encountered and their preferences for changes and improvements in dummy design. General topics included mechanical design, serviceability and maintenance, durability, certification, repeatability and reproducibility, and ease of use. The survey questionnaire was made available to a wide audience through NHTSA, SAE, ISO, and various individual contacts.

Responses were received from 38 individuals representing 29 organizations. The affiliation of the 38 respondents can be categorized as follows:

7	U.S. vehicle industry
9	Foreign vehicle industry
12	U.S. government
4	Foreign government
2	Dummy manufacturing
4	Independent research

Throughout the responses to this survey, a strong emphasis was placed on the need for a durable, stable, and repeatable test device, even at the expense of biofidelity. The lack of enthusiasm for an omnidirectional dummy, expressed by several respondents early in the survey, seemed to be based on an assumption that such a dummy could not be made to be as repeatable and reliable as a unidirectional test device, while retaining a suitable simplicity of design. Comments in later sections of the survey clearly indicated that considerable time and effort were required to prepare the Part 572 dummy for

testing, and that between-test repair, replacement, adjustment, and recalibration were frequent necessities. As the survey proceeded from theoretical design to more hands-on issues, the number of respondents decreased, but the conviction and level of detail of responses increased.

Respondents were generous with their advice as to how life with an anthropomorphic test device could be made easier. Designed-in means were needed for holding onto various parts of the dummy for transporting, positioning, and storage and for holding it fixed in space for certification tests. Also needed were visible indicators of the dummy's internal structural configuration and segment centers of mass. Joints were singled out as the assemblies in particular need of redesign. In addition, it was made clear that the performance characteristics of a dummy must be built up from the smallest components, but that performance checks of components in their assembled state were also necessary.

After reviewing the responses of this international group of dummy users, the term "advanced" in AATD begins to take on a broader meaning. Not only is there an opportunity here to advance the state of the art with regard to humanlike response and innovative instrumentation techniques, but there is a necessity to make significant design and materials improvements that will result in a more durable, repeatable, and trouble-free dummy.

Anthropometric Data and Biomechanical Response Simulation for AATD Design

This section indicates the anthropometric data available for use in developing design specifications for an AATD. The use of these data is also demonstrated in a limited simulation of dummy response using the CAL-3D crash victim simulation code(5). The parameters of particular interest are those associated with spinal flexibility and shoulder mobility, which are shown to play a major role in controlling torso and head motions and applied forces.

Anthropometric Data

Several data resources are available from the recently completed dummy anthropometry project on contract DTNH22-80-C-07502(6). These include mass and inertial properties, body surface shape, seated posture, estimations for the location of the bony structure, joint locations, and range of motion at the various joint structures. These data are all static and are for a midsized male driver in an average vehicle-seated posture. Mass and inertial properties are given for a traditional linkage and segmentation of the body in the static-seated posture. The mechanical term "linkage" implies the available data are most applicable to dummies or simulations based primarily on rigid-body mechanical models. The dummy response simulation presented later uses a lumped-mass, chain-linkage, dynamic simulation software package consisting of rigid masses connected at joint structures.

Details are given in the full report(7) of the body linkages used in the simulation, as well as data sources and methods for determining the segmentation of the shoulder, neck, thoracolumbar spine, and thorax. Of particular importance are (1) the division of the traditionally rigid thorax into one rib cage, three spinal, and two shoulder segments, and (2) the approach of coupling the rib cage to the spine to achieve mobility and rotation of the thorax with respect to the spine.

Mobility and range-of-motion data are in fair supply only for static mobility and voluntary motion. In other words, it is possible to estimate how far the segments can move with respect to each other before subjects say "ouch" or before outside forcing agents must be supplied to produce further motions. Similar quantitative data for dynamic mobility (dynamic motions voluntarily made or those that occur under the influence of an outside forcing agent, such as a deceleration device) are virtually nonexistent, except for the neck and, perhaps to a more limited extent, for the thoracic and lumbar spines. Dynamic torque data are not yet available for the thoracic and lumbar regions.

Other data necessary for simulating a dummy in a crash environment include force-deformation characteristics of various body regions and data on the crash event itself. Data sources included project literature reviews, accident data analyses, and vehicle specification packages.

Regarding the status of the anthropometry data base, it was concluded that the mass and postural data are available, but body segmentation needs to be refined to include spinal and shoulder girdle masses. The data base on joints also needs to be expanded to provide torque on joints versus relative angle of the segments. The most pressing need is for additional information on spinal flexibility and torsion properties.

Biomechanical Response Simulation

The purpose of this analysis was to study the effects of spinal and shoulder flexibility on whole-body response. Degrees of freedom not found in current dummies were added to the linkage model. Comparative results for stiff and flexible joints between the thorax components are presented for belted and unbelted occupants.

Figure 1 shows the difference in head excursion for 3-point-belted occupants with a flexible three-link thoracic spine versus a stiffer linkage similar to that used in current dummies. The positions are those at 100ms, and the more restricted forward head excursion with the stiff joints is apparent. For the unbelted case, there was a

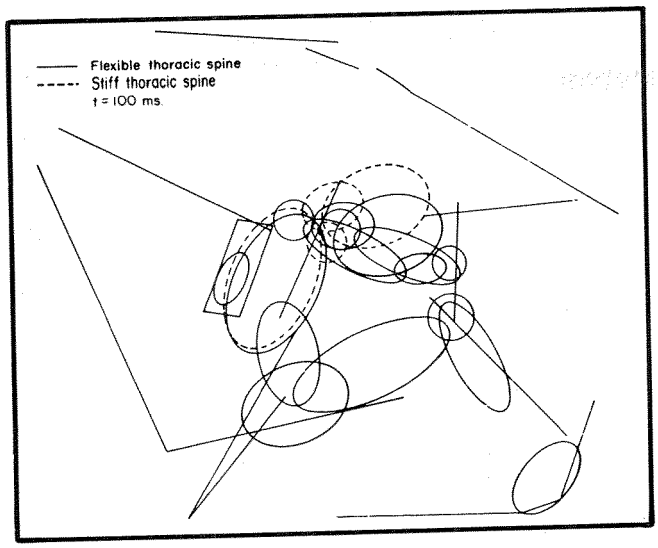

Figure 1. Effect of thoracic spine flexibility, belted case

marked reduction in the force of interaction between the thorax and the steering wheel when the shoulder masses were uncoupled from the thorax, even when the spine remained stiff.

It is clear from these exercises that crash victim simulation software can be used to study the effects of changing dummy design parameters. Specifically, it was shown that the addition of thoracic spinal flexibility has major effects on the crash victim motion. This is particularly noticeable in head excursion increases of several centimeters for belted occupants. In addition, it was shown that the uncoupling of the shoulder masses from the thorax has a major effect on the interactions of a crash victim with vehicle structures forward of the occupant, such as the steering column and the instrument panel.

ATD Critique

A review of current ATD designs was made from the standpoint of biofidelity, measurement capability, directionality, and impact testing performance. Details by body region can be found in Melvin et al.(7). Although a wide variety of currently available test devices was reviewed, primary emphasis is given here to the Hybrid III and the Side Impact Dummy (SID), since they represent test devices currently in use in research and development testing in the United States.

The Hybrid III was developed over 10 years ago, and its design is based on biomechanical knowledge available at that time. It is a frontal-loading-only ATD whose design represents an evolutionary improvement over conventional ATD design. For example, the rib cage uses the same design as the previous Hybrid II, but with altered structural stiffness to produce a humanlike impact response to midsternal moving-mass impactors. The Hybrid III also possesses humanlike hard-impact forehead response and midsagittal neck bending response. As presently configured, the Hybrid III has the greatest measurement capability of any ATD, with 44 data channels.

The SID was developed more recently than the Hybrid III and represents a modification of the chest region only in an otherwise standard (nonbiomechanical) ATD. The SID was developed to provide lateral chest response biofidelity under rigid and padded impacts. The shoulder response is included in the chest response, and, as a result, the design has no separate shoulder structure. The remainder of the SID structures are standard Part 572. Except for additional chest wall accelerations and lateral chest displacement, the SID has the same measurement capabilities as the Part 572 ATD.

Both the Hybrid III and the SID are examples of ATD's intended for use in restricted test conditions and/or directions, and as such they have only limited biofidelity in the principal directions and none in other directions. One of the most serious deficiencies of both ATD's centers around the designs of the thoraxes, both the rib cages, and the spines. The IPR analysis has indicated the great importance of the head and chest as primary sources of injury, disability, and death of unrestrained occupants. The development of effective countermeasures to minimize injury to these regions depends strongly upon having an ATD that produces realistic responses in terms of trajectories, contact points, and loadings. The combination of rigid thoracic spines with present neck designs (including that of Hybrid III) and inadequate thoracic rib-cage conformability are producing head contacts and chest/steering-system interactions that are quite unlike those in real-world crashes. All present ATD designs are quite inadequate in this respect in the crucial head/torso regions for frontal, lateral, and oblique impacts. The lack of realistic concentrated load response in the Hybrid III and SID chests is compounded for the case of shoulder-belt loading. Neither chest exhibits humanlike stiffnesses at the lower loading rates associated with belt restraint systems. This, again, will have an influence on both chest deformations and head trajectories.

To illustrate the improvement in overall effectiveness of an AATD with omnidirectional response and measurement capability in the frontal-to-lateral range, an analysis was made of the Hybrid III, SID, and AATD based solely on measurement capability and directionality. Direct-impact biofidelity was not taken into account. The IPR distribution for each body region (Table 1) was multiplied by the measurement capability of each ATD for each region, based on a rating of complete (100 percent) to partial (75 percent and 50 percent) to none (0 percent). This product was then apportioned according to the distribution of IPR to these body regions by direction of impact force. This process gave an estimate

of the proportion of the IPR addressed by each ATD in a given direction. An overall effectiveness of an ATD could then be estimated by summing these IPR proportions for the range of directions from frontal to lateral.

For the left-front unrestrained driver position, it was judged that the combination of Hybrid III and SID ATD's could address directions 11, 12, and 1 o'clock (Hybrid III) as well as 9, 10, and 3 o'clock (SID). The potential gap in the oblique direction between 10 and 11 o'clock is ignored to give the Hybrid III/SID the benefit of the doubt. The 2 o'clock PDOF, however, is not included because the SID is judged to be kinematically unreliable in far-side oblique impacts. In comparison, the AATD will be able to continuously address the full range of PDOF from 9 through 3 o'clock in a clockwise direction. In addition, the more extensive measurement capability to be available on the AATD will provide a higher level of injury assessment capability in those directions. Based on the above considerations, the AATD was found to address 90.5 percent of the total IPR (see Figure 2), while the combination of the Hybrid III and SID addressed only 43.4 percent. The AATD would thus be twice as effective as the combination of the two present ATD's.

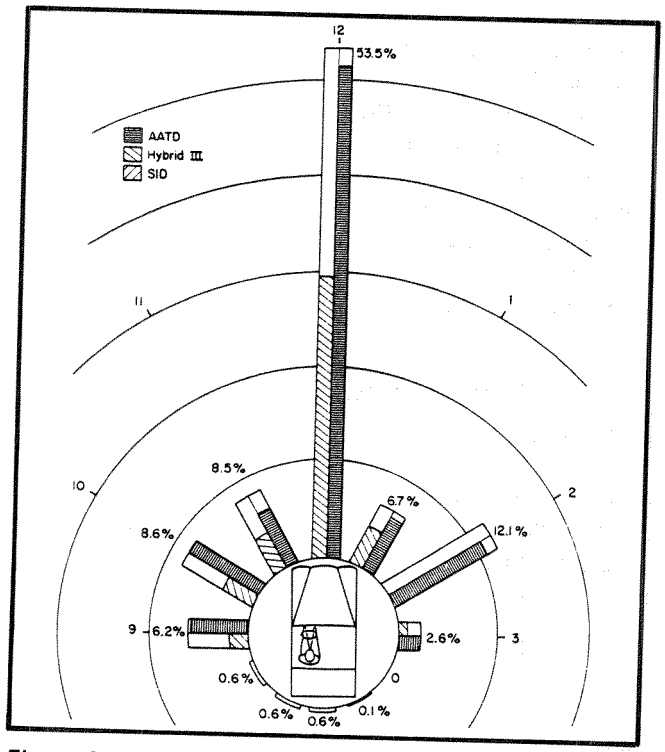

Figure 2. Estimated effectiveness of Hybrid III, SID, and ATTAD for unrestrained left-front occupants by principal direction of force (percentages denote proportion of horizontal force IPR in each direction)

Technical Characteristics and Design Concepts

This section brings together the results of our various reviews and analyses of accident data, biomechanical data, and other technical data to establish technical characteristics and to propose design concepts for the AATD and its data processing and certification systems. It is first necessary, however, to present a brief description of a major activity to develop a uniform biomechanical data base.

Biomechanical Data Base

Our ability to generate response corridors for specific body regions, but particularly for the chest, depended on the existence of a large data base whose signals could be analyzed in a uniform manner. Both previously unpublished data and those published data that warranted reanalysis were identified, consolidated, categorized, and recoded or given additional coding as appropriate. A total of 1,190 tests were initially identified by test number and source as candidates for inclusion in the data base. However, we were able to obtain and include adequate data for only 241 tests, consisting of the following:

1. A nucleus of 97 tests obtained from NHTSA that were already coded in the standard NHTSA biomechanics tape format
2. Four APR facial impacts and 41 ONSER pelvis impacts that were obtained from France on analog tapes and then digitized and coded at UMTRI
3. Fifty-eight tests conducted, digitized, and coded at UMTRI that included 26 NIOSH head axial impacts, 14 MVMA head side and frontal impacts, 11 GM whole-body sled tests, and 7 GM shoulder impacts
4. Twelve Heidelberg frontal and lateral sled tests and 5 FAT tests conducted at Heidelberg, both tapes having already been formatted

In addition, high-speed movies from 10 UMTRI thoracic tests were analyzed, and film readings were reformatted as "displacement" signals and incorporated with their corresponding sensor data. Finally, 10 Heidelberg tests containing 9 accelerometer signals were converted to the standard anatomical reference frame.

Various parameters were used as the basis for classification of the tests. These included (1) restraint type or impact surface, (2) severity of impact, in terms of impact velocity, (3) injury level, in terms of AIS rating, and (4) the subject size and condition. Test signals were further subdivided by body area, including the head, chest, spine, shoulder, and lower extremities. Once these groups were established, spectral analysis of each group was conducted to determine an appropriate filter to use for preprocessing. A procedure was developed to extract filter characteristics from the available pool of signals, and filter corners and

slopes were obtained for the near side and far side of impact for the chest and head. The area determined to have the highest priority for response characterization was the thorax, and thus emphasis was placed on generating corridors for rib and sternal accelerations. Summary data plots of chest response for a variety of test conditions (shoulder belt, airbag, rigid wall, and rigid disc) were prepared, the data having been filtered and mass-scaled. These are the basis for the performance specifications of the chest.

AATD Technical Characteristics and Design Concepts

The AATD will be designed to provide omnidirectional response in the range of ± 90° from the front in the horizontal plane. This accounts for virtually all the horizontal collision IPR and 82 percent of all IPR with known principal direction of force (PDOF). The exposure severity levels associated with cumulative values of 85 percent of the IPR are delta V's of 50mph for frontal impacts and 30mph for lateral impacts. It is expected that the AATD would be used unrestrained in such severe environments only if the vehicle structures and interiors to be tested incorporated advanced crashworthiness technology. Thus, these delta V levels are taken to be upper-limit exposure levels for the velocity of interaction with protective interior systems. The AATD will also be designed for upper-body vertical (superior-inferior) impact associated with nonhorizontal collisions. Such collisions account for 18 percent of all IPR with known PDOF.

Measurements to be made by the AATD are based on an analysis of ideal versus feasible measures. This analysis identified measures that would be desirable for injury assessment, given that an ideal test device could be developed that could reproduce all the anatomy and biomechanical responses of the human body. These were tempered by the state-of-the-art of measurement technology, and measurements were determined that would be consistent with the AATD design concepts for each body region. These measures are included in the following summaries of the desired technical characteristics and associated design concepts for the AATD, schematically presented in Figure 3.

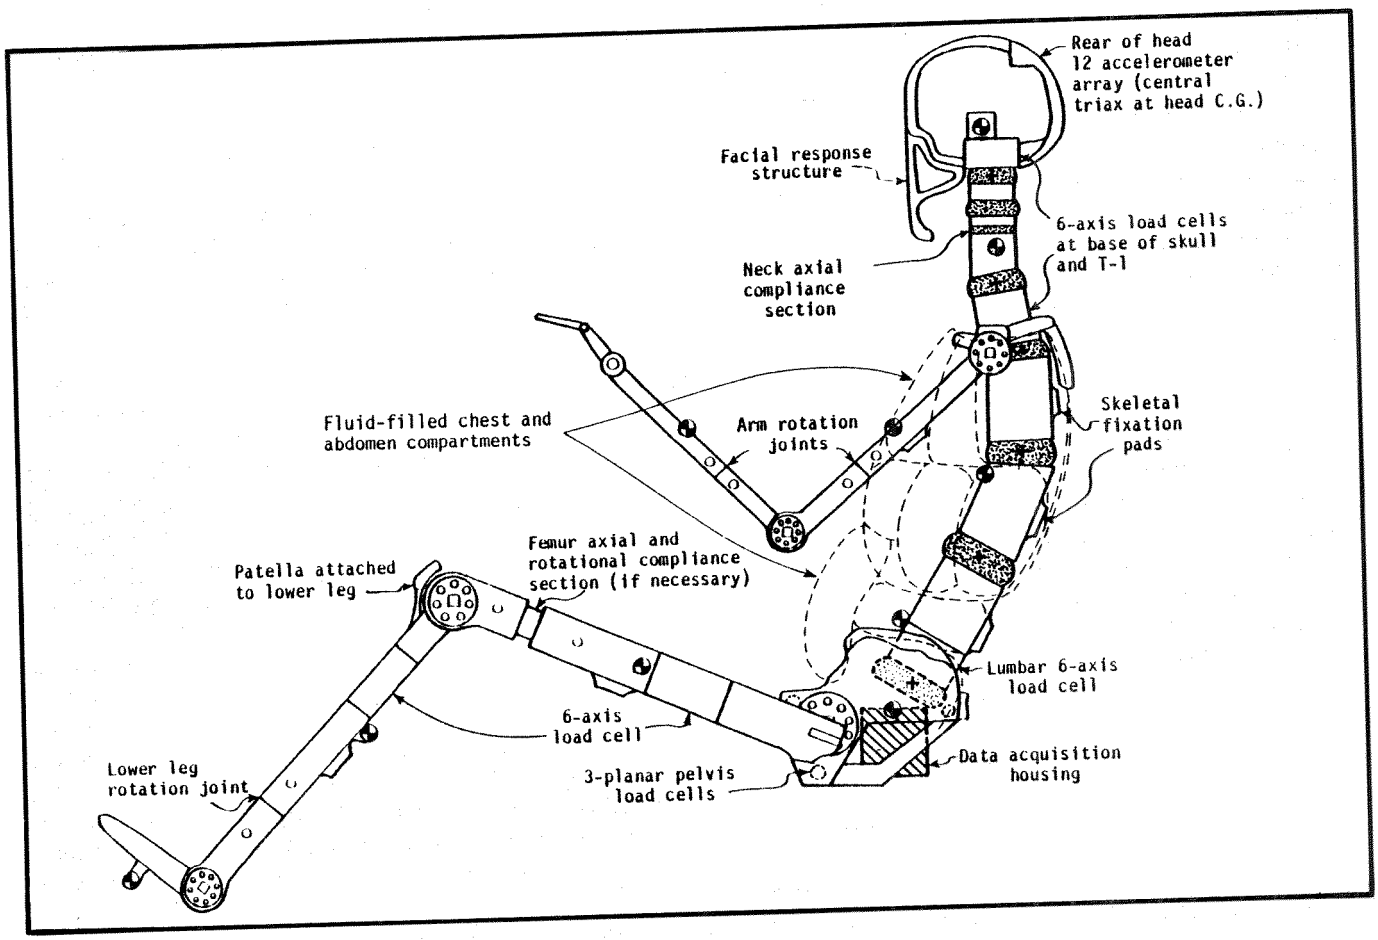

Figure 3. AATD design concepts

Head

The head will have biofidelity of response for front, side, and top rigid impacts as well as facial impact response biofidelity. Head instrumentation will consist of an array of 12 linear accelerometers to provide complete three-dimensional impact motion measurement as well as direct head center-of-gravity translational acceleration measurement. Certification testing procedures for head response will not require disassembly of the AATD.

The head will have a featureless face to aid in producing repeatable impact response. In addition, the facial structure will be designed to produce realistic head acceleration responses when the head is impacted in the face by a rigid mass. This face will be a durable structural element that can, however, be removed and replaced with an optional frangible insert for determination of facial bone fracture. The overlying soft tissue simulation of the face would similarly be replaceable with a lacerable option.

The skull of the AATD will be of cast aluminum with the front, side, and top sized to produce, in conjunction with the scalp material, biofidelity of rigid impact response. The base and rear structure of the skull will be separate from the front/side/top structure and will be designed as a mounting structure for a 12-accelerometer motion measurement array made up of four triaxial accelerometer units. As such, the base and rear structure will be very stiff to preserve the accelerometer alignment during rigid impacts to the head. The array will be configured to put one of the triaxial units at the head center of gravity for direct measurement of translational acceleration at that point and for subsequent HIC determination. The base of the skull will also serve as a mounting structure for a six-axis neck load cell.

Spine

The spine will be designed as a total system from the base of the head to the top of the pelvis. Spinal flexibility will be provided for the cervical, thoracic, and lumbar spine segments. The neck section of the spine will have biofidelity of response for frontal, lateral, and oblique indirect impacts. The specifications for these responses are based on analysis of human volunteer sled tests. These data provide static neck joint stiffness characteristics in bending (flexion, extension, and lateral), axial loading (tension and compression), and torsion, as well as dynamic head/neck junction bending moment/head-to-torso angle responses for flexion, extension, and lateral loading and accompanying head trajectory requirements. An additional requirement will be placed on matching the superior-inferior response of the head/neck system due to impacts to the top of the head. The mean force-time and acceleration-time responses of the head and spine, based on cadaver impacts, are the basis for this response requirement.

The thoracic and lumbar spine system will have biofidelity of midsagittal flexion and extension bending response based on static tests on human volunteers. The spine system will provide for adjustment of the initial spinal configuration. Six-axis load measurement (three moments and three forces) will be made at the base of the head, the base of the neck, and the base of the spine to aid in the interpretation of body loading from advanced restraint techniques.

The spinal structure will consist of a series of rigid links connected by joints at selected anatomical points. These joints will have omnidirectional motion capability and will be located at the head/neck junction, base of the neck (C7/T1), upper thorax (T4/T5), middle thorax (T8/T9), lower thorax (T12/L1), and base of the spine (L5/S1). Range-of-motion requirements in the cervical spine (75° flexion, 90° extension) require the introduction of a third neck joint near the middle of the cervical spine (C4/C5). This joint will also incorporate provisions for neck torsional stiffness and axial stiffness control.

The spine segment between T1 and T4 will provide the structural attachment for the shoulder, and the thoracic structure will be attached to the T5-T8 and T9-T12 segments. Provisions will be made at each joint to allow adjustment of the initial configuration through the use of wedge-shaped rigid blocks that can be inserted and fastened in place.

Six-axis load cells will be used at the top of the neck, base of the neck, and base of the spine to allow assessment of spinal loading due to restraint system inputs.

Shoulder

The shoulder will have a clavicle structure to carry shoulder belt and steering wheel impact loads but will also offer low lateral load resistance for side impact. The lateral stiffness and range of deflection of the shoulder will be matched to mean cadaver response. The shoulder linkage will be designed to reach its lateral deflection limit slightly after the chest reaches its lateral deflection limit.

Thorax

The thorax will be designed to provide biofidelity of response to frontal impacts for rigid disc, shoulder belt, and airbag loading conditions. Side impact response biofidelity will be required for rigid disc and rigid wall impacts. The response requirements will be met for different rates of loading as well as for different types of

loading. The response specifications are based on volunteer tests at lower impact severities and on cadaver tests at the higher levels. Mean impact force-time and acceleration-time corridors for all types of direct thoracic impacts and force-deflection corridors for rigid disc impacts are the primary specifications. They will be supplemented with static load-deflection data on volunteers. Thoracic cage deformations will be measured at multiple locations to allow the assessment of global chest deformation and deformation rates.

The thorax structure will have a thin, flexible, monolithic shell to define its shape and to provide load distribution. This shell is not intended to carry significant load and therefore will not have an influence on thoracic response. The response elements in the thorax will be an array of fluid-filled bag compartments within the shell. Each bag will be constructed of cord-reinforced rubber and will represent a flexible, constant volume reservoir. There will be five bags on each of two levels, compartmentalizing the chest into upper and lower levels with frontal, lateral, and oblique sections. Each bag will communicate with a common gas-pressure-controlled reservoir (accumulator) through a single orifice into that reservoir. One-way flow-control valves will be provided in the passages from the individual bags to the reservoir to prevent flow from one bag to another instead of into the accumulator. The bag volumes, the accumulator fluid volume and gas volume, the accumulator initial gas pressure, and the orifice size will be adjusted to produce the desired thorax response. The compartmentalization of the chest will allow positional variation of local response to better match human response to asymmetric loads such as those from shoulder belts.

Each bag will have a pressure transducer mounted in it as will the gas section of the accumulator. The bag pressure transducers will indicate the region of loading and the loading rate (related to flow rate) from the resistance to flow. The central accumulator gas pressure will indicate total global deformation of the chest independent of the region of loading. The use of well-defined materials, such as silicone fluids and nitrogen gas, to control response will minimize repeatability, reproducibility, and temperature sensitivity problems.

Abdomen

The abdomen will be a deformable system with dynamic response biofidelity based on the mean rigid armrest load-deflection response of laboratory-impacted cadavers. The deformations of the abdomen will be measured at multiple locations to indicate the degree of abdominal intrusion in frontal and lateral loading. The abdomen will be of similar general design as the thorax but with only three fluid-filled compartments, lower control pressures, and a softer outer covering.

Pelvis

The pelvis and its associated covering will be designed to exhibit rigid impact response biofidelity, based on mean force-time and acceleration-time corridors for cadavers in lateral impacts, and will have humanlike mass distribution. It will also be instrumented to sense lateral loading. The pelvic structure will be designed as a simple geometric shape for the purposes of (1) providing a lightweight, rigid structure for tying the extremities and torso together, (2) allowing lateral pelvic and hip joint load measurement, and (3) providing a protected space for housing a future data acquisition system. The anatomical details of critical points for proper restraint system engagement and interaction, such as iliac bones and ischial tuberosities, will be provided for only where needed. The mass of the pelvic structure and the accompanying soft tissue mass and stiffness will be matched to provide lateral impact biofidelity.

Lower Extremities

The legs will have knee/femur/pelvis impact biofidelity in rigid knee impacts and will have humanlike skeletal mass distribution. Soft tissue coupling to the skeletal structure will also be humanlike in response, and the knee structure will have realistic geometry. Six-axis load measurements will be made in the femoral shafts, and multiaxial loads will be measured in the lower legs. The extremity joints will be single-axis planar joints or combinations of such joints to achieve appropriate degrees of freedom. The ranges of motion of the joints will be humanlike, and the resistance characteristics will be adjustable to achieve resistance ranges from 0 to 2G. The resistive torque-angle response will be humanlike as will the joint stop characteristics.

Flesh

The flesh will be developed in conjunction with the underlying skeletal structures to insure proper overall system response, including tissue shear mobility in critical loading areas such as the buttocks and upper pelvis. The durability and stability of the flesh materials will be given special consideration.

Data Processing

The data acquisition and processing techniques that are currently used by crash and sled testing facilities to measure anthropomorphic dummy response data during impact testing were reviewed, and a number of recommendations are given regarding the development of an advanced dummy instrumentation system.

Based on the projected data channel requirements of from 72 to 100 data channels on-board the advanced dummy, and based on the present size of state-of-the-art instrumentation, the development of an on-dummy instrumentation system is recommended. This system should be designed to include integral memory but with capability to conveniently expand record times through use of external memory. The on-dummy instrumentation should be developed as a microprocessor-based system to perform on-dummy analysis and control functions as well as to allow transfer of measured data to an external computer-based test set. The on-dummy microprocessor would also function to perform self tests of individual data channels under both internal and external control.

A microprocessor-based external test set should be developed as an integral part of the advanced dummy instrumentation system. The test set should be designed to allow calibration signals to be injected into individual data channels on-board the dummy. The test set would also function to perform analysis of data channel response signals. The response signals may result from injected calibration signals or actual dummy responses generated during dummy certification tests. The test set would allow for rapid turnaround of results to provide pass/fail indications of channel performance immediately after a verification test was performed.

The advanced dummy instrumentation should be developed to meet the requirements for data systems as outlined in ISO 6487, *Road Vehicles—Techniques of Measurement in Impact Test—Instrumentation.* In specialized cases, as may apply to the nine component head accelerometer array, increased accuracy may be required. The recommended performance for the advanced dummy instrumentation is summarized in Table 4.

Procedures should be developed for use in calibrating accelerometers and other sensors. ISO 6487 should serve as a basis for the procedures. At a minimum, the following parameters should be calibrated at 6-month intervals:

- Amplitude linearity at a fixed frequency
- Amplitude response versus frequency
- Phase response

The advanced dummy instrumentation should be designed to meet specified environmental performance criteria. Recommended criteria and suggested limits are summarized in Table 5.

For further information, see Arendt et al.(8).

Table 4. Advanced dummy instrumentation requirements

Amplitude Linearity	2.5%
Amplitude Resolution	12 bits (0.02%)
Time Linearity	1%
Time Synchronization	0.1 ms
Time Zero Offset	0.1 ms
Sample Rate	8000 Hz
Record Time (per channel)	500 ms
Channel Capacity	72 expandable to 100

Table 5. Environmental specifications

Parameter	Design Limits
High Temperature	180°F.
Low Temperature	-10°F.
Temperature Shock	170°F.
Humidity	85%
Acceleration (linear)	10 G
Vibration	1 G RMS Random
Shock	500 G ½ ms (Head)
	200 G 1 ms (Chest, Pelvis)
EMI/RFI	Standard Industrial

Certification Test Procedures

The test procedures currently employed to certify the Part 572 anthropomorphic dummy for use in crash tests were reviewed, and approaches that appear promising for use with the advanced dummy are recommended below. These certification tests are intended to insure that dummy responses to impact stimuli are both repeatable and reproducible. A brief review of Hybrid III dummy certification procedures was also conducted.

Routine certification testing should be done on a completely assembled, advanced anthropomorphic dummy. Test procedures should involve dynamic exposure of the dummy to levels that are consistent with the automobile crash environment. That is, certification testing should mimic the in-use environment to the maximum extent possible. Test procedures and equipment must be developed that will allow efficient and rapid testing.

On-dummy instrumentation should be used in certification testing. It is recognized that additional electronic measurements may be necessary as a part of new test procedures; however, where possible, the sensors, instrumentation, etc., that are a part of the dummy should be utilized to provide certification test data. As this instrumentation is part of the dummy, it is reasonable that it should also be checked as a part of the certification process. However, a complete calibration of sensors is not viewed as necessary each time a dummy is certified. Rather, a calibration interval would be defined at which time all instrumentation would undergo calibration according to established procedures.

Performance criteria should include injury measures as well as engineering measures. That is, if HIC is used as an injury measure for the head, then a test procedure which results in a comparison of an HIC with established error bounds should be utilized. This approach results in a

better knowledge of error limits on the primary dummy outputs than is currently available. It should, however, be noted that measures of response in addition to injury measures may be desirable and even necessary for identification of sources of unacceptable component response.

Dummy disassembly and component level testing should be undertaken only if whole-body testing indicates a problem in meeting response limits. That is, component level testing should be undertaken as a diagnostic aid in determining a specific mechanical item in need of repair or adjustment.

For further information, see Arendt et al.(8).

Conclusion

Past dummy development has been an evolutionary process. Such a process does not allow for significant departures from traditional design solutions, because each change must take into account its effect on other dummy components that remain unchanged. Although the best aspects of past dummy designs will be drawn from for the AATD, past designs will not limit the innovative approaches to its design and development. Only by taking a fresh look at all dummy design concepts can the desired results be achieved. The technology is presently available to develop an AATD with greatly improved impact biofidelity, measurement capability, durability, maintainability, and certification ease. Design concepts, technical characteristics, and measurement requirements have been developed in Phase 1 for all body regions. These will be further developed and result in a complete prototype AATD by the end of Phase 2.

A New Dummy for Pedestrian Test

Introduction

Improvement of pedestrian safety is considered a priority in crash injury protection. However, analysis of evaluation methods currently available shows that present dummies are not able to give a humanlike and repeatable impact response in pedestrian tests(1).

For this reason, the Biomechanical Laboratory of ONSER in France and the Department of Traffic Safety of Chalmers University in Götheborg, Sweden, have decided to join efforts to study, design, and validate a new dummy for pedestrian testing. The lower part going from the hip joint and below was developed by Chalmers, whereas ONSER was in charge of developing the upper part.

General Characteristics of the New Pedestrian Dummy

In the agreed specifications, the new pedestrian dummy would represent the male 50th percentile for its first version. It would be symmetrical around its vertical axis especially to obtain a high repeatability. For this, it would have no arms and only one leg; however, a part of the arm weight would be included in the thorax weight.

This dummy would represent a pedestrian hit on his side. The dimensions of the dummy were selected from the main anthropometric data available(2,3,4,5) according to the parameters indicated in Figure 1. Table 1 contains the values of these parameters available in the five

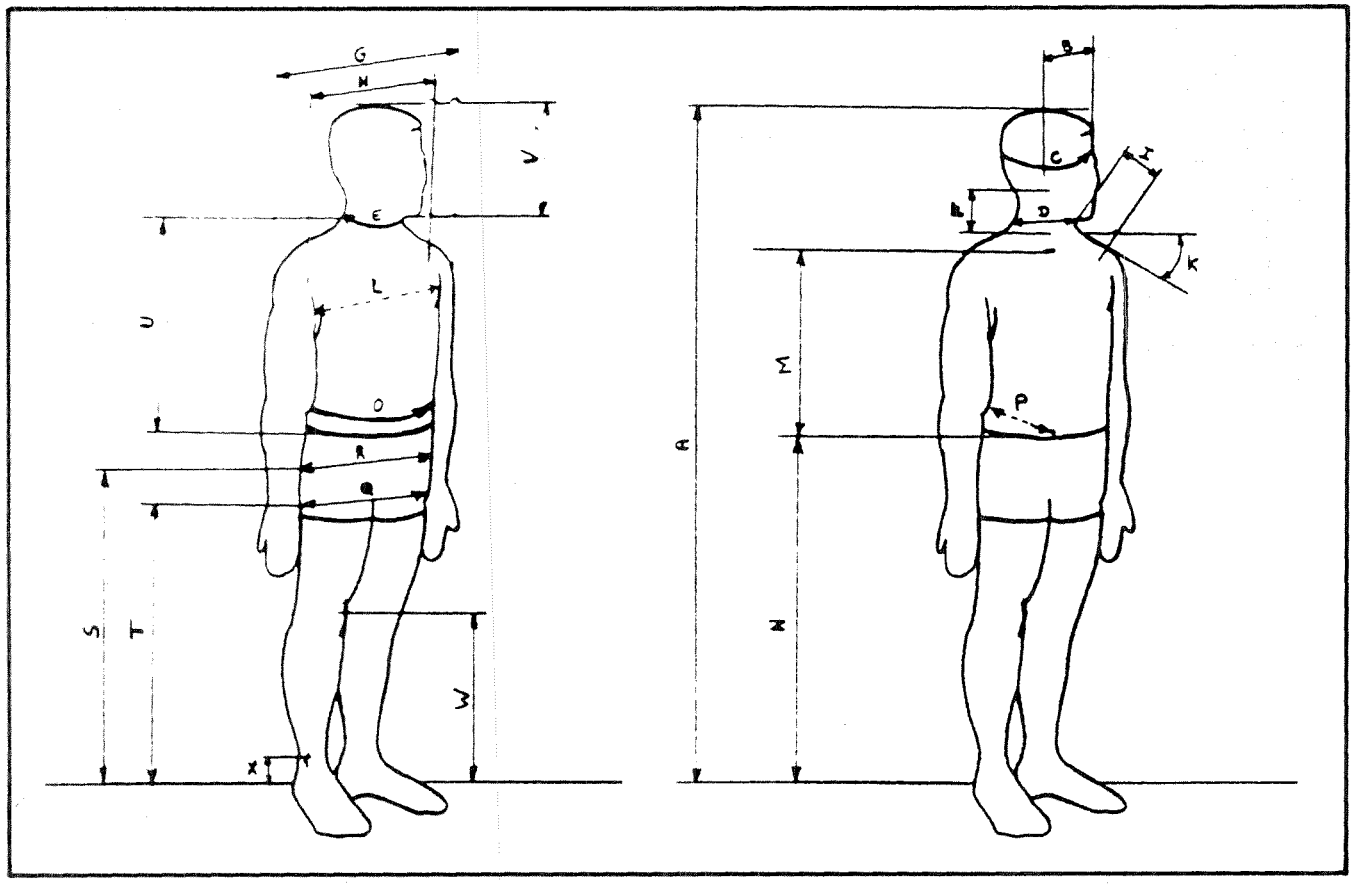

Figure 1. Dummy dimensions

selected publications and the selected values of the same parameters.

If the choice of the dimensions along the vertical axis is clear, it is much more difficult to choose the values of the diameters of the body segments: it was decided to consider the diameter of a circumference having the same length as the development of the considered body area(6), and, if there was a great difference between this value and the width of the body segment, the value of this diameter was adjusted. Table 2 gives the values of the diameters determined according to this method. On the basis of the values of these parameters, it was then possible to draw the general concept of this new pedestrian dummy as it is represented on Figure 2.

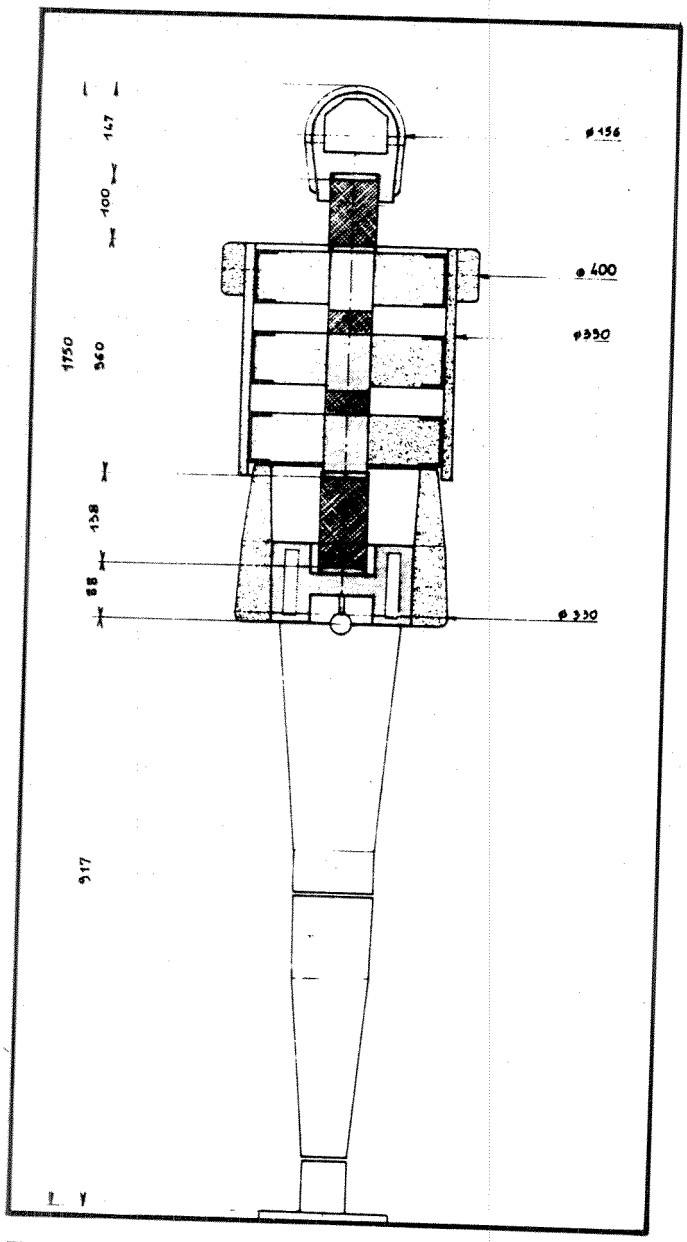

Figure 2. New dummy for pedestrian test.

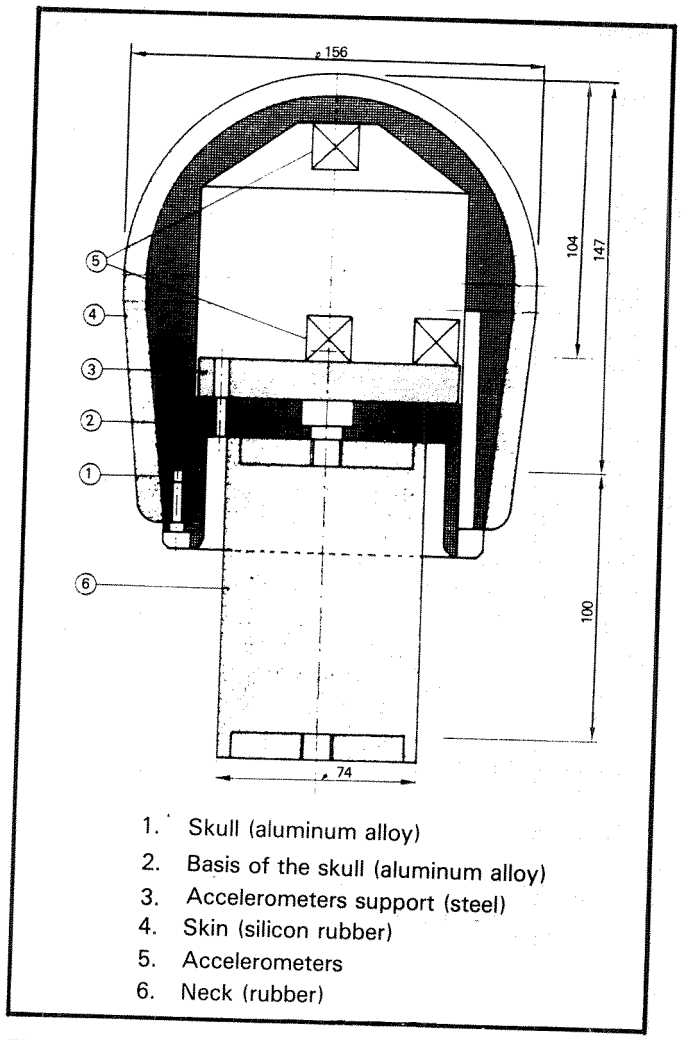

Figure 3. Head and neck assembly of the new pedestrian dummy

Part 1. The Upper Part of the Dummy (From Head to Pelvis)

The work for designing the new pedestrian dummy was divided in two parts. Part 1 includes the description of the head, the neck, the thorax, the pelvis, and the lumbar spine, which were developed by ONSER, whereas Part 2 describes the work done at Chalmers to design the hip joint and the complete leg.

Design of Head-Neck Assembly (Figure 3)

The size of the neck is the same as for the Part 572 dummy, but the stiffness characteristics are different; to give more flexibility to the neck, the rubber is softer and contains chemical adjuvant that produces a viscoelastic effect, as it was found in the same neck tested in frontal impact(7).

The skull is made of aluminum; its shape is half a hollow sphere, half continued by a trunk of cone. Accelerometers are accessible from the bottom of the head to avoid a junction plane between the sphere and the cone. The skull is covered with a 9mm-thick skin made from silicon rubber. The accelerometers plate allows five accelerometers to be screwed: one at the center of gravity and four at the periphery with an angle of 90° between each. It is also possible to screw another accelerometer at the top of the head.

The impact response of the head was evaluated in drop tests with a drop height of 25.4cm and 50cm. In these tests, one triaxial accelerometer was placed at the center of gravity and one uniaxial at the top of the skull. The results of these tests are listed in Table 3.

As indicated on Figure 4, these results were compared with the results of head cadaver tests(8) and with the

corridor of the Part 572 specification; if the response of the pedestrian dummy head is below the Part 572 corridor, it is inside the cadaver response. It is noticeable that the head sustained six impacts without damage.

Design of the Thorax

The thorax assembly is made with three identical wheels as indicated on Figure 5. Each wheel includes a central vertebra crossed by the spine cable and on which is fixed a photocell to measure the thoracic deflection. The external part is a rigid U-form rim made from fiberglass. Inside the rim, a lead plate is fixed to give a realistic mass distribution, and the rim is attached to the vertebra with a moulded soft polyurethane foam. The foam density is chosen to reproduce humanlike force-deflection characteristics. Between two following wheels, there is a polyurethane vertebra that allows a bending motion at the thoracic level. All of the thorax is covered with a 15mm-thick rubber foam, and the upper rim is covered with two other lays to reproduce the shoulders.

Design of the Pelvis

The pelvis is made in two main parts: a rigid central part attached to the lumbar spine and to the leg and a soft external part simulating the flesh (Figure 6). The rigid part is made from two rings attached to a central cylinder through three force transducers at each level. The angle between the force transducers is 120°. The upper rim represents the iliac wings and the lower one the great trochanter. With this system, it is possible to measure the forces exerted at the two levels and from any direction. It is also possible to measure pelvic acceleration at the center of gravity of the pelvis.

The flesh part is made from three lays of foam glued together and surrounding the internal metallic assembly. The thickness of the foam is chosen to give a correct external diameter to the pelvis.

The lumbar spine was generally developed for the EUROSID(9) and is made from the same rubber as the neck to give a correct erection posture to the dummy even with the soft lumbar spine. The pelvic flesh is in contact with the lower side of the lower thoracic rim.

Part 2. The Leg (From Hip Joint to Foot)

In normal walking, the feet are lifted one at a time with one foot not off the ground before the other touches. Studies of gait indicate that the body weight is supported only by one leg for about 80 percent of the total time(1). During this period, the vertical force against the ground varies between 80 percent and 120 percent of the static body weight(2). The reason for this varying load on the supporting foot is, of course, that the other leg has to be lifted and swung forward during this period. At the forward swing, the knee of this leg is flexed except for a very short moment when the heel hits the ground. Maximum knee flexion is 50° to 60°. From a side view, the two legs to a large extent are overlapping during this period. In a frontal view, however, the lower legs are separated by some 5 to 10cm when they pass each other.

Most of the accidents in which a person is hit by the front structure of a passenger car seem to take place in built-up areas when the pedestrian enters a traffic lane in an attempt to cross the street more or less perpendicularly. Since most adult pedestrians in this type of accident are elderly, their own velocity is quite low in relation to that of the car. The first contact between the two occurs when the most protruding part of the car front, which is usually the bumper, hits the pedestrian's lower extremities from the side.

The static level of the bumper in many cars is about 45cm above the ground. In normal driving, the bumper level is influenced by several factors. The most important is probably related to a possible application of the brakes before impact. Braking results in a more or less pronounced pitchdown of the front end of the car. This dive has its maximum about one-quarter of a second after full application of the brakes(3). This means the car will travel quite a distance from the moment the driver first observes the pedestrian and decides emergency braking is necessary until the bumper reaches its lowest position. In most pedestrian impacts, the bumper will probably not have reached its lowest position but will be at or just below the level of the knee of an adult pedestrian.

Two different positions are possible for the pedestrian's legs at the moment of impact. The swinging leg may be either the one nearest the approaching car or the one most distant. The foot of this leg will be off the ground for 80 percent of the time, and the knee of the swinging leg is more or less flexed during this period. The most probable bumper impact point will therefore be on the lower leg rather than in the knee region. Since the lower leg is not in a vertical position most of the time, the bumper contact will probably engage a larger area than if this part had been perpendicular to the bumper in its plane of motion.

Should the swinging leg be the one most distant from the car, this leg will generally first be impacted by the other leg and then by the bumper. In either case, the impact is probably distributed over a relatively large area of the swinging leg.

If, on the other hand, the bumper first hits the leg supporting the body, the contact is likely to be on its lateral or fronto-lateral aspect at or just below the knee joint. Due to the nearly vertical position of the leg, the bumper force will be concentrated over a small area. This part of the leg will in a very short time be accelerated at least to the velocity of the car at the moment of impact. Inertia of the leg and ground friction will create a bending moment about the knee, whereby the medial and cruciate ligaments are subjected to tensile and the lateral condyles to compressive forces. Shear forces will also occur, and the inertia of the foot in most cases will cause some torque about the longitudinal axis of the lower leg.

When the leg is forcibly bent in a lateral direction, the foot will come off the ground, which will substantially reduce the influence of ground friction shortly after the first contact. The lateral bending is minimal only if the point of impact is close to the center of gravity of the lower leg.

It seems the worst case would be where the bumper first impacts the leg supporting the body close to the knee. Due to the mobility in the hip joint, there is little influence on the pelvis due to the induced rotation of the legs during this first phase of the impact sequence.

The second contact between the pedestrian's body and the car front will often take place between the hip region and leading edge of the hood. If this contact is at a level close to the pedestrian's center of gravity, most of the impact energy transferred will result in a translational movement of the pedestrian body. If this second contact is with the thigh, more of the energy will result in rotation of the body in a vertical plane more or less parallel to the longitudinal axis of the vehicle. The speed at which the upper body hits the top of the hood is, therefore, mainly governed by this contact.

Rotation about the longitudinal axis of the pedestrian's body may also occur. This rotation is also of importance because the position of the nearest arm and shoulder at impact will greatly influence the kinematics of the trunk and head during this phase of the impact.

When cadavers as well as normal or slightly modified anthropometric test dummies have been used for simulated car-pedestrian impacts, it has been customary to place them with their feet separated and the dummy weight more or less loading both legs. This seems to represent a very rare accident situation. It does not represent the worst case as far as the risk for leg injuries is concerned, and this position of the legs may in some cases induce a rotation about the longitudinal axis of the body.

The presence of arms and shoulders and their construction will largely influence the later kinematics of these bodies. This may be a major source of the large scatter in recorded values of injury criteria often found in such tests. The present anthropometric dummies have, therefore, not been considered to be particularly well suited for this kind of testing.

It was mainly for the reasons mentioned above that it was decided to design and construct a new type of dummy more suitable for the assessment of car front aggressiveness in pedestrian impacts. To reduce as many as possible of the identifiable sources of scatter in recorded injury criteria, it was considered advantageous to make the dummy rotationally symmetrical about the longitudinal axis of the body. To achieve this goal completely, the dummy would have to be one-legged and the leg would have to have the characteristics of a human leg impacted on its lateral aspect. This did not seem to be a great disadvantage since the dummy would then always represent a worst case impact model.

General Requirements

The aim of this part of the work was to design and construct a rotationally symmetric mechanical representation of the lower extremity of an adult person. The appropriate dimensions were chosen to represent those of a 50th percentile U.S. male. The model should have the response characteristics of the leg of a pedestrian who is hit from the side by the front structure of a car. It should also have a similar influence on the kinematics of the upper part of this dummy as a human leg would have on a pedestrian's body in real-world accidents of this kind. Furthermore, it should be possible during tests with this dummy to record the physical parameters considered to be the most important injury criteria for this part of the body. At the present state-of-the-art, these are bending moments about the long bones and joints, tensile and shear forces at different levels, and torque about the longitudinal axis of the leg.

To be practically suitable for use under realistic test conditions, the main dummy parts would have to be strong enough not to break or distort permanently when hit by cars at speeds chosen for these tests. For this reason, the long bones are simulated by steel tubes with an outer diameter of 44.5mm and an inner diameter of 36.5mm.

The Hip Joint

This joint should attach the leg to the pelvis while allowing a 30° pendulum angle before contact is made between stiffer structures. This angle would correspond to the combined movements of the human leg with special reference to the adduction of the leg closest to the striking car. A ball and socket joint was chosen for this purpose.

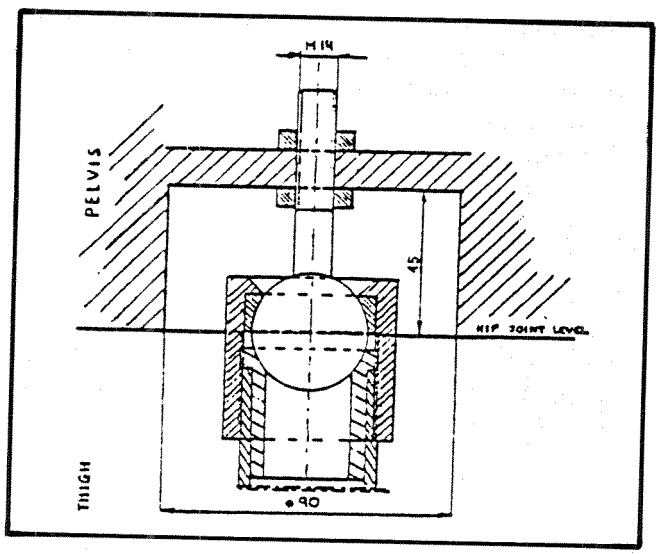

Figure 1. The hip joint.

The Knee Joint

To be able to balance the dummy on one leg and at the same time achieve, in all directions, the characteristics of a human knee struck from the side, it was decided to simulate this joint by a cylindrical steel bar inserted in the long bones. The bar is made of a standard steel (2172). Its

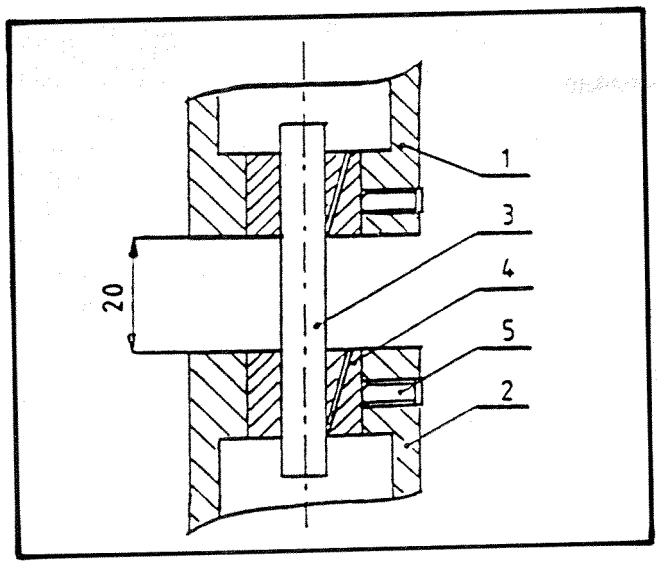

Figure 2. The knee joint

diameter is 8mm, and it is clamped in adjacent ends of the steel tubes in such a way that its free length is 20mm.

This bar will undergo plastic deformation at a bending moment of 70Nm. In a series of tests performed on cadaver legs, this bending moment was found to tear the medial collateral and the cruciate ligaments of the knee. At slightly higher bending moments, fractures of the tibial condyle were also seen(4). The angle of deformation in the knee can, for practical purposes, be used as an indication of the level of the bending moment in tests performed at the same speed. Since the inertia of the lower leg at subsequent impacts can change the angle of permanent deformation in the bar, this angle will have to be determined from film analysis of the sequence.

The Ankle Joint

This joint is similar to the knee joint, but the diameter of the steel bar is 6mm and it has a free length of 20mm. Plastical deformation of this bar will begin at 40Nm. This was found to be the average value in seven tests with cadaver legs when the foot was forced into rapid pronation. As is the case in the knee joint, a rough estimation of the bending moment about this joint can be made from the angle of deformation in tests performed at the same speed.

The Thigh

This segment is 421mm long between the centers of the joints at the hip and the knee. It has a mass of 8.2kg. The center of gravity is adjusted to its correct position at 239mm above the center of the knee joint by means of a lead weight secured by a pair of screws inside the steel tube. To adapt the thigh's contour to that of a human leg

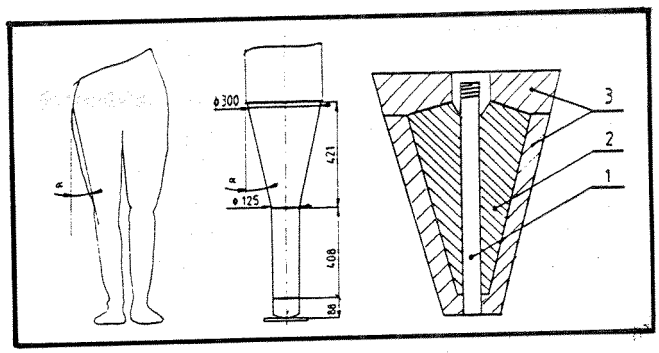

Figure 3. The thigh segment

in this aspect and to the dimensions of the pelvis, a cone of wood is placed over the steel tube. The soft parts are simulated by a 40mm-thick plastic foam with a compliance similar to that of human soft tissues, and a vinyl skin is used for additional protection. It is believed that by this design the hood edge of a car will contact this segment in a similar way as it would a pedestrian in real-world accidents.

The Lower Leg

This segment is 408mm long between the centers of the knee joint and the ankle joint. It has a mass of 3.8kg. The center of gravity is adjusted to its proper position at 231mm above the center of the ankle joint by means of a lead weight secured inside the steel tube by a pair of screws. The soft parts are simulated by a 40mm plastic foam. The damping characteristics of this foam are chosen to insure that the force pulse shape from a bumper impact is similar to that recorded in previous cadaver leg tests.

The Foot

The length of the foot segment is 88mm and has a mass of 1.1kg. The center of gravity is 30mm above ground level when placed on the simulated shoe. The soft parts are then continued from the lower leg over the ankle joint and foot. To allow the foot to tilt at low impact levels on the lower leg, the lower end of this segment has a spherical shape. In the center of this surface, there is a steel peg that fits into a hole in the center of the circular wooden plate simulating the shoe. The steel peg can transfer shear forces to the wooden plate, which has a diameter of 170mm. The simulated shoe has a lower surface of the size of a normal shoe and is covered by rubber.

The reason for not fastening the "shoe" to the foot is that, if the leg is bent, the foot will come off the ground at an early stage and leave the "shoe" on the ground to prevent it from being entangled in the front structures of the car.

Instrumentation

Ten sets of four strain gauges are glued to the metal skeleton as shown in Figure 4. Strain gauges in the B series are placed on the surface of the tube parallel with its longitudinal axis at 0°, 90°, 180°, and 270° of the circumference. They measure deformation caused by bending and shear stress. T_1 and T_2 are glued at right angles to each other and at an angle of 45° to the longitudinal axis of the tube. These measure deformation caused by torsional stress. The D gauges are glued in pairs at 0° and 180° of the circumference in such a way that one pair is parallel and the other at right angles with the longitudinal axis of the tube. They measure deformation caused by tensile stress.

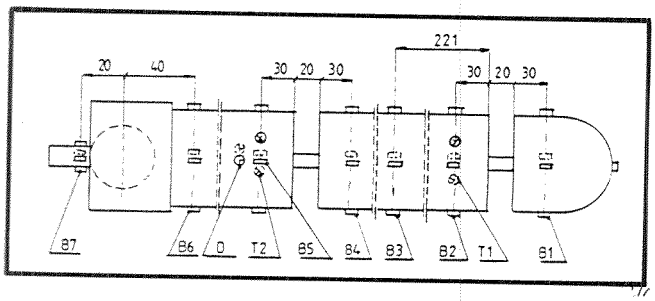

Figure 4. Distribution of strain gauges on the leg model

If the leg model is used in a general way and the impact direction is not predetermined, 17 channels will have to be recorded to enable the more complicated calculations of the various parameters. If on the other hand the impact direction can be predetermined, e.g., to be from 0°, only 10 channels will have to be recorded and still enable calculation of all the parameters.

For calculations of bending moment and shear force about the joint, the signals from corresponding strain gauges on both sides of the joints are used. Although both moments and forces are in fact nonlinear, they can be treated here as linear. Since the gauges are placed close to the joints and the masses in these regions are quite small, the error in this case can be considered as small.

A bending moment about a joint will cause deformation as illustrated in Figure 5.

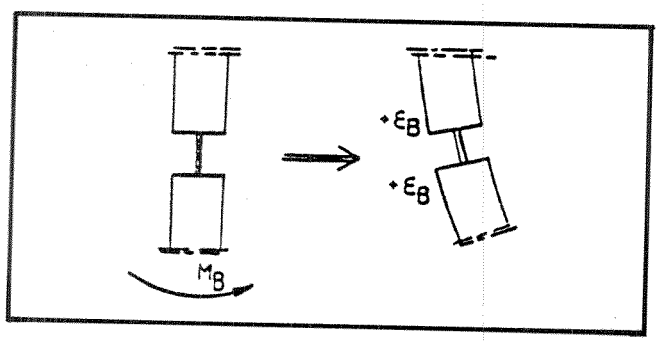

Figure 5. Deformation caused by bending stress

At impact loading of the lower leg, there is also a deformation in the shear mode, and the material will deform as shown in Figure 6.

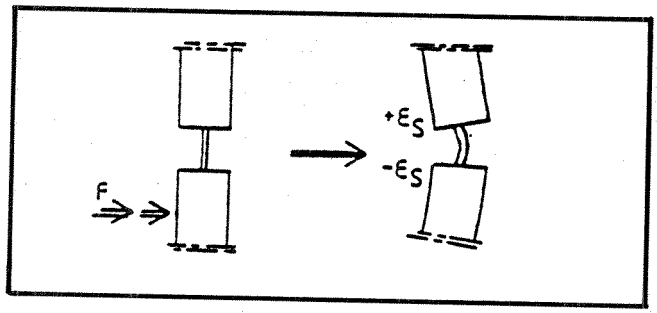

Figure 6. Deformation caused by dynamic shear stress

Each B signal has two components.
Signal B′ from above the knee contains $+\varepsilon_B$ and $+\varepsilon_S$.
Signal B″ from below the knee contains $+\varepsilon_B$ and $-\varepsilon_S$.
Deformation caused by the bending moment is then

$$\frac{B' + B''}{2}$$

Deformation caused by shear froce is then

$$\frac{B' - B''}{2}$$

In these calculations of bending moment and shear force, the measured deformation and the material constants for this model are used. Tensile force and torque can be derived directly from the deformations (D and T signals) and the corresponding material constants.

Wiring diagrams to be used if the model is impacted from a defined direction at 0°.

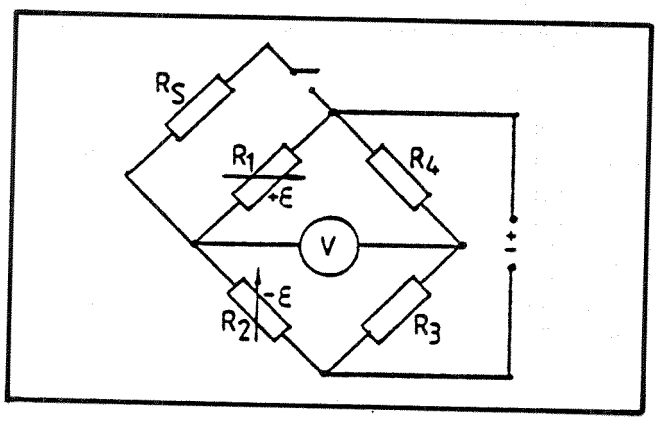

Figure 7. Wiring for strain gauges of the b series

This system is not sensitive to tensile and torsional stress.

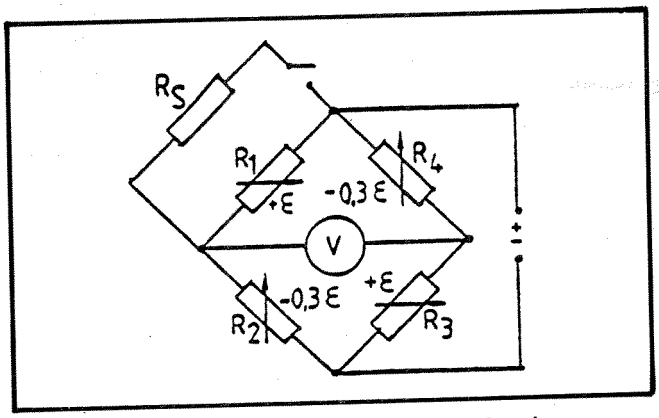

Figure 8. Wiring for strain gauges of the d series

This system is not sensitive to flexural and tensile stress.

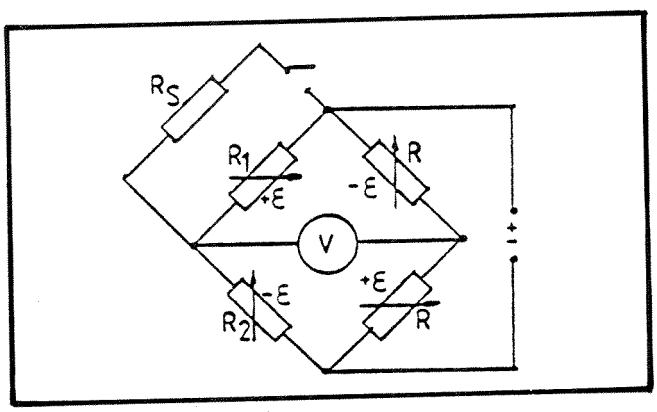

Figure 9. Wiring for the strain gauges in the t series

This system is not sensitive to flexural and tensile stress.

Wiring diagrams to be used if the model is impacted from any direction. Each set of strain gauges in the B series will have to be divided into two bridges.

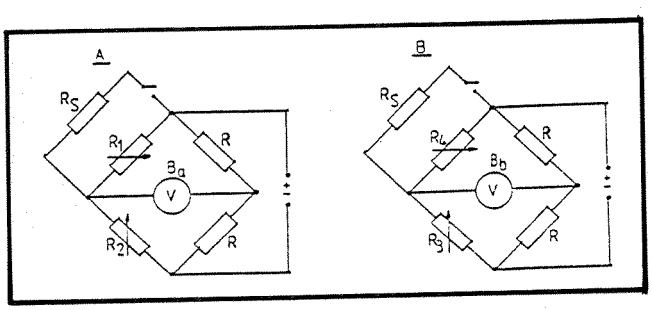

Figure 10. Wiring for the gauges in the b series

Bridge A will produce signal B_a and bridge B signal B_b. The combined deformation is: $|B| = \sqrt{B^2_a + B^2_b}$ and the sign will have to be determined from analyses of the signals and the state of deformation.

Conclusion

This paper gives the results of a first attempt to develop a round symmetrical dummy to be used in pedestrian tests.

The dummy is designed according to the latest available anthropometric and biomechanical data. Its symmetry around the vertical axis would allow it to have good repeatability for the kinematic as well as for the injury parameters. It allows a measurement of "uncommon" biomechanical parameters that are related to injury mechanisms. Its leg is instrumented to determine the distribution of forces and momenta applied to the leg.

The several body segments were tested separately, and the next phase will be the validation of this dummy in car pedestrian tests.

Head and Neck Injuries in Human Cadavers From Lateral Impacts

Michael J. Walsh and
Barbara J. Kelleher
Calspan Corporation

Charles M. Severin
State University of New York at Buffalo

Abstract

Head-neck injuries occur frequently in pedestrian and occupant automotive accidents even at relatively low speeds. This paper describes the results of laboratory impact experiments using human cadavers in pedestrian/vehicle impacts and lateral-to-medial head impacts at well-known, controlled speeds. Cerebral trauma, with and without skull fracture, is discussed as a function of impact configuration and velocity. Cervical spine and cord injuries are also discussed with regard to the same parameters. Data presented include impactor mass and velocity, head acceleration measurements, complete autopsy and dissection results, and the clinical evaluation of the effect on a person of the observed trauma.

Eighteen cadavers have been exposed to lateral-to-medial head impacts by two mechanisms. Eight of the subjects were exposed to pedestrian impacts wherein their head contacted the hood of the striking vehicle, and 10 were subjected to linear impactor tests in which the head was struck by a 52lb impactor with a flat faceplate that was rigid for some experiments and padded for others. The presentation and discussions of these experiments in this paper will be directed toward the clinical results and evaluations of the trauma observed in the brains of the cadavers in addition to the measurements of accelerations and the calculations of the Head Injury Criterion (HIC) values. It must be understood at the outset that while lesions in areas of the brain can be determined in impact experiments using human cadavers, and the bodily functions that would be affected by the lesions in these various areas can be identified, the extant functions over a period of time cannot be determined. Even with sectioning of the brain and quantification of the depth (for example) of the trauma in a given area, it is not possible to ascertain the level of recovery that a living subject might be capable of achieving. It is the belief of the authors, however, that the reporting of the types of trauma to the brain and the functional impairment that may be realized (even qualitatively) from specified impacts is important as initial data base information for dissemination to the transportation safety community.

Cadaver selection criteria and the handling and testing protocols were the same for these experiments as those described in (1).

Test Procedures

The eight cadavers that were exposed to head impacts to the hoods of cars were used in pedestrian sled tests. Seven were struck on their left side and one (CM22), because of a previous left leg injury, was struck on the right side. All of these cadavers were instrumented in the head with a 9 accelerometer head mount (3-2-2-2) attached at the apex of the skull. There was also a triaxial accelerometer package installed in the mouth of the subjects. The 9 accelerometer head unit (9AU) was positioned using a Kapf stereotaxic frame that had been modified for a human skull and measurements of three points were recorded in the A-P, M-L, and S-I directions. Using this same device, measurements were taken of three points on an extension of the mouth mount. Accelerometers for the mouth were affixed to a dental impression tray, and the tray was secured in the mouth with an acrylic resin.

The 10 cadavers exposed to the lateral-to-medial head impactor tests were also instrumented with the 9AU mount on the apex of the skull, but the mouth mount was not used during these experiments. The impacting device was a flat-faced, 52lb, linearly accelerated ram with its vertical centerline aligned on the Frankfort plane. The striking surfaces ranged from 28in^2 (6in diameter), 54in^2 (6-3/4in by 8in rectangle, to 80in^2 (8in by 10in rectangle). All of the impacts were to the left side of the head of the subjects. Eight experiments were performed with the bare aluminum face of the impactor striking the lightly shrouded head, and two were performed with foam padding covering the hard aluminum face plate. With the exception of two exposures, the velocity at impact was held at approximately 13fps. The exceptions were a 7fps impact chosen to obtain a data point at the impact velocity used in test dummy certifications and an 11fps impact as an intermediate point. Table 1 presents information on the tests performed.

For the impactor experiments, the cardiovascular system of the brain was pressurized. The procedure used was one in which a catheter was inserted bilaterally into the internal carotid arteries to a level of ½in below the base of the skull. The external carotids were ligated, and the internals were tied around the catheters to form a seal. Dianeal, with a mixture of India ink and Toluidine blue, was injected and the pressure was maintained and monitored during impact. In general, good perfusion to

the brain, by the dye, was noted in all subjects allowing for an accurate evaluation of impact-induced lesions in the various regions of the brain. This technique had not been developed at the time of the pedestrian impacts and therefore was not used in those experiments. Post-mortem brain lesions were observed in some of the pedestrian subjects, but because of the lack of pressurization and staining, it is possible that some may not have been identified.

The velocities listed in Table 1 are the velocity of the head in the medial-to-lateral direction at the time of impact with the hood of the vehicle for the pedestrian tests and the velocity of the impactor just prior to contact for the impactor tests.

Clinical Results

Cerebral trauma was observed with and without skull fracture during these experiments. Skull fracture was observed in only one of the pedestrian tests (CM23) and two of the impactor tests (CM29 and CM35). A clinical description of the trauma observed is presented below along with an evaluation of the responses that could be expected based on injury to these areas of the brain. As noted earlier, the depth or extent of these responses and the temporary or residual impairment of a living person cannot be determined from these experiments with human cadavers.

Cervical spine injuries were observed in five of the eight pedestrian tests. These extension-type injuries were caused by the kinematic responses of the cadaver after the upper torso and the head had contacted the hood of the vehicle. In these cases, the cadaver, having been struck by the vehicle on the left side, would roll onto the hood and eventually be in a position where the head and the chest were flat on the hood surface. The forces that had been imparted to the lower extremities of the subject(1) caused the cadavers to rotate about the neck and put it into hyperextension.

In this section, the acceleration versus time graphs of the head impacts are presented along with a computed HIC value for each of the 18 cadavers. A narrative description of the observed trauma and a summary of the neurological deficit that would be expected from the injury follow each graph. An Abbreviated Injury Scale (AIS) code is assigned for each subject. Table 2 presents the definition of the codes as described in (2).

The peak acceleration data are resultants computed from the mouth-mounted accelerometers in the pedestrian (PED) subjects and from the 9AU mount X0, Y0, and Z0 in the impactor (IMP) subjects. They are filtered at channel class 1000 in accordance with the SAE recom-

Table 2. Abbreviated injury scale (AIS)

Code	Description

mended practice J211b. While it is understood that these instruments are not located at the head c.g., the HIC values were calculated for the purpose of having a common reference number. The mouth mount is closer to the c.g. than is the 9AU mount, but in the lateral-to-medial impacts the head translated laterally almost as a rigid body in these experiments.

The anterior and posterior longitudinal ligaments, spinal cord, left prevertebral muscles, and the sympathetic chain were severed. Cervical vertebra number 6 (CV6) was displaced anteriorly.

The subject would demonstrate quadriplegia, and probably be incontinent. He would suffer from permanent constriction of the pupils and lack of ability to perspire around the eyes. The blood vessels in the area of the eyes would be permanently dilated causing the skin in that area to feel hot (Horners syndrome). These injuries would constitute an AIS 5.

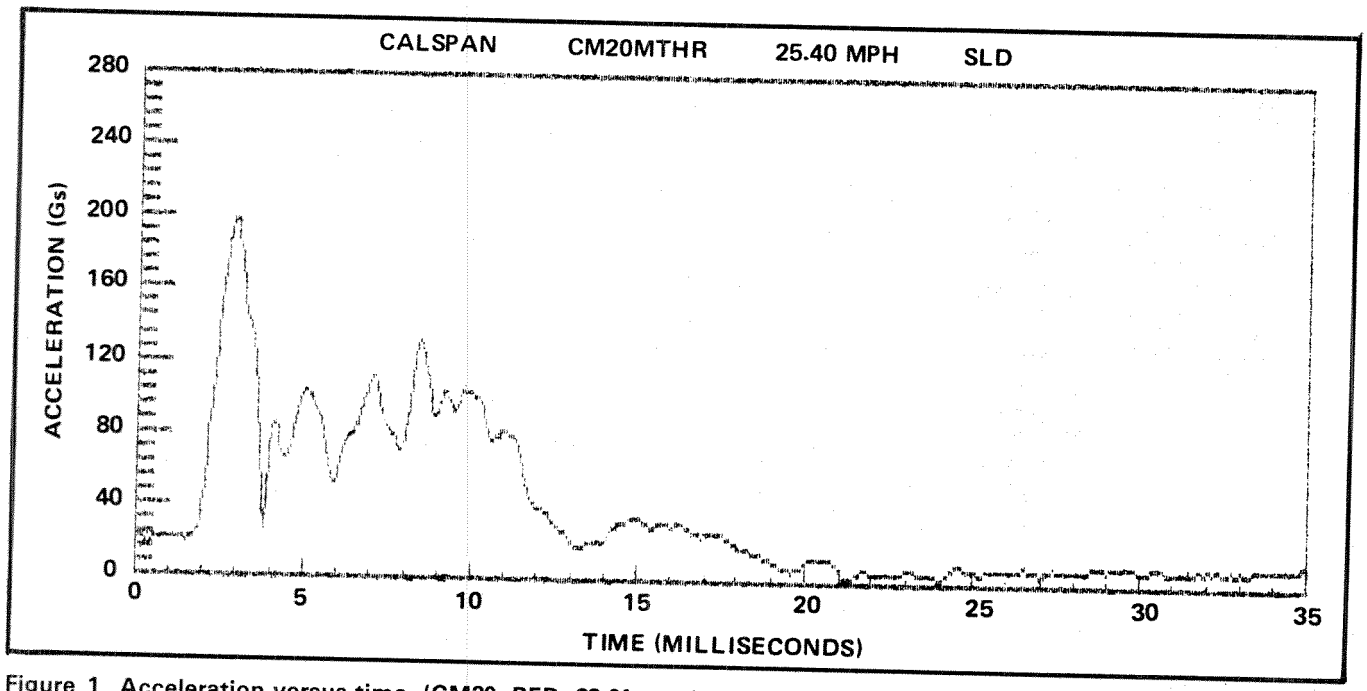

Figure 1. Acceleration versus time. (CM20, PED, 33.0fps velocity at impact. HIC = 868)

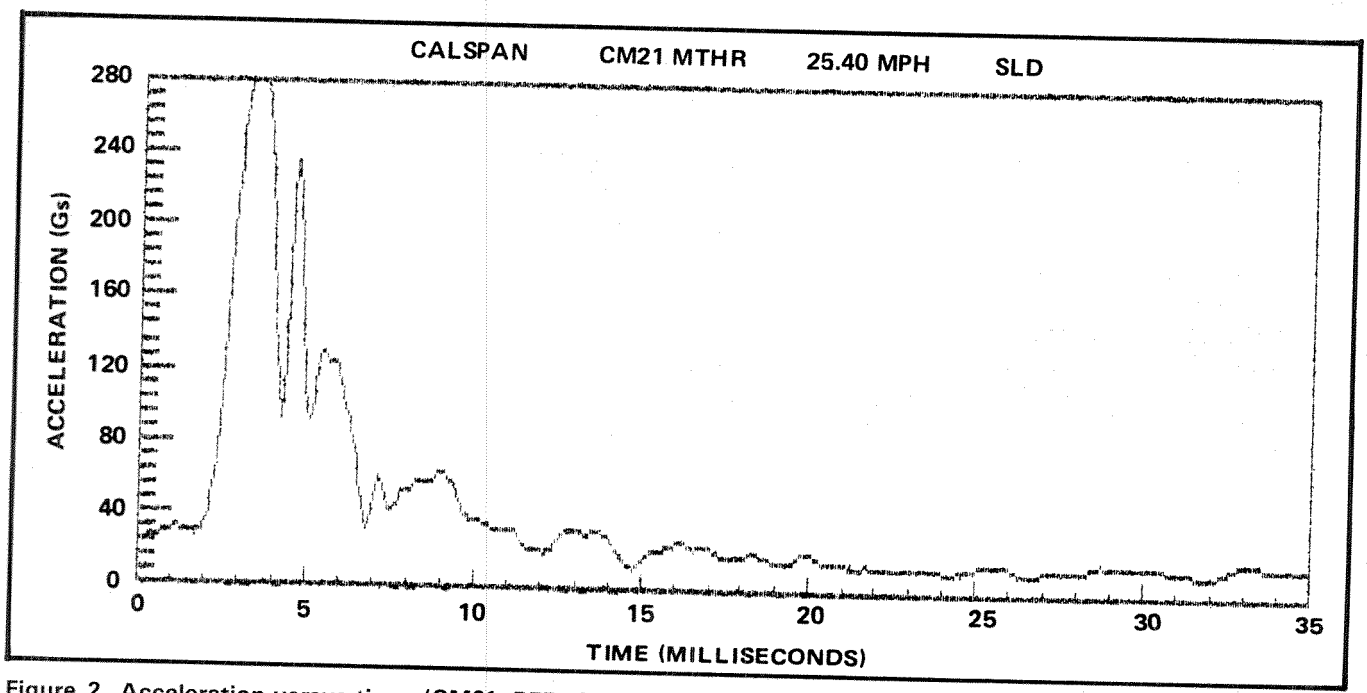

Figure 2. Acceleration versus time. (CM21, PED, 29.6fps velocity at impact. HIC = 1864)

There was a fracture of the cervical spine at CV7. TV1 was also fractured. No spinal cord involvement could be determined. There was slight traumatic subarachnoid hemorrhage on the interior surface of the right temporal lobe. Serial sections of the brain did not show any areas of hemorrhage.

The fractures of CV7 and TV1 would involve the nerves of cervical segments (CS) 7 and 8 and perhaps T1 causing damage to the ulnar nerve, thereby a loss of sensation in the ulnar region of the forearm and hand. Subarachnoid hemorrhage can cause serious damage in the living, depending on the duration and amount. It was not possible to estimate potential duration and amount in this subject. These injuries would constitute an AIS 3 in the neck and an AIS 3 in the head.

Undisplaced fractures were observed at the level of CV2-CV3 and CV7-TV1. The pedicles of CV2 were also fractured. The anterior and posterior longitudinal liga-

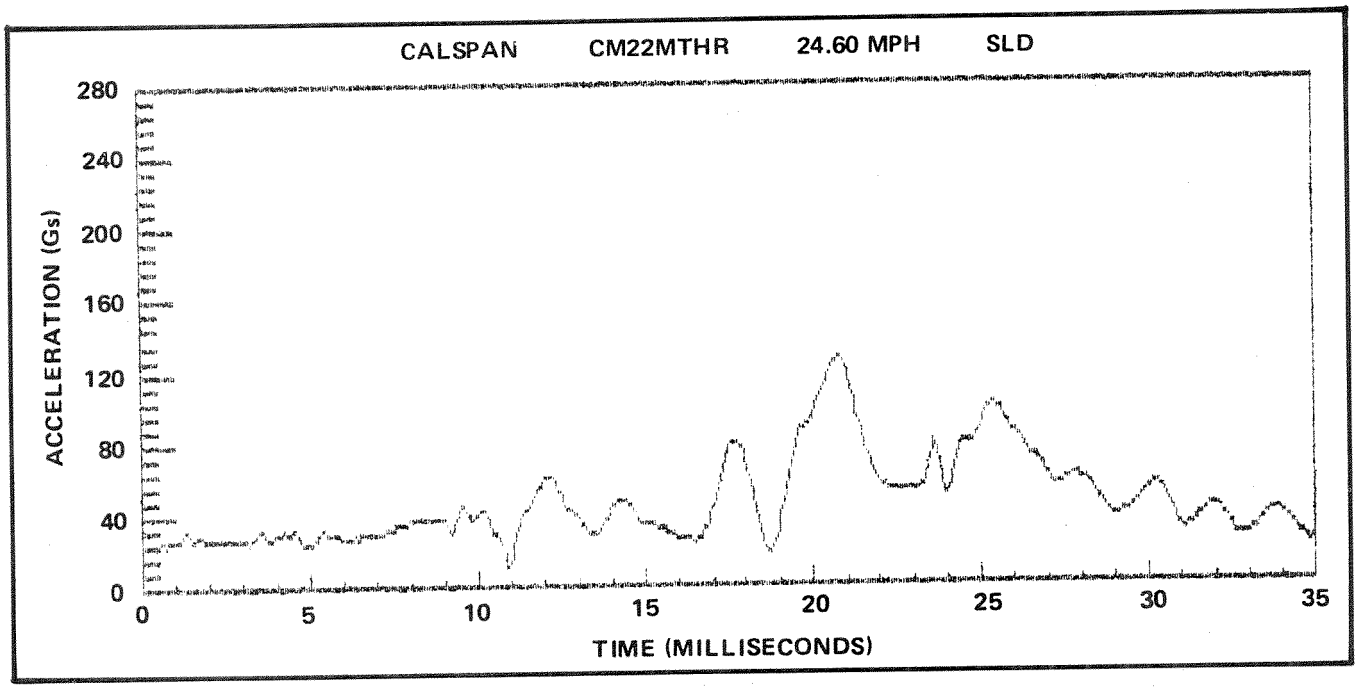

Figure 3. Acceleration versus time. (CM22, PED, 28.5fps velocity at impact. HIC = 525)

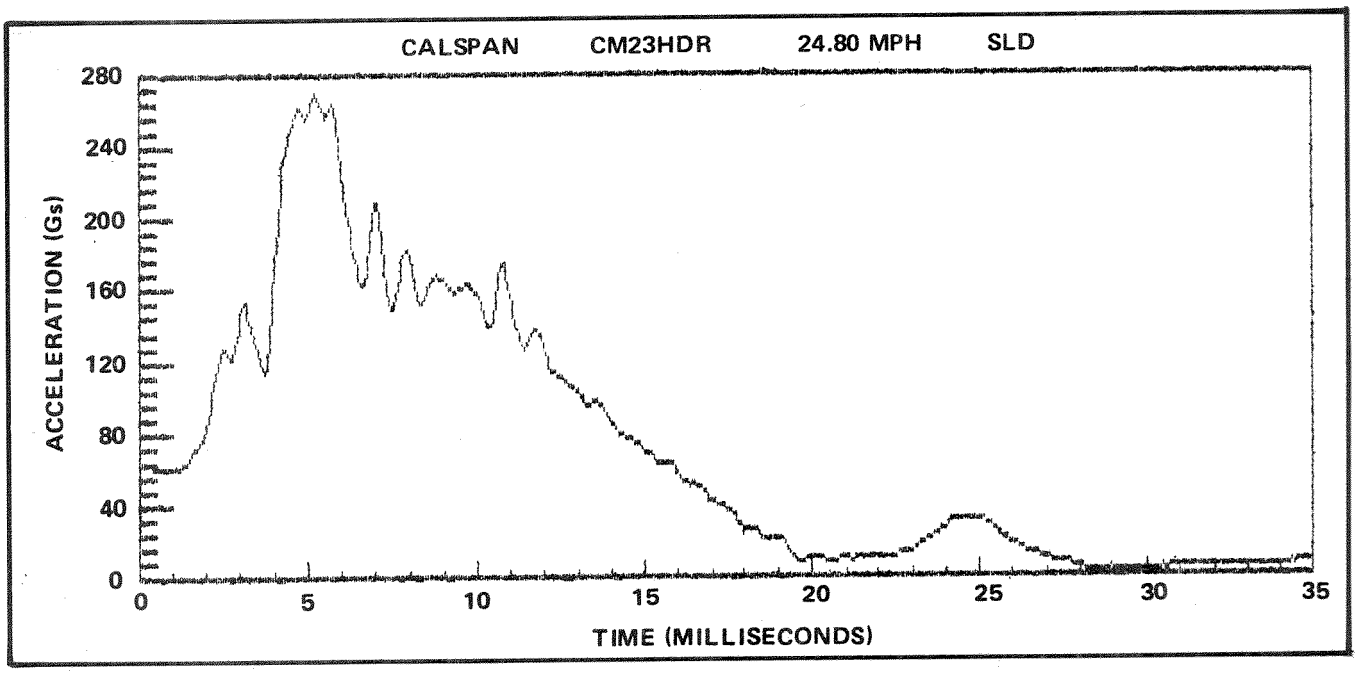

Figure 4. Acceleration versus time. (CM23, PED, 35.2fps velocity at impact. HIC = 3967)

ments were torn. Upon removal of the calvaria, there was no epidural hemorrhage present. Slight subdural bleeding was present over the brain. There was evidence of slight subarachnoid hemorrhage in the temporal lobes. Slight bleeding was seen into the ventricular cavity.

There would be a probable loss of sensation over the shoulders, on the back of the head, and on the side of the neck due to the potential nerve involvement in the kinematics during the fractures. The potential consequences of subarachnoid hemorrhage noted above hold for this subject. Also, there was no way of determining the duration or amount of bleeding that would have contributed to the bleeding that was observed into the ventricular cavity. This subject would also be assigned an AIS 3 for both the head and neck injuries.

The subject experienced fractures of the skull. There was a separation at the zygomatico-frontal suture, and the periorbita beneath the suture was lacerated. The lateral part of the frontal bone was fractured into five pieces. The opterion was displaced internally. Upon dissection, the orbital laminar (lamina papyracea) of the ethmoid bone was found to be fractured. The bony fragments were displaced interiorly with the bone piercing the periorbita. Fragments of the orbital part of the frontal bone lacerated the periorbita and extended into the periorbital fat. Branches of the opthalmic artery and veins, the optic nerve, and extraocular nerves and vessels as well as the temporal branches of the facial nerve were intact.

When the calvaria was removed, blood was found in the epidural space beneath the frontal bone fractures. This blood appeared to be caused by a laceration of the middle meningeal vessels. On the right side of the anterior cranial fossa, the orbital parts of the frontal bone were fractured at the suture between the orbital plate of the frontal bone and the lesser wing of the sphenoid bone.

Examination of the brain did not reveal any identifiable damage. The epidural hematoma would cause a displacement of the brain and thereby an increase in pressure within the cranial vault. The magnitude of these would be dependent upon the duration and amount of the hemorrhage. These could not be estimated in this subject. As noted earlier, however, there had been no attempt to pressurize nor maintain pressure on the brain during contact. These injuries would be assigned an AIS 4.

There was no injury observed to the head, brain, neck, or spinal cord of this subject. An AIS value of 0 would be assigned.

The damage involved the anterior one-third of the superior, middle, and inferior frontal gyri. The anterior one-quarter of the superior, middle, and inferior temporal gyri was also damaged.

The damage to these areas would indicate that the subject would most likely undergo personality changes. He may become indifferent. This damage would be an AIS 3.

There was a total rupture of the ligaments forming the anterior longitudinal ligament capsule of the vertebral joint between CV3 and CV4 as well as CV5 and CV6 and CV6 and CV7. The spinal cord appeared to be intact, however. The skull and brain were normal.

The potential deficit associated with this type of injury could not be assessed. However, an AIS 3 would be assigned for the neck injuries.

Examination of the neck showed a displacement between CV6 and CV7, with the intervertebral disk

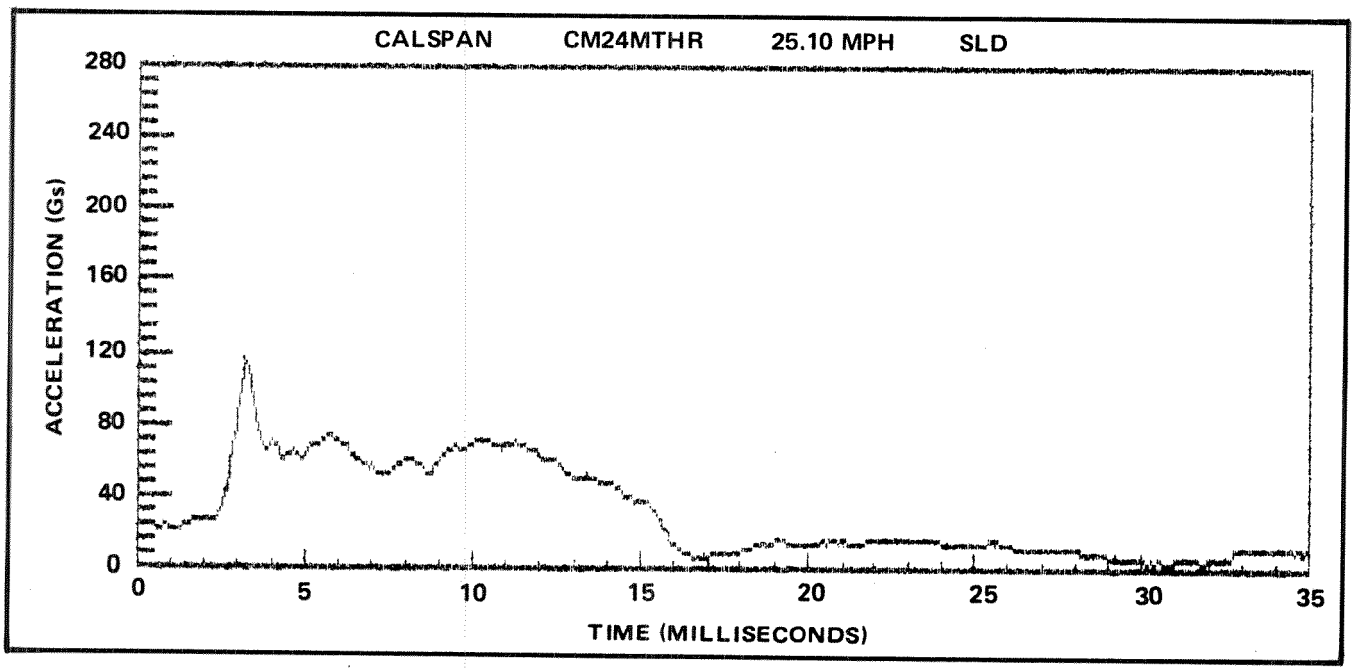

Figure 5. Acceleration versus time. (CM24, PED, 28.0fps velocity at impact. HIC = 468)

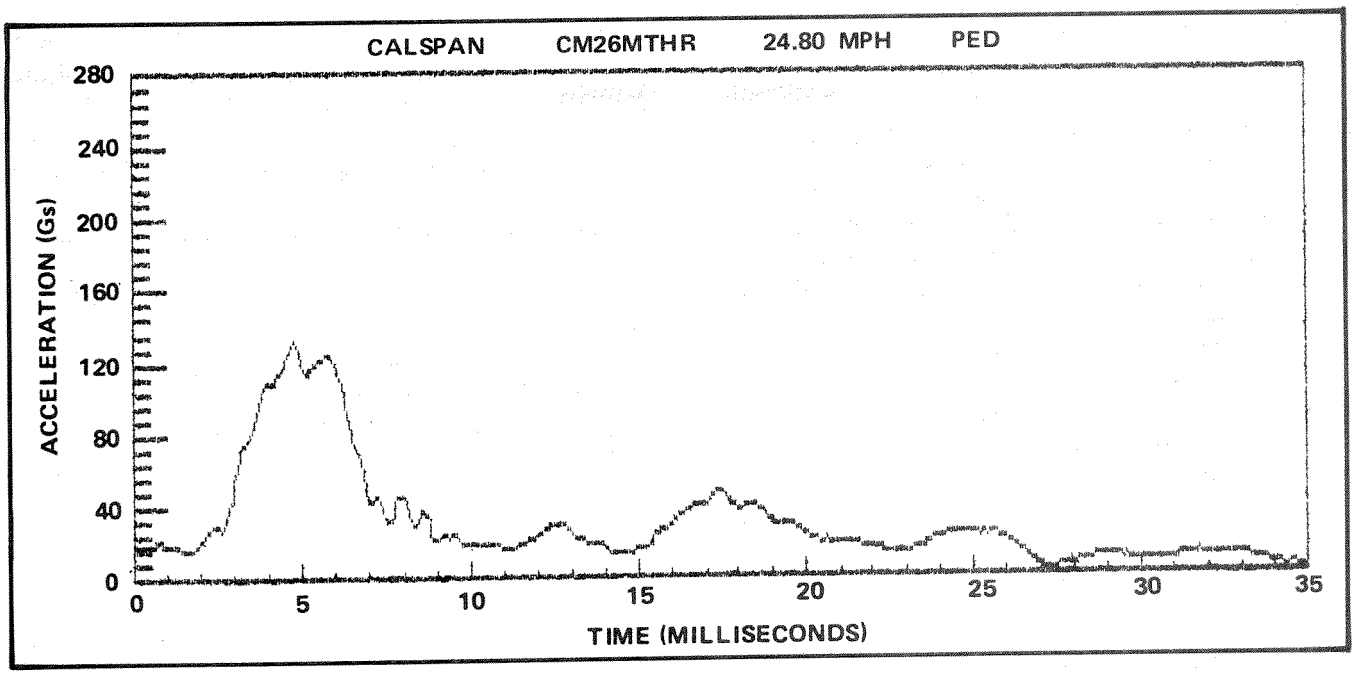

Figure 6. Acceleration versus time. (CM25, IMP, 13.1fps velocity at impact. HIC = 1021)

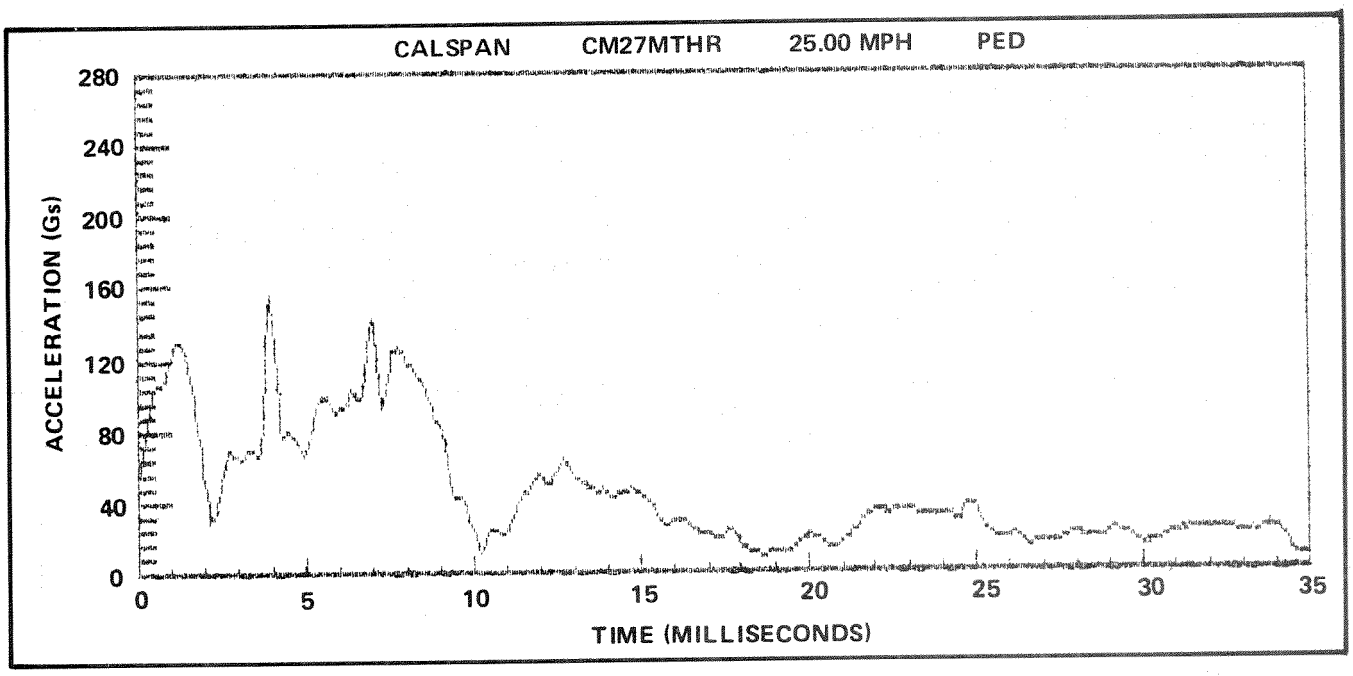

Figure 7. Acceleration versus time. (CM26, PED, 35.8fps velocity at impact. HIC = 417)

attached to CV7, which ruptured the anterior longitudinal ligament but did not sever the spinal cord. There was no damage to the skull, dura, meningeal vessels, or brain.

The potential deficit associated with this type of injury could not be assessed. These neck injuries would be an AIS 3.

There was no injury observed to the head, brain, neck, or spinal cord of this subject. An AIS value of 0 would be assigned.

This cadaver experienced a skull fracture splitting the sphenopetrosal suture in the middle cranial fossa on the left side. The greater superficial petrosal nerve on the left side was cut, and there was a contusion of the inferior part of the temporal lobe on its medial side. There was also damage to the left uncus (areas 34 and 35)(3) and to the medial part of the parahippocampal gyrus (areas 28, 35, and 36).

There would be a loss of lacrimation and a decrease in mucous production on the left side of this subject. The skull fracture would constitute an AIS 3.

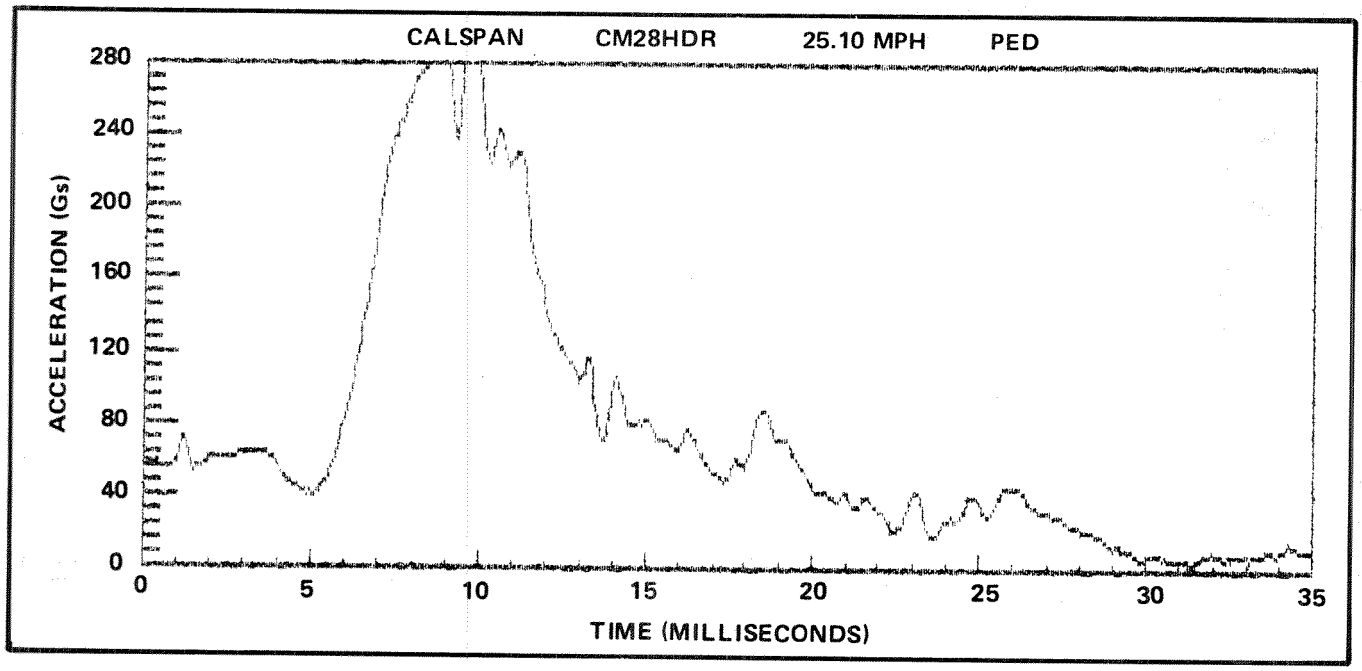

Figure 8. Acceleration versus time. (CM27, PED, 34.5fps velocity at impact. HIC = 761)

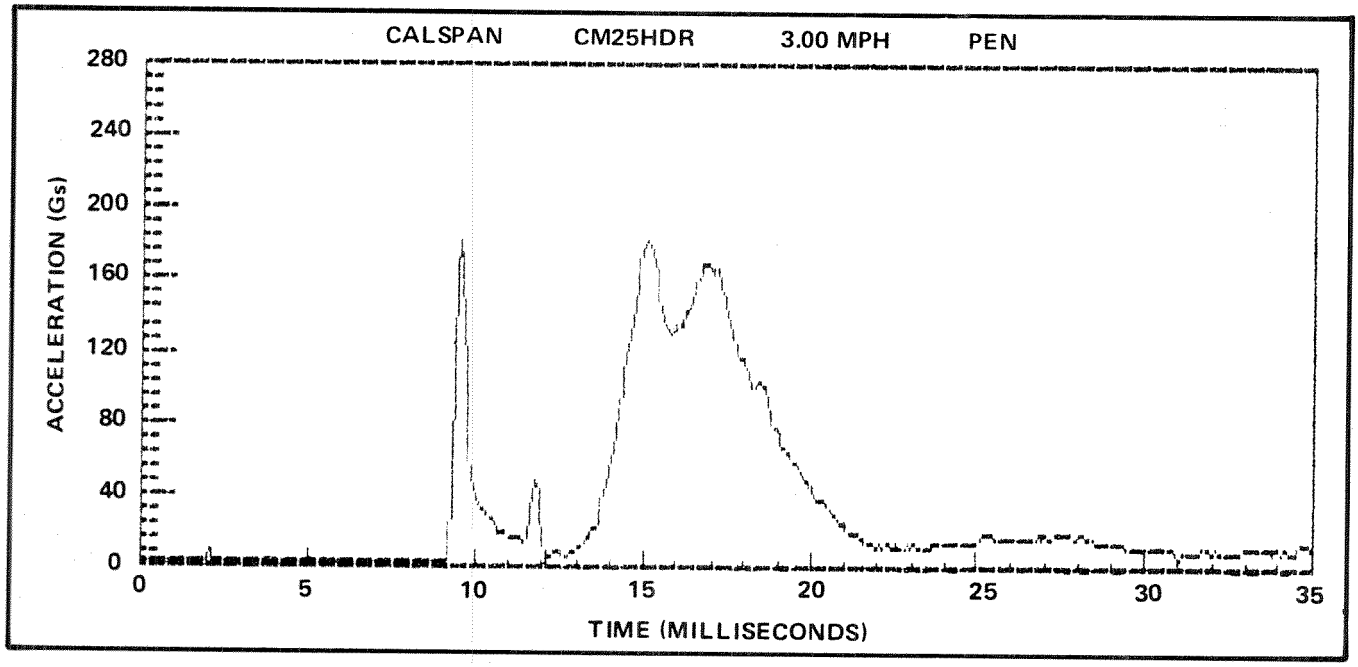

Figure 9. Acceleration versus time. (CM28, PED, 34.6fps velocity at impact. HIC + 4787)

On the right side, the subject exhibited damage to the superior lateral part of the pre- and post-central gyri and to the paracentral lobule (areas 4, 3, 1, and 2) and the pars opercularis and triangularis (areas 44 and 45). On the left side, in addition to damage to areas 4, 3, 1, 2, 44, and 45, the subject demonstrated damage to the caudal one-half of the superior frontal and middle frontal gyri (areas 6 and 8) and the superior temporal gyrus (area 22).

The damage to areas 4 and 6 would cause paresis or paralysis depending on the severity. The damage to area 8 would show no noticeable deficit, while that to areas 3, 1, and 2 would cause an inability to feel any sensations. Aphasia would be the result of the trauma to areas 44 and 45, and the aphasia notwithstanding the damage to area 22 would cause the inability to speak meaningful sentences. These brain injuries would be an AIS 3.

Multiple brain contusions were observed on this subject. In general, they were similar to those observed in CM30 with the exceptions that areas 3, 1, and 2 were not damaged but the angular gyrus on the left side (area 39)

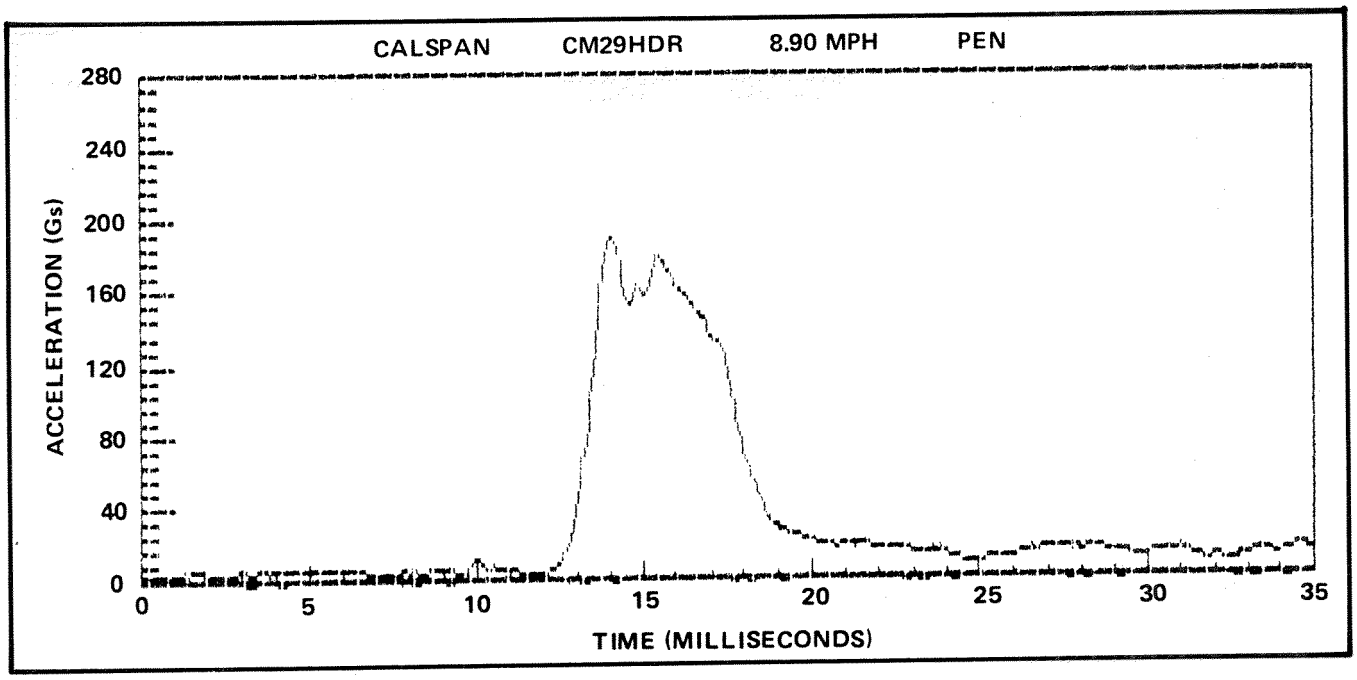

Figure 10. Acceleration versus time. (CM29, IMP, 13.2fps velocity at impact. HIC = 1290)

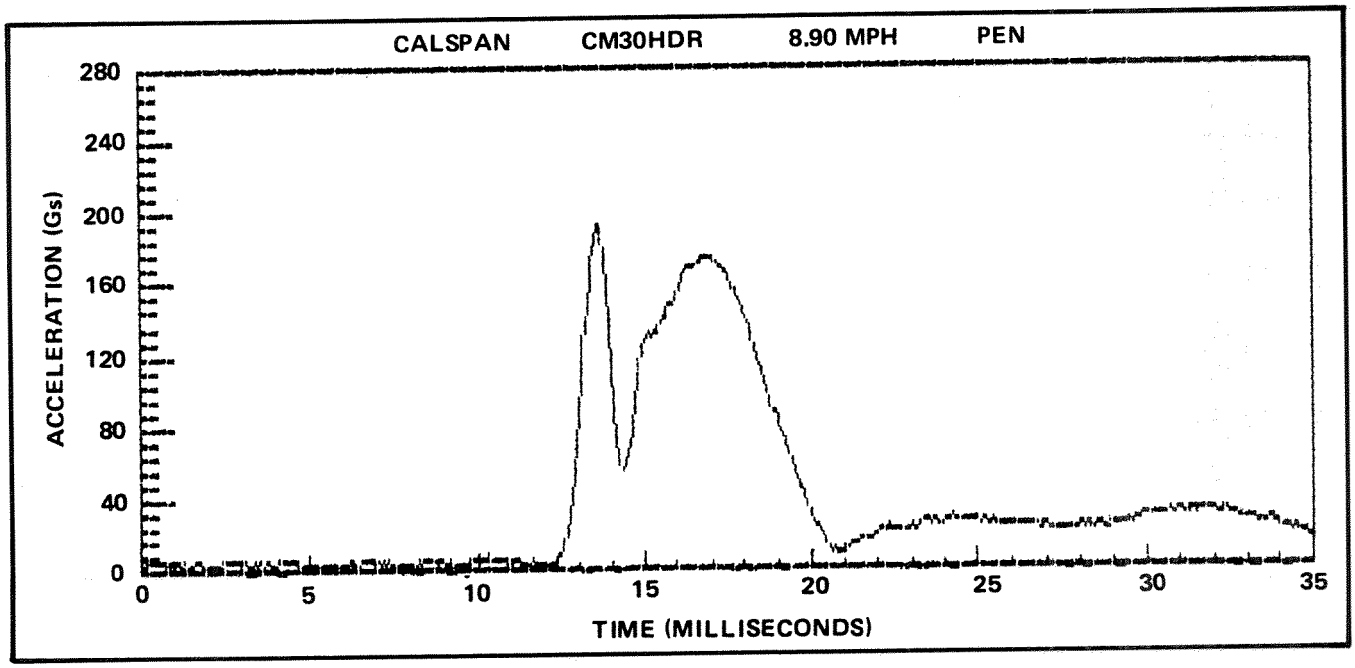

Figure 11. Acceleration versus time. (CM30, IMP, 13.1fps velocity at impact. HIC = 1306)

was damaged, in addition to the anterior temporal poles bilaterally. This subject then exhibited damage to areas 4, 6, 8, 44, 45, 39, and 22.

In addition to paresis or paralysis, aphasia, and the inability to form meaningful sentences but without the ability to feel any sensations (areas 3, 1, 2), the person would demonstrate a problem in recognizing certain written words (area 39). These injuries would constitute an AIS value of 3.

There was no damage observed during the dissection of the brain of this subject.

Since there was no identifiable damage observed, no noticeable deficit could be determined, and an AIS value of 0 would be assigned.

Brain contusions were found in the right cerebral hemisphere in the inferior part of the pre- and post-central gyri involving areas 4, 3, 1, and 2. There was some damage to the left uncus.

Paresis or paralysis (area 4) and an inability to feel sensations (areas 3, 1, and 2) in the head/neck regions would be exhibited by a subject with these types of trauma. This brain damage would be an AIS 3.

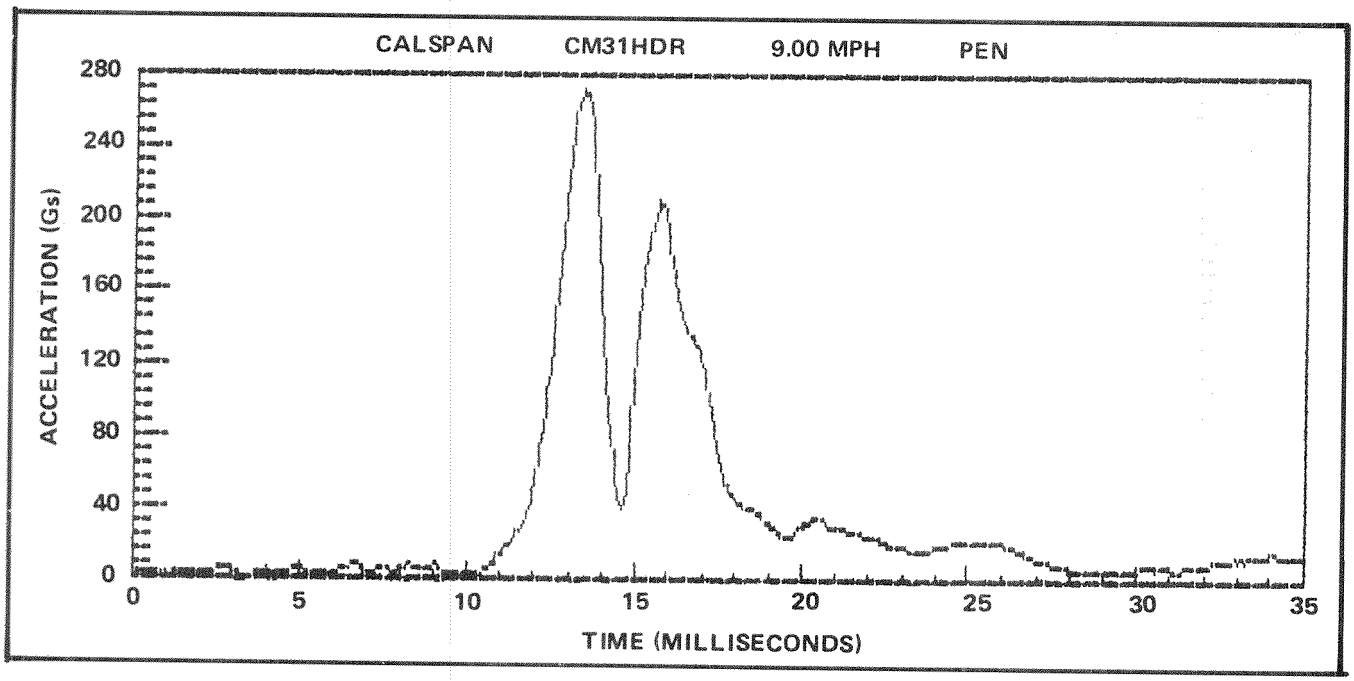

Figure 12. Acceleration versus time. (CM31, IMP, 13.2fps velocity at impact. HIC = 1545)

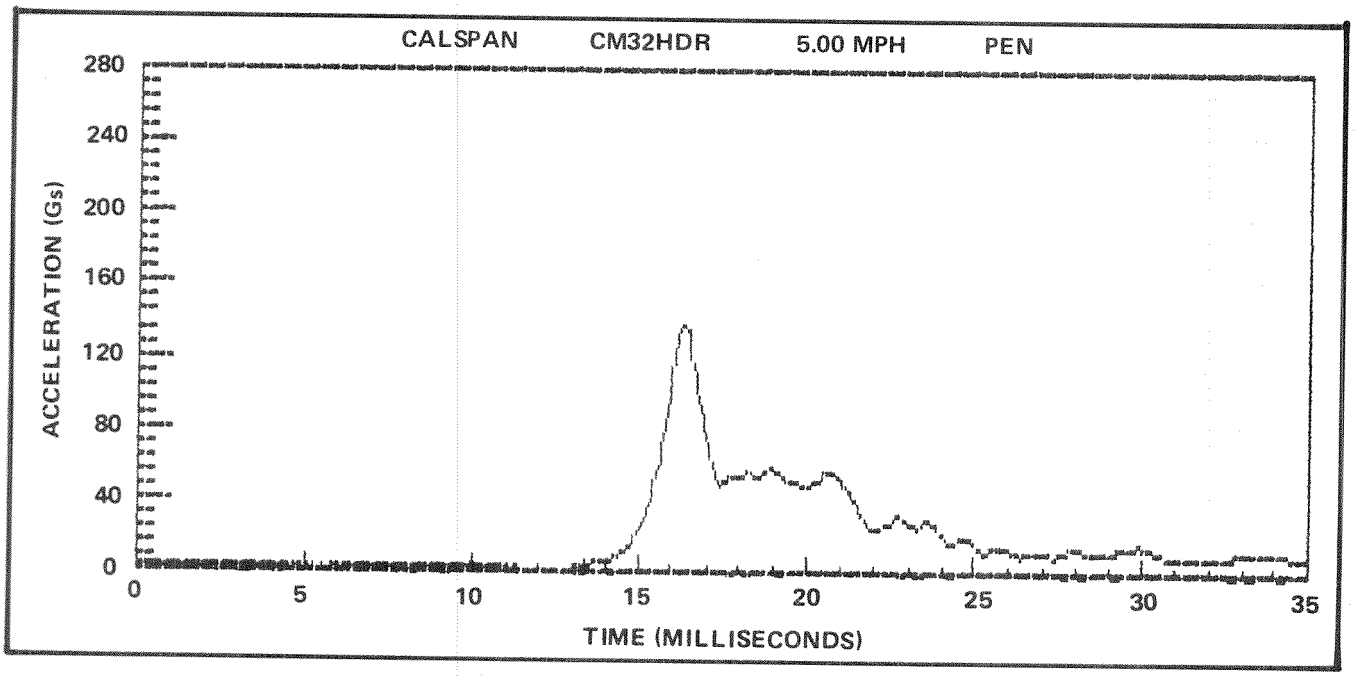

Figure 13. Acceleration versus time. (CM32, IMP, 7.3fps velocity at impact. HIC = 206)

On the right side, brain contusions of the superior and lateral parts of areas 4, 3, 1, and 2 were observed. Additionally, there was damage to the superior parietal lobule (areas 5 and 7).

The inability to feel any sensations notwithstanding areas 5 and 7 would cause a problem with the person's ability in localizing sensations. The paresis or paralysis caused by the damage to area 4 is noted. This brain damage would also be assigned an AIS value of 3.

The middle cranial fossa displayed a fracture just anterior to the petrous portion of the temporal bone. The fracture passed directly through the tegmen tympani toward the cavernous sinus. The fracture did not cross the basilar part of the occipital bone, nor the hypophyseal fossa. Upon examining the tympanic, cavity, no damage to the tympanic membrane, ossicles, chorda tympani, or facial nerve was observed. The semicircular canals were also intact. On the impacted side, contusions were

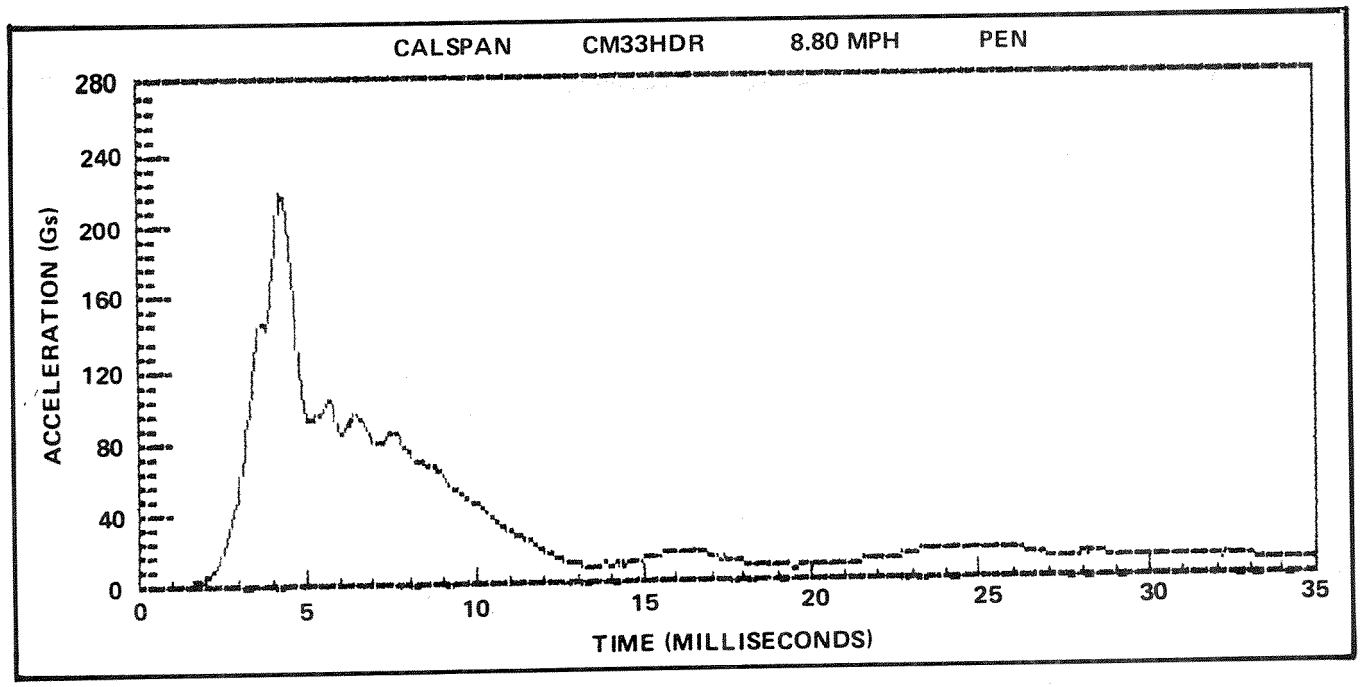

Figure 14. Acceleration versus time. (CM33, IMP, 12.9fps velocity at impact. HIC = 658)

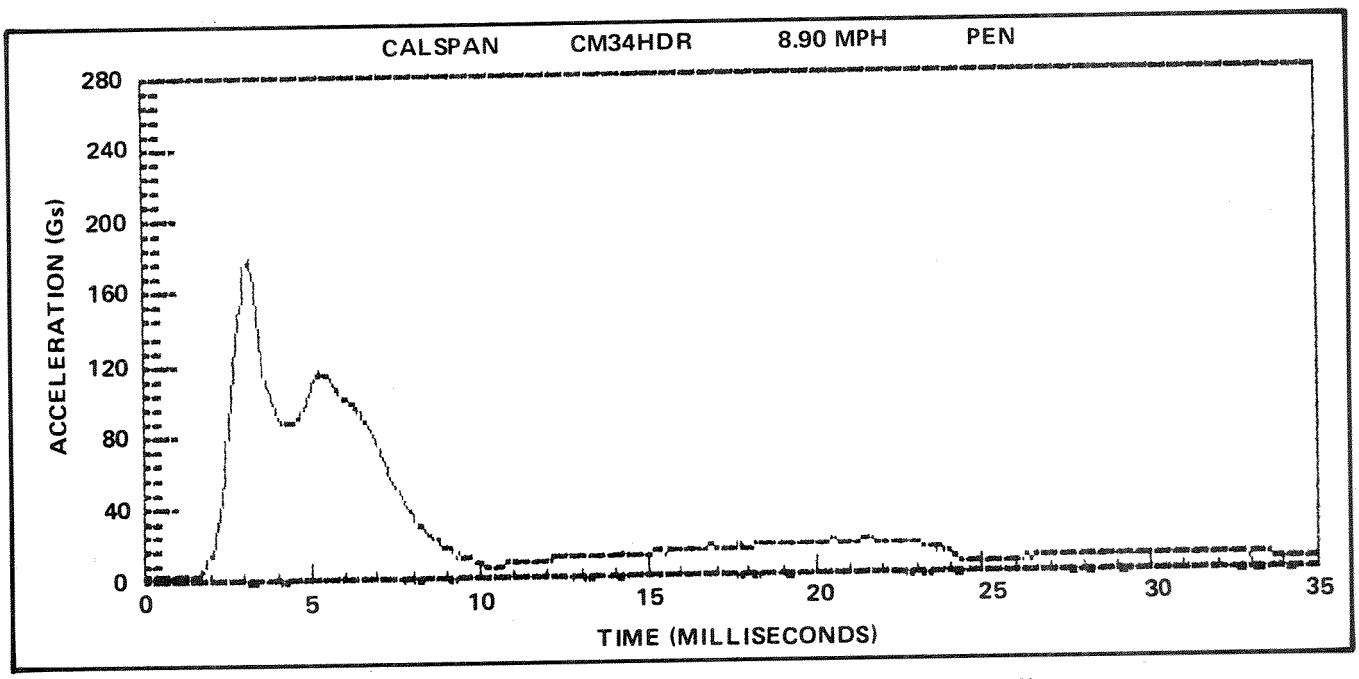

Figure 15. Acceleration versus time. (CM34, IMP, 11.0fps velocity at impact. HIC = 549)

evident on the superior portion of the central sulcus affecting areas 4 and 6 and areas 3, 1, and 2 as well as 5 and 7 in the head region. On the contrelateral side, contusions were evident on areas 3, 1, and 2 and areas 5 and 7 in the head region and in area 4 in the upper extremity region.

The effect of the contusions on this subject would be as noted in the other subjects with damage to areas 4 and 6 (paresis or paralysis), 3, 1, and 2 (inability to feel any sensation), and 5 and 7 (problem in localizing sensation). An AIS 3 would be assigned to this subject.

There was no damage observed during the dissection of the brain of this subject.

Since no trauma could be identified, no neurological deficit could be determined. An AIS of 0 would be assigned to this subject.

Brain contusions were found bilaterally on the entire frontal lobe extending posteriorly to the precentral gyrus. On the right side, damage occurred to areas 44 and 45.

Aphasia would result to some degree in this subject along with a potential for personality change. An AIS of 3 would be assigned for these brain contusions.

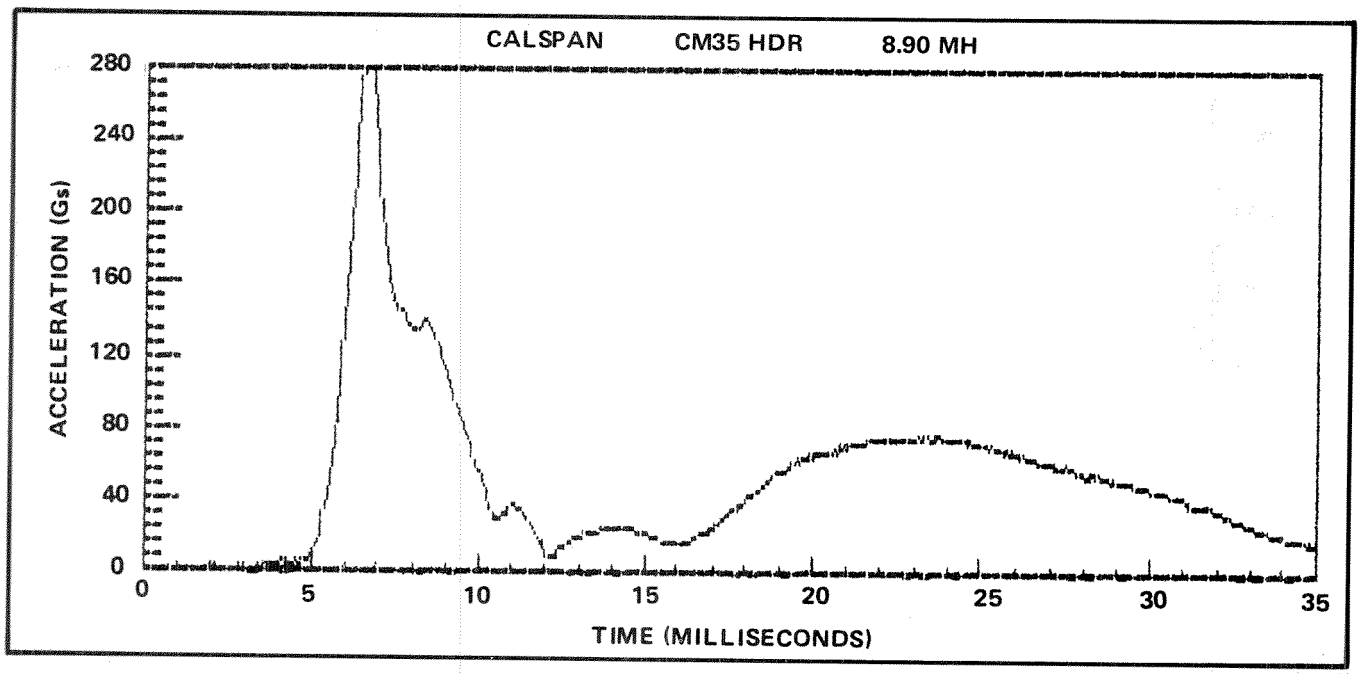

Figure 16. Acceleration versus time. (CM35, IMP, 13.1fps velocity at impact. HIC = 1284)

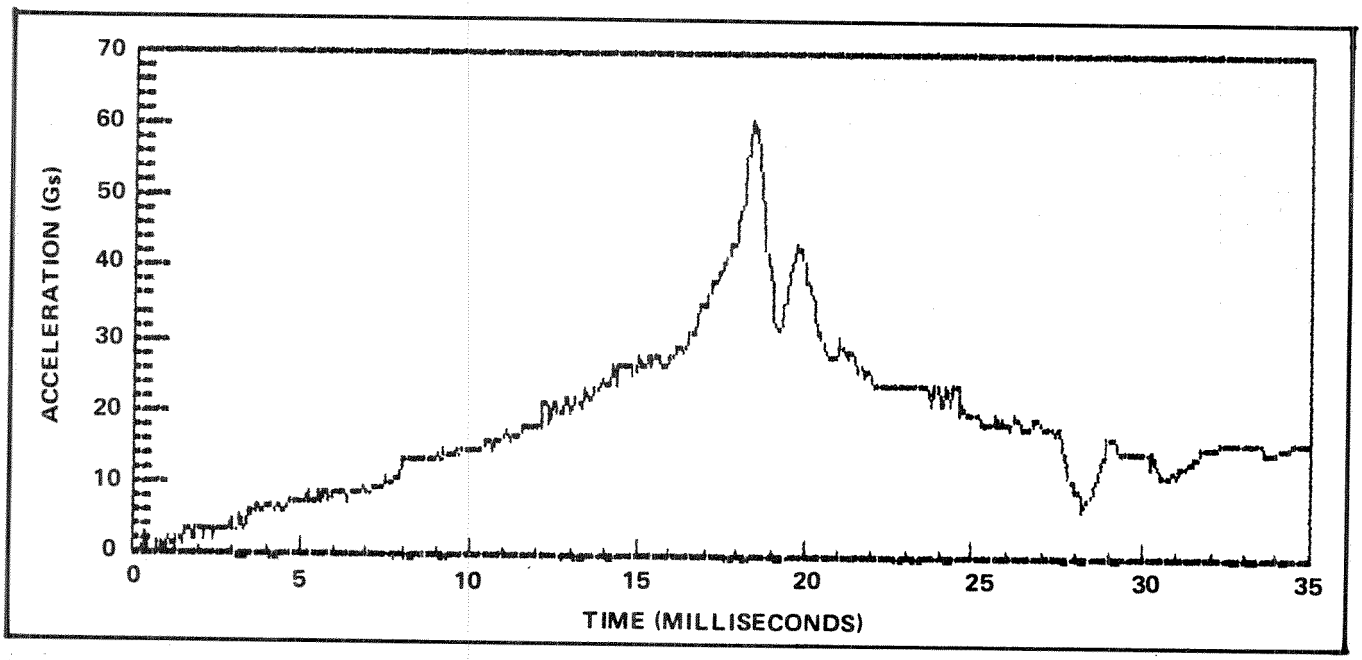

Figure 17. Acceleration versus time. (CM36, IMP, 12.7fps velocity at impact. HIC = 63)

Conclusion

With the exception of those four cadavers that experienced no discernible injury (AIS 0), and CM20 (severed spinal cord, AIS 5) and CM23 (epidural hematoma, AIS 4), all of the subjects demonstrated an AIS 3 either in the head or the neck and, in some cases, in the head and the neck. If only the head injuries are considered, a range of HIC values from 525 through 3967 produced AIS 3 level injuries. CM23 with an HIC of 3967 in addition to the epidural hematoma experienced multiple skull fractures. There is essentially no correlation demonstrated in these results between HIC value and brain injury. AIS 0 levels were observed at a range of HIC values of 63 (CM36) through 4787 (CM28). The acceleration versus time history (Figure 9) and the high-speed movies of CM28 indicate that there is no artifactual contribution that would distort the HIC calculation, but other than this value all of the AIS 0 subjects demonstrated HIC values below 500.

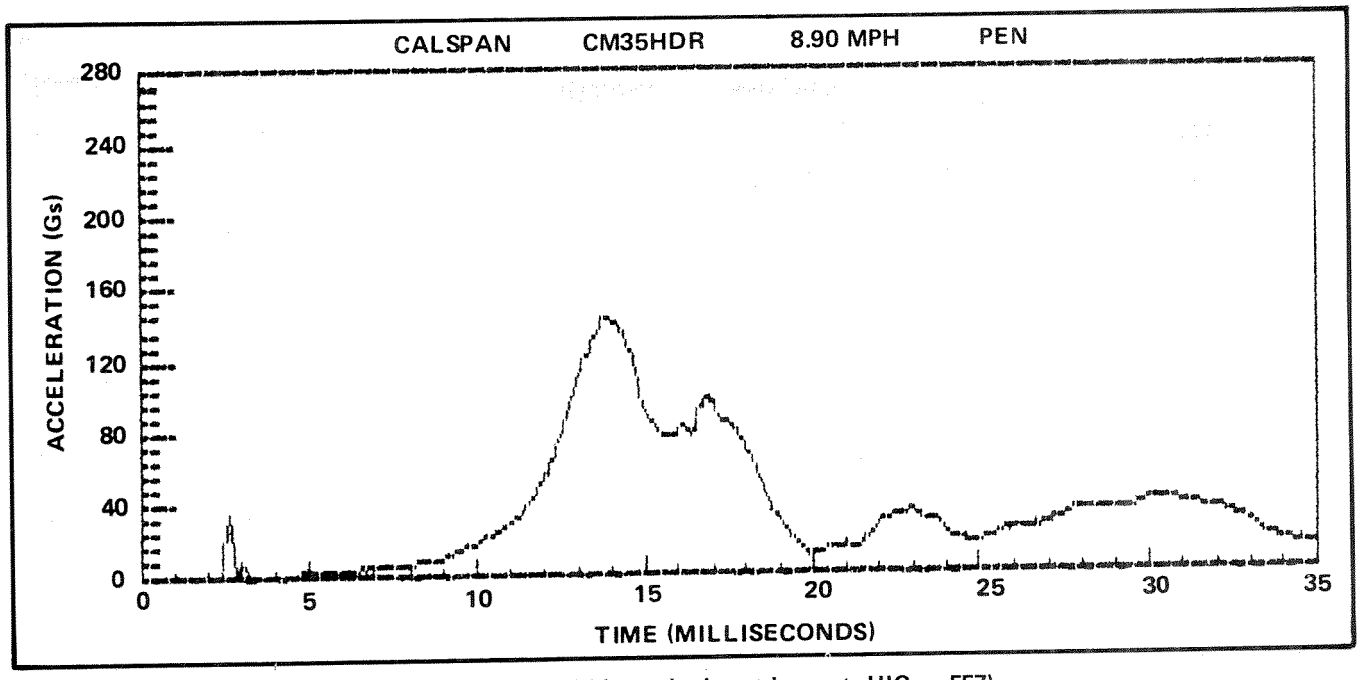

Figure 18. Acceleration versus time. (CM37, IMP, 128fps velocity at impact. HIC = 557)

These data indicate that the AIS coding for trauma to the brain is not as precise as is needed for this type of research. For example, any brain contusion is coded as an AIS 3. There are, of course, the Loss of Consciousness(L.O.C.) severity levels, but they are of no aid in assigning severity levels to injuries that are observed in cadavers that have been impacted in the laboratory. Additional effort is required to better map the thresholds of injury in head impacts and at the same time to better define injury codes for the trauma observed. A case in point might be made with a comparison of the CM34 and CM37 tests. CM34 was impacted at 11fps with a hard-faced impactor, and CM37 was struck at 12.8fps with 1in of padding on the impactor face. Essentially identical HIC values (549 and 557, respectively) were obtained, and identical AIS values of 3 were assigned. What is left undetermined in this information is whether the damage to areas 4, 3, 1, 2, 5, and 7, with the subsequent loss of the ability to localize and/or feel sensation and the paresis or paralysis, should be considered more or less severe (or equal in severity) than the damage to the entire frontal lobes and areas 44 and 45, with the potential change in personality and aphasia.

The data obtained from these 18 subjects agree in general with the data presented by Prasad and Mertz(4), especially in the area of brain damage as reported by Got et al.(5), Tarriere et al.(6), and Nahum and Smith(7,8). No attempt was made to quantify the skull thickness of the subjects reported herein, but skull fractures were experienced at HIC values of 1290 and 3967. These results agree in general with the data presented in (4) by Tarriere et al.(6), Got et al.(9), and Hodgson(10,11).

Abstract

This paper addresses the risks of motor vehicle involvement in highway accidents. Such risks are determined from U.S. accident experience in the past 10 years. Risks are analyzed as a function of vehicle type, car market class, make, nameplate, and model year for accidents of various types and various severities. Both absolute risks, per unit exposure, and relative risks are addressed. The influence of many exposure variables is examined and necessary adjustments, to a common set of exposure conditions, are made. The control variables for this purpose are: calendar year, car age, driver's age, sex, and alcohol involvement; time and place of travel; and various roadway characteristics. Adjusted risks are reviewed versus major characteristics of cars as implied by make, nameplate, and model year. Single driver accidents and rollovers, whether pre- or post-impact, receive special attention due to their risk sensitivity to car class.

Introduction

In the past 10 years, the motor vehicle fleet in the United States has undergone significant changes in the mix of vehicle types on the road, the mix of car classes, the design and engineering of cars, and the introduction of new components and equipment. In addition, strong factors were at work in the early 1980's that individually or collectively had and have the potential to influence highway safety significantly. A depressed economy inhibited travel growth, especially for the higher risk discretionary travel. Highway safety programs, e.g., campaigns against drunken drivers and seatbelt use programs, were initiated and pursued vigorously. The questions we are addressing in this paper are whether or not and how all these changes are affecting accident risks, as determined from the accident experience of motor vehicles on U.S. roads in the past 10 years.

We treat accident risks as dependent variables where the independent variables are: calendar years, accident types, and accident severities; motor vehicle attributes such as vehicle types, market classes, makes, models, and model years; driver attributes such as age, sex, and alcohol involvement; and exposure attributes such as time, highway type and location, travel speed, roadway characteristics, etc. A companion paper (12) addresses occupant casualty risks as a function of crash attributes such as type of impact and impact severity; occupant attributes such as seating position, restraint status, and occupant age; and vehicle attributes such as those mentioned above.

Major Changes in the Motor Vehicle Fleet and Travel

In the period between the mid-1960's and the mid-1980's, the number of motor vehicles on U.S. roads grew faster than the number of drivers or the number of people in general.

Two vehicle types with particular safety problems, namely trucks and motorcycles, have grown much faster than cars. The number of trucks on U.S. roads today is about 40 million, or more than three times their number in the mid-1960's. Motorcycle registrations, approaching 6 million today, are more than four times as many by comparison to the mid-1960's. In contrast, car registrations have barely doubled in the same period.

However, significant changes took place within the car fleet. These include the introduction of radial tires, disc brakes, variable brake proportioning, and changes in the design and engineering of suspensions and steering. Furthermore, since about 1976 the entire fleet of new cars, primarily those domestically produced, was fundamentally redesigned to yield significantly lighter vehicles with predominantly front wheel drive.

Three car characteristics—weight, wheelbase, and front wheel drive—are given special consideration because they are frequently discussed and analyzed in connection with accident and casualty risks. A summary of changes in these characteristics for new cars retailed in the United States is given in Table 1, by market class. The changes refer to mean values of those characteristics between model years introduced in the early 1970's and model year 1983.

Note in Table 1 that the front wheel drive percentages are the shares in model year 1983. The same shares were virtually equal to zero for model years up to 1976. Also note that the domestically produced fleet shows substantial

Table 1. Percent change in mean weight, mean wheelbase, and percent front wheel drive of model year 1983 cars by comparison to new cars of the early 1970's

Market Class	Percent Change Mean Weight	Percent Change Mean Wheelbase	Percent* with Front Wheel Drive
U.S. Subcompact	-18.0%	-2.5%	80%
Compact	-23.5	-8.1	65
Intermediate	-22.8	-6.8	33
Standard	-11.5	-4.3	14
European Subcompact	+5.9	+1.9	99
Other	+9.9	+2.2	16
Japanese Subcompact	0.0	+1.6	72
Other	+5.8	0.0	18

*Shares in model year 1983; these were virtually zero up to model year 1976.

reductions of weight and wheelbase, all across the board, while this is not the case for the fleets of European or Japanese origin. Apparently, redesign practices and market shifts in these latter fleets, which consist of predominantly subcompact cars, led to modest increases in weight and wheelbase.

As a result of these developments, subcompact cars of U.S., European, or Japanese origin have become virtually indistinguishable, when viewed in terms of the three major characteristics discussed above. Moreover, the standard, intermediate, and compact U.S.-produced cars of model year 1983 have essentially assumed the weight and wheelbase characteristics of the intermediate, compact, and subcompact cars of the early 1970's, respectively.

Because of the prominence of car weight, wheelbase, and front wheel drive in safety reviews, we treat the changes summarized above with more detail and more quantitatively in Appendix A. In the same appendix, we also address changes that took place in the travel of motor vehicles and in the various aspects of exposure to accident risks.

Accident Involvement Risks and Risk Descriptors

Several descriptors are convenient for the characterization of the accident experience of motor vehicles, depending on the particular aspects of the problem at hand and on the availability of relevant data. Risk descriptors for accident-involved vehicles are usually expressed as:

$$R_{ijk} = V_{ijk}/E_{jk} \quad (1)$$

where

V is the number of accident-involved motor vehicles, categorized by i, j, k

E is the amount of exposure (e.g., travel) categorized by j, k

i designates accident categories including accident type (e.g., collision with other motor vehicle, collision with fixed object, overturn, etc.) and also including accident severity (e.g., fatal accident, or accident with injury only or property damage only, etc.)

j designates vehicle categories including vehicle type (e.g., car, pickup, van, heavy truck, etc.) and also including further subclassifications (e.g., car market classes, make, model, model year, etc.)

k designates travel-related exposure categories including driver attributes (e.g., age, sex, alcohol involvement) and also other travel attributes (e.g., time, day, urban or rural environment, roadway and traffic characteristics, etc.)

Risks as defined by Equation (1) are absolute. The most customary type of exposure used for risk estimation is vehicle travel, expressed in vehicle miles. However, several other alternatives may be and are being used in this paper. The number of registrations is an acceptable alternative, if differentials in travel per vehicle are not important or if means are available for taking into account such differentials whenever they appear to be important.

Another alternative applied in this paper is the concept of the conditional risk. This, as an example, addresses the question: "Given an accident in general what is the risk of this accident being fatal?"; or the question: "Given an accident in general what is the risk of this accident being a rollover?" In other words, we count the vehicles involved in fatal accidents and divide by the count of the same vehicles involved in accidents of any severity, or we count vehicles involved in rollovers and divide by the count of vehicles involved in any type of accident. In this process,

we may retain in both the numerator and denominator any desired characterization of vehicle, driver, or environmental categories.

A summation of Equation (1) over subscript i, i.e., over all accident categories, yields:

$$R_{jk} = V_{jk}/E_{jk} \quad (2)$$

Furthermore, dividing (1) by (2) yields Q_{ijk}, the conditional risk, i.e.:

$$Q_{ijk} = R_{ijk}/R_{jk} = V_{ijk}/V_{jk} \quad (3)$$

It is noted that the amount of exposure E_{jk} drops out when Equation (1) is divided by Equation (2). This is certainly a loss of rigor. However, it is compensated by a strong advantage, namely, better compatibility between numerator and denominator in the vehicle categories and exposure categories represented respectively by subscripts j and k.

Note that in the estimation of conditional risk by Equation (3), both the numerator and denominator are vehicle counts, most likely to be obtained from one and the same file or at least from very similarly structured casualty files. This minimizes the errors arising from differences in the classification of vehicular and circumstantial characteristics used in the estimation process. However, this is not the case in the estimation of absolute risks by Equation (1), where the numerator and denominator are obtained from data files of very different origins.

For example, the numerator in Equation (1) is obtained from a casualty file such as NHTSA's Fatal Accident Reporting System (FARS)(1) or NHTSA's National Accident Sampling System (NASS)(2) or from a State accident file. None of these casualty files contains information about the denominator. Values for this denominator must be assembled from other files: motor vehicle registration files such as those provided in (4) and motor vehicle travel files such as any one or several of those in (6) to (10). Because of the very dissimilar origins of the data necessary for the estimation of absolute risks, it is a challenge to achieve numerator/denominator compatibility in Equation (1).

In addition to minimizing the chances of error in risk assignments, the use of conditional risks also offers the advantage of a wider range of attributes for examination. This is particularly true for environmental and circumstantial attributes such as curving or sloping roadway, wet or dry pavement, road intersection or not, etc., which are unlikely to be available for the estimation of the denominator in Equation (1) but are available in the case of Equation (3). For the reasons discussed above, we use extensively conditional risks in conjunction with absolute risks in the exploration of the state-of-the-art in accident avoidance, discussed in this paper.

Risks of Fatal Accident Involvement

A motor vehicle's risk of involvement in a fatal accident stood at about 5.67 ± .13 per 1,000 vehicles involved in all police-reported accidents on U.S. highways. This is the mean and standard error derived from six individual values, each obtained from the data for each of the six years 1979 to 1984. It refers to all types of accidents, all categories of vehicles, and all model years. It varies very little within the specified time period (see Figure 1) in spite of the significant changes in the fleet and travel patterns discussed earlier.

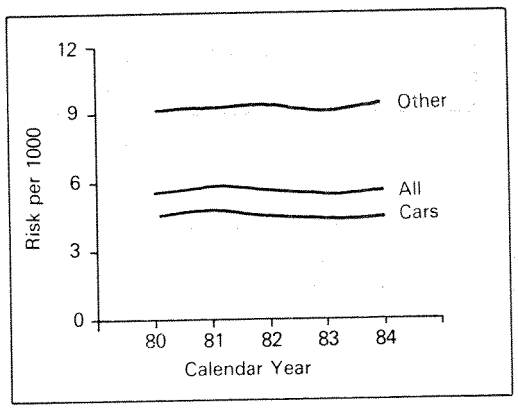

Figure 1. Risk of motor vehicle involvement in fatal accidents per 1,000 vehicles in all police-reported accidents

The data for the determination of this conditional risk are provided by two accident files of national scope, i.e., by FARS and NASS(1,2). Specifically, a total count of all vehicles involved in fatal accidents (national census) is obtained from FARS, and this is divided by a national estimate of all motor vehicles involved in all police-reported accidents, as recorded in NASS. This process is repeated for each of the calendar years 1979 to 1984.

When disaggregated by accident, vehicle, driver, or circumstantial attributes, the risk under consideration varies within a wide range. This, of course, has been known for a long time. However, the relatively recent availability of several years of FARS and NASS data of national scope provides an opportunity for quantitative results. Furthermore, the relative similarities in the structure of these files minimizes the chances of error due to incompatibilities in the classification of attributes. Risks for the two most important accident and vehicle attributes, namely accident type and vehicle type, are shown in Tables 2 and 3, respectively. These results are based on FARS and NASS data.

The risk values reported in Tables 2 and 3 are means and standard errors over the 1979 to 1984 calendar year span. Most of the characterizations are self-explanatory.

Table 2. Risk of motor vehicle involvement in fatal accidents per 1,000 vehicles in police-reported accidents as a function of accident type (first harmful event)

Accident Type	Percent of Vehicles*	Risk per Thousand in Row
Collision with Other MV	83.7 ± .27	3.83 ± .05
Collision with Object	11.7 .48	10.6 .52
Collision with Nonmotorist	2.06 .08	38.2 1.7
Overturn	1.68 .09	22.6 1.3
Other Noncollision	.87 .26	9.23 2.6
Total	100.0	5.67 .13

*In all police-reported accidents

Table 3. Risk of motor vehicle involvement in fatal accidents per 1,000 vehicles in police-reported accidents as a function of vehicle type

Vehicle Type	Percent of Vehicles*	Risk per Thousand in Row
Cars	77.8 ± .12	4.51 ± .03
Pickups	12.7 .12	7.44 .03
Vans	3.30 .13	5.47 .11
Straight Trucks	1.80 .11	7.99 .33
Combination Trucks	1.96 .06	20.0 .73
Buses	.59 .05	5.43 .33
Motorcycles	1.80 .02	25.8 .17
Total	100.0	5.67 .13

*In all police-reported accidents

Nonoccupants in Table 2 include pedestrians and bicyclists. Overturn is a rollover usually not preceded by an impact with another motor vehicle or with an object. A variety of less frequent events such as fire, explosion, immersion, etc., are included under "other noncollision." In Table 3, pickups and vans are vehicles with a gross vehicle weight rating under 10,000 lb. Straight trucks are nonarticulated trucks and vans over 10,000 lb.

It is evident in the summary of Table 2 that collision with another motor vehicle is the most frequent event but also the least risky. By reference to this, a motor vehicle's risk of fatal accident increases by a factor of 3 when a collision with an object occurs and it is 5 to 6 times higher for an overturn. Overturn as a first harmful event as well as rollover, an event subsequent to an impact, will be addressed in more detail later. The riskiest events are collisions with nonoccupants, for obvious reasons. However, the reader should note that the risk magnitude is not the only determinant of the importance of a problem. The frequency of occurrence of the circumstances that give rise to the risk is as important, if not more important. Consider, for example, the results in Table 2 to see why car collisions with other motor vehicles receive a lot of attention, in spite of the risk of fatal accident in such events being the lowest.

The summary of Table 3 shows cars running the lowest risk, in spite of their overwhelming share as vehicles in all police-reported accidents. Vans and buses show higher risks but not much higher than the risk for cars. The risks for pickups as well as for other nonarticulated trucks is about double that of cars. Much higher risks are evident for the heavy articulated trucks and also for motorcycles. Risks assigned to joint accident-vehicle type attributes show generally trends expected on the basis of the results given in Tables 2 and 3. Figure 2 displays risks for cars, pickups, and all motor vehicles as a function of accident type.

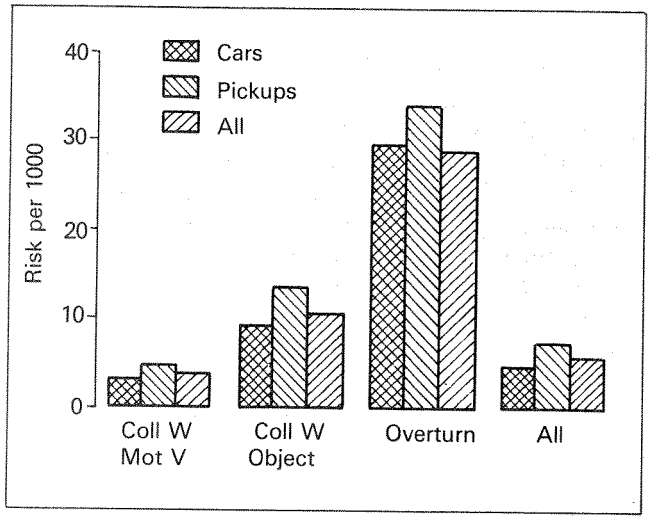

Figure 2. Risk of motor vehicle involvement in fatal accidents per 1,000 vehicles in all police-reported accidents (shown for cars, pickups, and all vehicle types, as a function of accident type)

Fatal Accident Involvement of Cars

Because of their overwhelming share of the vehicles in all police-reported accidents, cars are receiving further attention in this paper in connection with their risk of fatal accident involvement.

According to Table 3, a car's risk of involvement in a fatal accident is 4.5 ± .03 per 1,000 cars involved in all police-reported accidents. This is the mean and standard error for the 6-year period of 1979 to 1984. The smallness of the error indicates relatively little variation of the risk, whether random or systematic, in this period. This is also shown in Figure 1.

However, when this risk is resolved according to car travel attributes and type of accident, the resulting values vary within a range of two to three orders of magnitude.

This is evident in the results shown in Table 4. These are means and standard errors of car risks in the early 1980's. A difference by a factor of 2 to 3 is seen between day and night and by about 5 to 7 between urban and rural travel when all types of accidents are considered. Risks for certain types of accidents, such as overturn and collision with an object, are remarkably insensitive to car travel attributes. Risks for other types, such as collision with pedestrian and collision with motor vehicle, show a large sensitivity.

Like other vehicles, cars show fatal accidents risks that are strongly dependent on the type of accident. The last row in Table 4 quantifies this point. The highest risk is observed for overturns, followed closely by the risk in case of collision with nonmotorists. The risk in collisions with an object is three times lower than that of collisions with nonmotorists, but still three times higher than the risk of fatal accidents in car collisions with other motor vehicles.

It is common knowledge that car involvement in fatal accidents is influenced much by driver attributes. We have used the same data files as discussed above, namely the FARS and NASS, to quantify these influences, by calculating risks of car involvements in fatal accidents per 1,000 police-reported accidents, nationwide. In this case, uniform quality data are available for the 3 years 1982 to 1984. For this period, we report the mean values of risks in Table 5. The risk value 4.5 in the last row and last column of the last cluster in the table is recognized as the overall risk cited earlier. The 36 entries of this table resolve the overall risk by driver age, sex, and alcohol involvement.

The results of Table 5 quantify certain influences that have been qualitatively evident for a long time. Of the three driver attributes under consideration, alcohol has an overriding influence that makes a difference of a factor of 7 to 8, with remarkable consistency and uniformity all across the age and sex brackets. The standard errors for the mean values in Table 5 are about 3 percent in general except for the entries "With Alcohol Involvement" where the errors are about 10 percent. Furthermore, the reader should keep in mind that alcohol involvement as reported in accident files is a subject to be treated very cautiously because of potential error due to the nonuniformities in the investigation and reporting procedures.

The other two driver attributes in Table 5, namely driver's age and sex, have weaker but easily noticeable influences. Risk variation with age is minimal for all age brackets until the last, where a 40 to 50 percent jump is observed. This holds true generally, regardless of other driver attributes. Similarly, male drivers show risks about 30 to 40 percent higher than female drivers all across the driver age and alcohol involvement brackets.

Generally speaking, these influences are intuitively expected with one major exception. The young drivers, whether with or without alcohol involvement, show risks that are not higher than those of all other drivers, contrary to a commonly held notion. This is not necessarily a contradiction. Table 5 shows young drivers incurring about the same risk of fatal accident as all other drivers, given an accident. However, young drivers may have more accidents in general and thus more fatal accidents per driver, due for instance to more travel or to any other reason. Nevertheless, on a per accident basis, younger

Table 4. Resolution of risk of car involvement in fatal accidents by type of accident and travel attributes (cars in fatal accidents per 1,000 cars in all police-reported accidents)

drivers are not much different than other drivers in their risk of fatal accident involvement. Another reason why young drivers do not appear overinvolved in fatal accidents is that they are more able to survive trauma(12).

So far in the discussion, we have reported risks averaged over several years in the early 1980's. We know that the overall risk of fatal accident involvement has varied little in this period as shown in the plots of Figure 1. The question remains whether specific aspects of this risk show time variations in the period under consideration. An examination of the raw data, before averaging over the calendar years, shows variations that are predominantly random and are reflected in the standard errors reported in Tables 2 to 5. In relatively few instances, there are indications of systematic increase or decrease of the risk versus calendar year. One such instance, with a rather well-pronounced time variation, is illustrated in Figure 3.

Plotted in this figure is the risk of fatal accident involvement for cars in rural daytime travel versus calendar year. The average risk over all these years is about 10 as shown in Table 4. However, according to Figure 3, this risk has been increasing substantially as the years progress from 1980 to 1984. Incidentally, a similar but weaker trend is observed for the risks either in rural

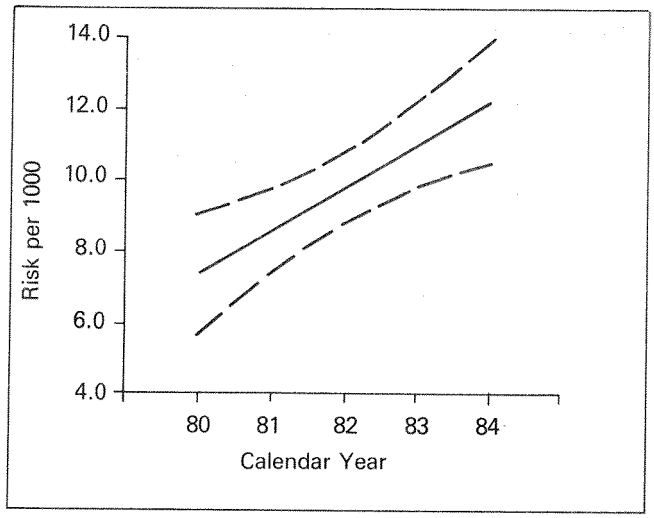

Figure 3. Risk of car involvement in fatal accidents per 1,000 cars in all police-reported accidents for rural daytime travel

travel regardless of day or night or in daytime travel regardless of urban or rural. The combination of rural and day travel amplifies the trend.

The general implication of the data shown in Figure 3 is that the exposure severity is increasing in rural travel during daytime. It is very tempting to correlate this finding and even tentatively assign it to the increasing noncompliance with the 55mph speed limit, taking place in the same period. (See, for example, Table A-6 and the related discussion in Appendix A.) However, a further review of the FARS and especially of the NASS data is required before definitive conclusions can be drawn about the rather unusual risk increase shown in Figure 3.

Car attributes may also influence the risk of fatal accident involvement. The influence of attributes such as origin of make, market class, nameplate, weight, wheelbase, etc., is reviewed and discussed in the next section. However, before closing this section, we address the conditional risk of fatal accident involvement for cars as a function of car age, and thus as a function of model year. For this purpose, we use again the fatal accident experience in FARS and the police-reported accident experience in NASS for car accident involvements in the early 1980's, combined.

We segregate the cars in four slots according to car age, i.e., according to calendar year minus model year, and we determine the risk of fatal accident involvement for each slot. The results are shown in Figure 4 for all drivers and separately for the young drivers (16 to 24 years old). These results lead to the conclusion that on a per-accident-involved driver, neither the age of the driver nor the age of the car makes much difference to the risk of the involvement being fatal.

The only obvious exception to our conclusion is the risk for the oldest cars, which is higher by 25 percent

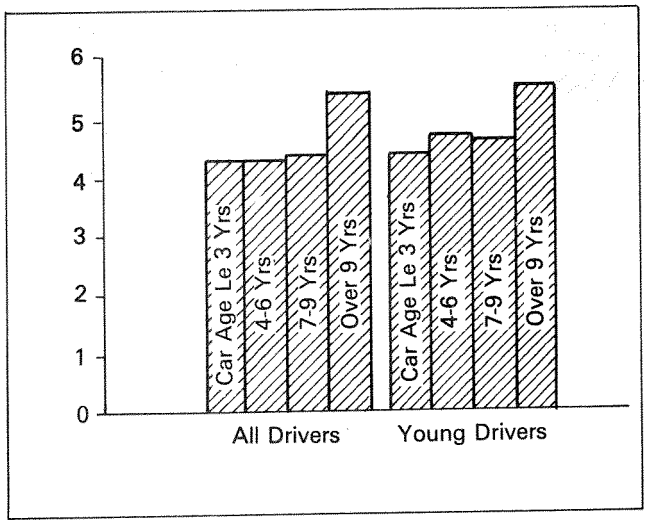

Figure 4. Risk of car involvement in fatal accidents per 1,000 cars in all police-reported accidents (shown as a function of driver age and car age)

compared to younger cars. Furthermore, it should be kept in mind that in these data, car age is covariant with car model year. Thus, due to this unavoidable ambiguity, we may state an alternative conclusion: The risk of fatal involvement per accident-involved-car does not appear to be very sensitive to the car's model year. However, even for the oldest cars, the risk may be confounded and possibly artificially increased by the fact that these cars are regularly reported by the police in fatal accidents but might be underreported in nonfatal accidents. This is especially true when the value of an old car happens to be under the threshold for reporting.

Determination of Absolute Risks

To address the influence of car attributes on car accident experience, we focus our analysis on the new cars that traveled on U.S. roads in the 1975 to 1984 period. This is also the period during which major changes took place in car attributes, as discussed earlier and as detailed further in Appendix A. For the purpose of our analysis, we define new cars as those with an age (i.e., with a calendar/model year difference) not exceeding 3 years. This is a compromise between retaining as much uniformity as possible in travel and exposure attributes while dealing with sufficiently large samples in the accident experience.

Under these constraints, we found it difficult to make the conditional risk determinations, by a combined examination of FARS and NASS data, as discussed in the last section. This is so for several reasons: NASS data for car characterization (e.g., by make and model) are not available in a form compatible with FARS data until about 1981; NASS cell populations become rather small when the accident experience is subdivided by the many combinations of car market classes, makes, nameplates, and other specific attributes, especially when these subdivisions are made on new cars only. Furthermore, there are good reasons to suspect that NASS as a sample of the national accident experience may be biased in connection with car make/model content. For example, California and the West Coast in the United States are underrepresented in NASS, while the same regions are overrepresented in imported makes.

The conclusion from the above discussion is that we may not apply Equation (3) for the task under consideration here because we have no means of obtaining reliable values for the denominator. This is an extra reason for using Equation (1), which is appropriate for the determination of absolute risks. In this section, we shall deal with Equation (1) integrated over all travel-related exposure categories, i.e., we shall drop subscript k and write for the risk:

$$R_{ij} = V_{ij}/E_j \qquad (4)$$

where i and j represent accident and vehicle-related attributes. Later we will examine the influence of circumstantial and environmental attributes represented by subscript k.

The raw data necessary for the application of Equation (4) are provided by FARS(1) for the numerator and by (4) for the denominator. FARS contains records of about 100,000 new cars involved in fatal accidents in the 10 years between 1975 and 1984. Accident type and car nameplate are known for the great majority of these cars. Furthermore, their total count is generally adequate for analyses that demand disaggregation by several attributes of interest here.

Car registrations from (4) are used to quantify the denominator in Equation (4) by car descriptor j (nameplate and model year) for each of the calendar years included in the analysis. Although car exposure in general may not be characterized accurately by car registrations alone, our constraining the analysis to new cars only introduces a uniformity in the travel per car and other attributes sensitive to car age. Furthermore, a set of adjustments are made to the risks (determined for each model year and calendar year) to bring them all under a common reference exposure.

The selected reference exposure is that experienced by 1-year-old cars in the calendar year 1980. The adjustments, detailed in the first part of Appendix B, account for travel and exposure severity variations taking place in the 10 calendar years under consideration for new cars (i.e., 1-, 2-, and 3-year-old cars). Risk adjustment factors are shown in Table B-2 of Appendix B, as a function of calendar year and car age or model year. As may be seen, the adjustments are generally small and although they may have uncertainties, these are small by comparison to the risk differentials we shall consider worth pointing out.

To achieve numerator/denominator compatibility in the application of Equation (4), we disaggregate both the

accident-involved car data (numerator) and the car registration data (denominator) by car nameplate, model year, and calendar year. We found nameplate, i.e., make and model, disaggregation more suitable than disaggregation by weight or by wheelbase. Disaggregation by weight often introduces ambiguities due to weight variations on account of optional engine sizes and other optional equipment. Furthermore, when disaggregating by weight, borderline cases may fall in one weight slot for the numerator data but in a different weight slot for the denominator data. However, the main advantages of disaggregation by nameplate are that much more information is potentially available about the car under consideration, even if this information is not always publicly available, and the number of unknowns is very small.

Risk determinations may be made at the nameplate, model year, calendar year level by straightforward applications of Equation (4), with subsequent adjustments as discussed earlier. At this level, sample sizes are generally adequate for most purposes. Given our analysis is focused on new cars, we calculate risks separately for the 1-, 2-, and 3-year-old cars, all adjusted to the common reference exposure conditions, and form the mean of the three. In the process, we obtain the standard error of this mean.

In many instances, risks for new cars, whether by nameplate or by higher levels of aggregation, are available for several calendar years within the 1975 to 1984 span. In such cases, we also calculate means and standard errors, in addition to reviewing the data for systematic variation versus calendar year. Thus, the standard errors we report are more conservative given they embrace not only purely statistical fluctuations but all other variations whether random or systematic.

Results for levels of aggregation above nameplate are obtained as follows. The raw data, whether cars in accidents or car registrations, are pooled together and the procedures described above are repeated. This leads to risk determinations for new cars aggregated by make, car body family designation, market class, origin of make, and the entire fleet of new cars. The market class designations used in this paper are those commonly used in the automotive trade literature. Furthermore, all traditional sports car nameplates and other low-volume specialty cars have been excluded from consideration because of possibly singular characteristics and circumstances.

Absolute Risks for New Cars

Results obtained according to the procedures described above are presented and discussed here for new cars. The absolute risk of fatal accident involvement per 10,000 registrations of new cars is 3.41 ± .09 when averaged over all car market classes and all types of fatal accidents that occurred in the period 1975 to 1983. First we shall resolve this risk by fatal accident type and by car market class within each accident type. The results of this resolution are shown in Figures 5 to 10. Each figure refers to a type of fatal accident. Within each figure, the risk is resolved by market class of new cars.

Keeping in mind the differences in the scales of these illustrations, we see that the principal contributions to the overall risk come from collisions with other motor vehicles and collisions with objects. Smaller contributions are made by collisions with nonmotorists and by overturns, i.e., rollovers not provoked by a preceding impact. However, these findings are evident in the accident experience alone and could be obtained from the FARS

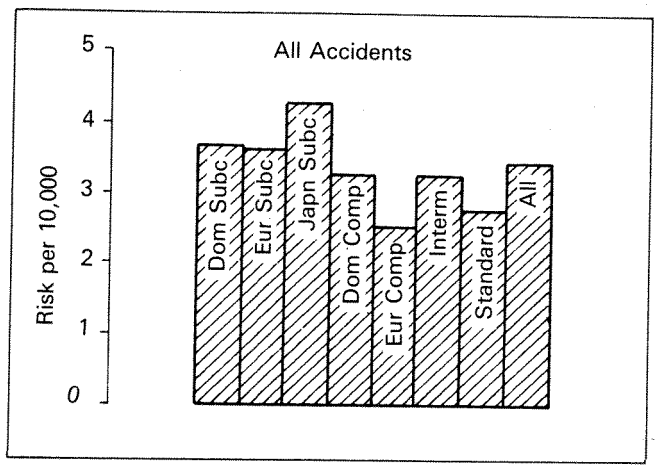

Figure 5. Risk of new car involvement in all types of fatal accidents per 10,000 new car registrations as a function of market class

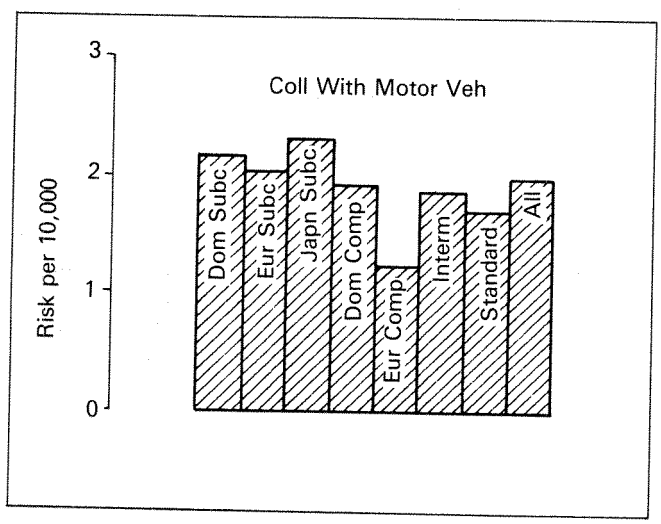

Figure 6. Risk of new car involvement in fatal collisions with other motor vehicles per 10,000 new car registrations as a function of market class

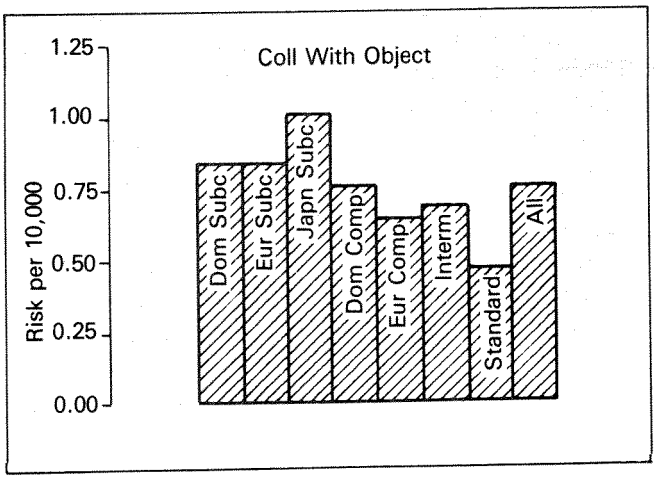

Figure 7. Risk of new car involvement in fatal collisions with objects per 10,000 new car registrations as a function of market class

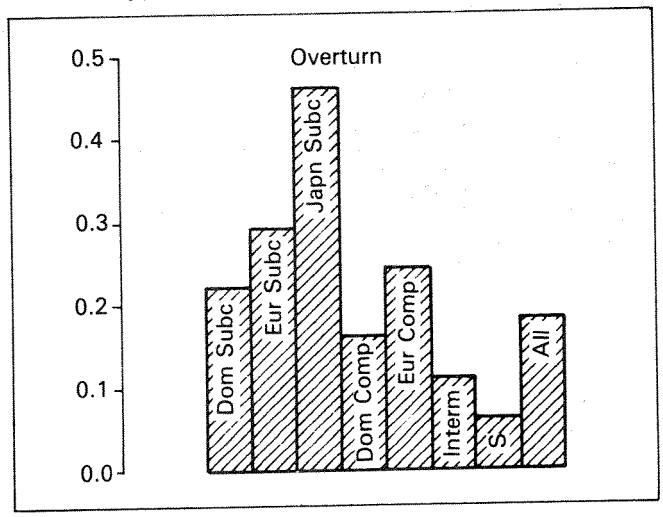

Figure 8. Risk of new car involvement in fatal overturns per 10,000 new car registrations as a function of market class

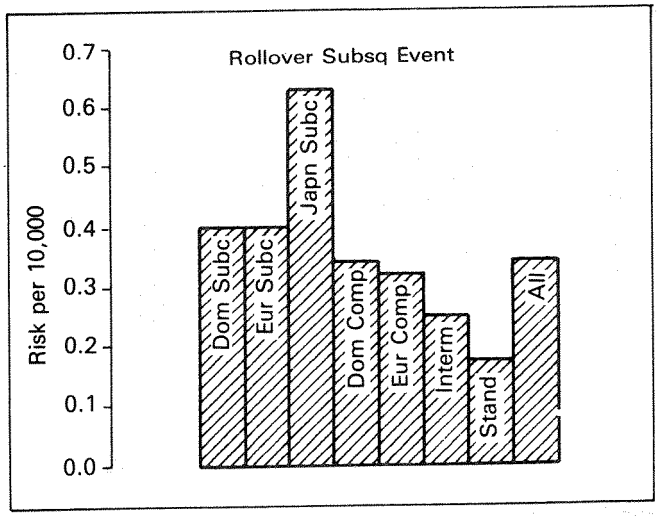

Figure 9. Fatal involvement risk of new cars in post-impact rollover per 10,000 registrations by market class

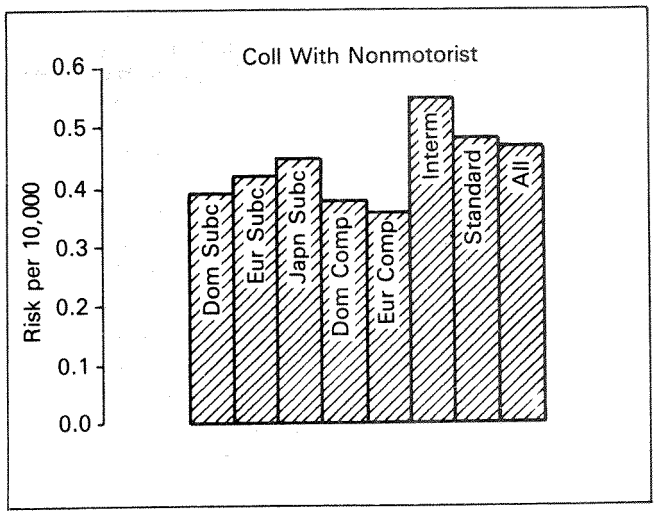

Figure 10. Risk of new car involvement in fatal collisions with nonmotorists as a function of market class

file without any additional information about exposure. The new information shown in Figures 5 to 10 is the sensitivity of these risk components and of the total risk to car attributes, as implied by the market class and origin of make designations.

It is evident that the risk of some accident types, such as collision with other motor vehicle (Figure 6) or with nonmotorist (Figure 10), shows relatively little sensitivity, while the risk of other accident types, such as collision with an object (Figure 7) and especially car overturn or rollover as a subsequent event (Figures 8 and 9), shows a high sensitivity. Car rollover, as an event subsequent to an impact with another motor vehicle or with an object, is an entirely different type of accident than overturn, which is usually not preceded by noticeable impact. These two events are mutually exclusive for all practical purposes and, when combined, they result in a risk that is a substantial component of the overall fatal accident risk with high sensitivity to car class.

Most of the sensitivities shown in Figures 5 to 10 may be established well beyond the statistical or other fluctuations that may be contained in the results. This is evident in the data shown in Table 6, which displays the risk values appearing in these figures together with their standard errors.

The data included in the overviews of Figures 5 to 10 and in Table 6 represent the national census of accident experience of over 250 million new car years. This total is subdivided into the market classes discussed above as shown in Table 7, which is formatted as Table 6 for convenience. Table 7 also presents information about the major characteristics—weight, wheelbase, and percent front wheel—drive of new cars in each of the market classes under consideration. Keep in mind that these are weighted means over the 1975 to 1983 period.

Table 6. Risks of involvement in fatal accidents per 10,000 new car registrations by market class and type of accident. Shown values are means and std. errors over calendar years 1975 to 1983

* Includes about 8 percent of the total not classified in the above categories for various reasons

Superimposed on the sensitivity of certain accident risks to car market class is an equally strong sensitivity to nameplates within each market class. This is especially true for new cars in the market classes of smaller cars and most strongly pronounced for accident types such as overturns, post-impact rollovers, and collisions with objects. Relevant results are given in Table 8, which displays the risks of new car involvement in these and all fatal accident types. In addition, the table displays the exposure and also the major characteristics of new cars for each entry.

Risk Changes Versus Model Year

The results shown in Figures 5 to 10 and Tables 6 to 8 are averaged over all calendar years 1975 to 1983. In spite of the fact that they address new cars only, they are essentially averaged over as many as 10 model years. Given that much change has taken place in new car design during this period, the question arises whether or not the risks of fatal accident involvement are changing. To address this question, we examine the data as a function of calendar year and thus as a function of model year for new cars.

Figure 11 displays the variation of the total risk of fatal involvement in all types of accidents and for all new cars, regardless of market class. The actual data, available for each calendar year, have been treated here by a linear regression that yields the fit, shown by the solid line, and the 95 percent confidence bounds, shown by the dashed corridor. The slope is statistically significant and equal to

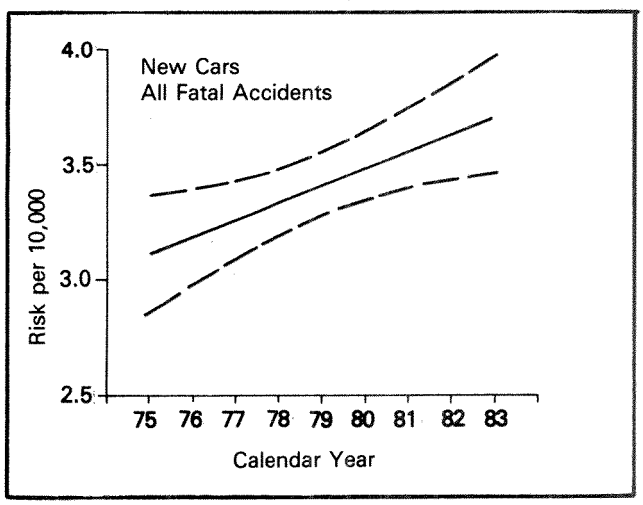

Figure 11. Risk variation versus calendar year for new cars in fatal accidents per 10,000 registrations

.076 ± .023 per year. In a 10-year period, this amounts to .76 ± .23 fatal accident involvements per 10,000 new car registrations. This is not insignificant when compared to the mean of the risk for approximately the same period: 3.41 ± .09 shown in the last entry of Table 6.

In spite of the statistical significance of the above estimates, the reader should keep in mind that the risks under consideration, obtained from the raw data for each of the past 10 calendar years, have been adjusted for variations in travel and exposure severity. These adjustments were discussed earlier and are detailed in the first part of Appendix B. Such adjustments, although well intended, could have introduced a bias that accounts for the observed increase, in part or entirely.

With full awareness of these uncertainties, and for information purposes only, we have proceeded to examine the possible origins of the estimated risk increase by fatal accident type and market class of new cars. For this purpose, we repeated the procedure discussed above in connection with Figure 11. The results are shown in Table 9 as estimates of the risk increase for a 10-year period. Only cases with statistically significant (95 percent confidence) results are shown. All other cases show the entry "none." Note that Table 9 has an entry-by-entry correspondence with Table 6. The latter displays means, while the former displays change within the 10-year period under consideration.

Influences of Car Weight, Wheelbase, and Front Wheel Drive

An examination of Table 8 leads us to believe that market class and especially nameplate designations appear to influence the risk of fatal accident involvement as much, if not more, than weight, wheelbase, or front wheel drive. To quantify these notions, we have examined the data—risk versus car weight, car wheelbase, or front wheel drive—for over 500 nameplate model year combinations, each weighted with exposure (registered car-years). We have applied log-linear regressions and have segregated the data by accident type in addition to examining them for all accident types combined.

The results of these regressions are shown in Table 10 as regression coefficients and their standard errors. The upper part of the table shows the coefficients of separate regressions, i.e., the effect of weight with no control over wheelbase variation and vice versa. The same data result in a very small, statistically nondistinguished from zero, sensitivity to front wheel drive. The striking similarity between the weight and wheelbase effects is no mystery, given these two variables are covariant in the fleet of cars. Accordingly, the question arises whether one and which one of the two effects is dominant. Thus, the risk data were also regressed versus weight and wheelbase concurrently.

The coefficients of these regressions are given in the lower part of Table 10. They show the effect of car weight when the wheelbase variation is controlled and vice versa. It is evident in these results that the car weight influence is not only small in general and smaller than the wheelbase influence, but also, contrary to a popular notion, that risk increases with weight reduction. Note in Table 10, negative coefficients indicate a risk reduction per unit weight reduction. This is what is observed for the car weight influence on accident risks for all types of accidents, except collisions with other motor vehicles where the influence is zero for all practical purposes.

Table 9. Estimates of risk increase in the last 10 years for new cars involved in fatal accidents of shown type

	Collision with Motor Vehicle	Collision with Object	Over-turn	Collision with Nonmotor Vehicle	All Types

Table 10. Fatal accident risk variation for new cars by accident type as a function of car weight and wheelbase

Accident Type	Percent Risk Increase: Per 500 lb of Car Weight Reduction	Per 5 in of Wheelbase Reduction
Collision with Motor Vehicle	5.6 ± 1.3	5.2 ± 1.1
Collision with Object	11.3 2.7	12.5 1.4
Overturn	33.8 2.4	30.8 2.3
All Types	8.9 1.0	8.3 .8
	Per 500 lb of Car Weight Reduction at Fixed Wheelbase	**Per 5in of Wheelbase Reduction at Fixed Car Weight**
Collision with Motor Vehicle	1.1 ± 2.9	4.7 ± 2.4
Collision with Object	-19.1 3.9	28.7 3.2
Overturn	-20.0 5.7	48.5 4.8
All Types	-6.6 3.0	12.9 2.5

The influence of car wheelbase, at fixed car weight, appears to be substantial and quite sensitive to the type of accident. Although there may be certain physical reasons for expecting this influence, a much stronger influence may be attributed to nameplate or market class designations, as is evident in the results shown in Table 8.

Car Involvement as a Function of Accident Severity

This paper so far has addressed almost exclusively the car involvement in fatal accidents. There are obvious reasons for this emphasis. However, there are also two questions that need to be addressed: (1) Are the sensitivities observed in the fatal accident experience also evident in accidents of lesser severity? and (2) Are the results presented so far, based on the fatal accident experience recorded in FARS, seriously biased due to the FARS threshold of fatal accidents only?

To address these questions, we have analyzed the accident experience of cars in accidents of all severities as recorded in NASS and also in the accident records of several States. The NASS data have the advantage of national scope and national representativeness in general, but also have certain limitations when it comes to disaggregation of cars by nameplate—limited sample sizes and possible biases due to geographic nonuniformities of nameplate distributions.

Many States have provided NHTSA with a census of their accident records for the past 5 to 10 calendar years.[1] Collectively, these represent the experience of many millions of cars involved in accidents of known severity and known type. Several States also record the car nameplate with sufficient resolution to allow the analyses performed so far in the paper to be repeated. Other States record very general vehicle characteristics but also car make, which allows a general classification into market classes.

The complete examination of this accident experience, as a supplement to that of NHTSA's national scope files such as FARS and NASS, is a long-range project because of the enormity of the data base and the many variations of recording protocols. However, several analyses have been performed for addressing the questions raised earlier. Table 11 shows summary results concerning car propensity to overturn, a type of accident found in the FARS file to be most sensitive to car market class and nameplate.

In this table, we compare the accident experience of cars included in the records of FARS, NASS, the State of Texas, and the State of Washington. These two States have been selected for comparison with FARS because car nameplates are recorded, categorically and with a small fraction of unknowns, in a fashion most compatible with that used earlier in FARS categorization. Also the sample sizes in the State accident files are sufficiently large to allow the shown disaggregation by accident severity. This is not the case for NASS, where we show all accident severities only.

To bring the data from these many different files on a compatible basis, we employ the conditional risk descriptor of cars involved in overturns per 100 cars involved in all types of accidents. Conversion to absolute risks is obtained by multiplying the shown conditional risk with the absolute risk for all types of accidents. A review of the results in Table 11 leads us to believe that car propensity to overturn is sensitive to car attributes

1. These data bases have been provided on a professional courtesy basis. Data retrievals and analyses and any conclusions following from these analyses are the sole responsibility of the author and in no way represent the views of the States or of NHTSA.

Table11. Risk of car overturn per 100 accidents as a function of market class and accident severity. Comparison of results from the national files of FARS (1975-1983) and NASS (1981-1983) and the State accident files of Texas and Washington (1978-1983)

	Risk of Overturn per 100 Accidents

not only in the fatal accident experience recorded in FARS but also in that of other accident files and not only for fatal accidents but for accidents of any severity. Similar results have been obtained by an examination of the accident experience in other States. Moreover, similar observations hold not only for overturn but also for other accident types that show risk sensitivity to car classes.

The Possibility of Confounding Factors

The observed sensitivity of certain accident risks to car class or nameplate is not immune from the confounding effects due to variations in the distribution of circumstantial but influential attributes among the car classes or nameplates under consideration. Included in these possible confounding factors are not only obvious attributes such as driver age and alcohol involvement or attributes such as rural or urban travel and night or day travel, but any factor that (1) has a substantial influence on the risk, and (2) has a significantly varying distribution among the car classes under examination.

A more detailed discussion of this subject is given in Appendix B in connection with Equations (B-1) to (B-8). In the same part of this appendix, we address what determinations are necessary to estimate the likelihood of confounding effects and what adjustments are appropriate to control their influence. We have applied these procedures in the examination of the data concerning sensitivity of overturn risk to car class. We selected this type of accident for a more detailed examination because of the magnitude of its sensitivity.

The number of circumstantial attributes that may influence the outcome of a car accident as an overturn is large, and their complexity is also large. We have considered the following among the most likely to be influential: the age and alcohol involvement of the driver, time of travel, urban or rural character of roadway, roadway speed limit, roadway curve occurrence, wet pavement occurrence, and topographical characteristics of travel. This last attribute was addressed by aggregating the FARS accident data into two categories by State. One category includes the States (mountainous, low population density) in which topography may promote the occurrence of overturns, while the opposite is true in the other category. The purpose of this is to control for possible effects due to nonuniformities in the geographical distribution of car classes.

We address first the distributions of these attributes and their possible variation by car market class. We did this for all accident types, whether overturns or not, and also for all single-car accidents. We selected single-car accidents for closer scrutiny because this is the pool from which the overturns are drawn. Summary results for single-car accidents are shown in Table 12. Note that for brevity in this table the shown circumstantial attributes have a binary categorization and the shown frequency values, in percent, concern the shown category. The percent value for the not shown category is obviously 100 percent minus the shown percent.

It is evident in the data of Table 12 that the distribution of circumstantial attributes among car market classes shows no significant variation or any pattern conspiring to enhance the overturn propensity of any given market class. Similar results are obtained when all accident types are considered instead of single-car accidents. The frequencies by circumstantial attribute are different, but they remain relatively insensitive to car class. On this basis alone, we may expect no substantial confounding effects on the risk determinations, unless the risk sensitivity to these attributes is overwhelming. Accordingly, we have resolved the risk of car overturn by the circumstantial attributes of interest here for each of the car market classes under consideration. These results are shown in

Table 12. Frequency of circumstantial attributes in single-car fatal accidents (FARS 1975-1983)

Market Class	Percent by Circumstantial Attribute						
	Young Driver	Alcohol Involv.	Night Travel	Rural Travel	High Speed Limit Rd.	Road Curve	Wet Pavement
Subcompact							
Domestic	26	50	69	68	66	42	18

Intermediate	22	53	71	65	64	43	16
Standard	23	52	69	64	65	40	17
Entire Fleet	24	52	70	65	64	43	13

Table 13. The table also shows the overall risk for overturn, with and without adjustments.

The unadjusted overall risk is obtained from the data of Table 6 by forming the ratio of overturns/all types of accidents, for the entries appearing in Table 6. All other entries to the left of the unadjusted overall risk display values of the risk controlled for each slot of each circumstantial attribute shown in the table.

The not unexpected variation of risk according to circumstantial attributes (variation within each row) is evident. However, it is also evident that the pattern within each column is retained, for all practical purposes, regardless of the particular circumstantial attribute under consideration. This is a second indication (the first indication comes from the data of the type shown in Table 12) that no major confounding effects are to be expected. Indeed, when the overall unadjusted risk is adjusted, no major differences are observed. This is shown in the last two columns of Table 13.

The adjustment under consideration is carried out following the procedure discussed in Appendix B in connection with Equation (B-7). Very similar results are obtained when the procedure discussed above in connection with fatal car accidents is applied to car accidents of all severities. The results for all car accidents in the State of Texas, as an example, are shown in Table 14.

The above analysis leads us to the conclusion that no major confounding influences are in effect in the determination of accident involvement risks when cars are aggregated by market class. This is especially true for car involvement in overturns, where the risks appear to be quite sensitive to car market class. However, the reader should not generalize this conclusion. First, it should be kept in mind that there is no automatic assurance that all potentially influential confounding factors have been examined. In addition to possible unsuspected factors recorded in the accident files, there may be influential factors that are not recorded.

Another equally important consideration deals with the degree of desired disaggregation of the data in relation to the magnitude of the risk differentials we are attempting to examine. When relatively small differentials must be examined for a large number of classes and subclasses, the procedure of controlling for confounding factors can be very frustrating.

Appendix A

Major Changes in the Motor Vehicle Fleet and Travel

While the resident population in the United States grew at an average rate of 1.1 percent per year in the past 15 to 20 years, the number of licensed drivers grew faster, at an average rate of about 3 percent per year. An even faster growth took place in the number of registered motor vehicles and in the miles of travel of these vehicles each year. Both of these grew at a rate of about 4.5 percent per year. In addition to growth, significant changes took place during this period in the composition and major characteristics of the motor vehicle fleet.

Shifts in Fleet Shares by Vehicle Type

Between the early 1960's and 1980's, the mix of vehicle types in the fleet on the road changed significantly. In the early 1960's, vehicles other than cars were a relatively small fraction of the fleet. Since then two fleet components, trucks and motorcycles, have grown and are growing faster, as shown below:

	Registration (Millions)		
	Cars	Trucks (All Types)	Motorcycles
Early 1960's	55-65	10-13	1.3
Early 1980's	105-110	35-39	5.8

It is evident that while car registrations have barely doubled in 20 years, truck registrations have easily tripled and motorcycle registrations have more than quadrupled. Furthermore, new truck sales as a percent of all motor vehicle sales have risen from about 12 percent in the early 1960's to about 22 percent in the early 1980's.

These two vehicle types have been and still are of concern in the safety community because they are in general substantially more involved in accidents than the average vehicle type (see Table 3 in the main text). They also present special problems that are size-related. Trucks are more aggressive and motorcycles more vulnerable than the average vehicle type.

Changes in Major Car Characteristics

Three car characteristics—weight, wheelbase, and front or rear wheel drive—are singled out for general consideration because they are often discussed and analyzed in connection with accident and casualty risks. Significant changes have taken place in these characteristics in the past 10 years for most makes and market class categories, especially of the domestically produced new cars. Table A-1 shows car weight changes, and Table A-2 displays the wheelbase changes in an identical format. The growth of front wheel drive car shares is shown in Table A-3 in a similar format.

For the market class characterization in these tables, we have followed the practice of the domestic car trade literature, i.e., a classification by nameplate or car line into market class categories. European makes are classified as subcompact except for makes with a wheelbase above 100in (e.g., Mercedes Benz, Audi, BMW, Volvo, and a few others). Also, the great majority of the Japanese makes are subcompacts with few low-volume exceptions. Furthermore, we have used the R.L. Polk registration counts by nameplate and model year for obtaining the weighted means of car weight and wheelbase and for the percentages of front wheel drive cars.

Travel and Exposure Pattern Changes

Gasoline supply disruptions, the 55mph speed limit, the rising cost of highway travel, and various cycles in the economy have influenced travel and exposure patterns in the past 15 years. The resulting variations are noticeable but lesser than the changes in the motor vehicle fleet discussed above.

The average annual travel per vehicle has fluctuated by less than 5 percent in the period under consideration. However, larger fluctuations have been observed for specific vehicle categories as shown in Table A-4. The source of the data in this table is(5). The annual travel of cars, for example, shows a significant reduction between 1973 and 1974 and again between 1978 and 1981. Car travel is generally more responsive to and follows the pattern of major influencing factors.

1978	10.0	9.25	49.3	4.50	10.1
1979	9.49	9.18	49.7	4.00	9.58
1980	9.14	10.1	42.7	3.14	9.41
1981	9.00	11.0	47.0	2.57	9.48
1982	9.53	9.81	50.1	2.09	9.64
1983	9.64	9.71	52.4	2.15	9.73

In the late 1960's and early 1970's, car travel showed minor fluctuations around 10,000mi per year. A significant decline occurred between 1973 and 1974 due to the oil embargo at that time. From 1974 to 1978, car travel per year increased slowly but steadily until 1979, when another oil crisis forced an abrupt reduction. This reduction was prolonged and deepened well into 1981 due to a depressed economy.

The increase of annual travel per car, starting in 1982, has coincided with the economic recovery that also started at that time. Note the annual travel for other vehicles, especially trucks, is much less discretionary and does not necessarily follow the pattern of car travel. The pattern for all motor vehicles agrees with that of cars because car travel dominates.

Annual travel per car is known to vary substantially as a function of car age (or of model year in a fixed calendar year). Variations may also exist as a function of market class. The data for a detailed and systematic examination of these patterns and their variation in the past 10 to 15 years are not at hand. However, the available information is generally consistent with the summary shown in Table A-5, which addresses relatively new cars, i.e., of age 3 years or less.

Table A-5. Annual travel per car as a function of car age and car market class

Car Market Class	1st Yr. Travel Thousand Miles/Car	Travel Ratio 2nd Yr./1st Yr.	Travel Ratio 3rd Yr./1st Yr.
Subcompact	13.2 ± .47	1.00 ± .02	.95 ± .03
Compact	12.1 .51	.91 .05	.89 .07
Intermediate	13.3 .60	.89 .02	.82 .03
Standard	13.6 .36	.91 .03	.84 .02
All	13.0 .2	.94 .02	.87 .03

The data in each entry of this table are averages of corresponding values provided by a large number of sources(2,3,6,7,9,10) spread over several years between the mid-1970's and early 1980's. The raw data in these sources have very dissimilar origins. In spite of this, fair agreement is observed for car ages up to 3 years or with respect to car market classes. This is reflected in the relatively small errors that arise when data from all these sources are averaged, as shown in Table A-5. Furthermore, no significant or systematic trend has been found in the data with respect to calendar year variations, again for car travel categorized as in Table 5.

Travel speed patterns have also changed substantially in the past 10 to 15 years. The 55mph speed limit went into effect nationwide early in 1974. Before that time, the prevailing average speed on interstate highways was about 65mph. This average speed dropped to about 57.5mph in 1974. In the following years, this speed increased steadily, slowly in the second half of the 1970's but faster in the early 1980's. Table A-6 shows the percentage of motor vehicles noncomplying with the 55mph speed limit while driving on U.S. highways(5).

Table A-6. Percent of motor vehicles on U.S. highways exceeding shown speed in the early 1980's

Year	55 Mph	65 Mph	75 Mph
1980	49.3	16.8	4.1
1981	48.5	18.4	5.2
1982	52.6	24.2	7.9
1983	54.1	25.4	8.5

Travel speed is one of the factors that influence the severity of the exposure to accident and casualty risks. Many other factors, driver, environment and vehicle-related, may also be influential with varying strengths. As an overall descriptor of exposure severity, we have considered the rate of accidents per unit travel for all vehicles on U.S. roads. Table A-7 shows how this rate has varied in the past 10 years. The source of these data is(11).

Table A-7. Fatal accidents and nonfatal injury accident rates per 100 million vehicle-miles traveled on U.S. roads by calendar year

	Accidents per 100 Million Miles	
Year	Fatal	Nonfatal Injury
1975	2.85	133.0
1976	2.87	133.3
1977	2.91	129.8
1978	2.92	135.9
1979	2.97	137.5
1980	2.96	132.8
1981	2.84	130.1
1982	2.45	123.6
1983	2.30	121.6

Appendix B

Errors and Adjustments in Risk Determinations

The most common and serious source of error in the estimation of absolute risks, by application of Equation (1), is the absence of coincidence in the categorization of attributes represented by subscripts j and k, between the numerator and denominator. The discussion following Equation (3) in the main text explains why the estimation of absolute risks is more vulnerable to such errors than the estimation of conditional risks, by application of Equation (3). The steps we have taken to minimize this type of error have been outlined in the main text in connection with absolute risk determinations.

A second, but separate, concern is the number of vehicle and exposure categories, subscripts j and k, that must be introduced to obtain the desirable resolution in the computation of risks. It is desirable, although not always feasible, to resolve the matrix jk into as many cells as necessary to obtain fairly uniform risks within each population. This, however, must be traded off against the statistically insignificant results obtained when a large number of cells yields populations that are too small.

Even after the concerns discussed above are satisfied, further adjustments may be appropriate to deal with nonuniformities in the exposure conditions relevant to risk determinations. This appendix discusses such adjustments.

We consider first a normalization procedure that is used for relatively new cars (1 to 3 years old) traveling on U.S. roads in any of the calendar years 1975 to 1983. The exposure variations experienced by these subfleets were discussed in the last section of Appendix A. Tables A-4, A-5, and A-7 display relevant data. When comparing or aggregating these subfleets, it is convenient and appropriate to normalize their accident experience to an arbitrary but common basis. For this purpose, we have selected the 1-year-old cars, under the travel and exposure severity conditions of the calendar year 1980.

In practice, normalization is performed through factors that multiply the risks of accident involvement per vehicle registration to normalize them to the reference exposure conditions. Table B-1 shows normalizing factors A and B for annual travel per car by calendar year and for exposure severity, respectively. Factor A is obtained from the car travel data shown in the first column of Table A-4, by making 1980 the reference year. Similarly, Factor B is obtained from the data of Table A-7.

Table B-1. Normalization factors by calendar year for annual travel per car (column A) and for exposure severity (columnB)

Calendar Year	A	B
1975	.95	1.04
1976	.94	1.03
1977	.93	1.02
1978	.91	1.01
1979	.96	1.00
1980	1.00	1.00
1981	1.02	1.04
1982	.96	1.21
1983	.95	1.29

The product of Factors A and B is the composite normalization factor for 1-year-old cars. This product appears in the first column of Table B-2. The other two columns of this table show the composite normalization factors for 2- and 3-year-old cars, respectively. These factors have higher values, which reflect the travel reduction taking place as the car age increases. The relevant data for these transformations are shown in the last row of Table A-5.

In addition to travel per vehicle and exposure severity in general that show variations from year to year, there are many exposure attributes that influence accident risks, even in the absence of calendar year or model year considerations. In fact, attributes such as driver age,

Table B-2. Normalization factors for travel and exposure severity by car age and calendar year

Calendar Year	Car Age 1 Year	2 Years	3 Years
1975	.99	1.05	1.14
1976	.97	1.03	1.11
1977	.95	1.01	1.09
1978	.92	.98	1.06
1979	.96	1.02	1.10
1980	1.00	1.06	1.15
1981	1.06	1.13	1.22
1982	1.16	1.23	1.33
1983	1.23	1.31	1.41

alcohol involvement, vehicle type, time of day, travel speed, etc., may have influences stronger than those addressed in the discussion so far. Accordingly, adjustments would be necessary to bring the determination of risks under exposure conditions as comparable as possible, when such comparability is desired. When necessary, these adjustments are made according to the procedure discussed below. Consider first the risks R_1 and R_2 concerning two different vehicle classes 1 and 2, as determined from aggregated data of vehicle involvements and exposure:

$$R_1 = \text{Sum } V_{1k} / \text{Sum } E_{1k} \quad \text{(B-1)}$$

$$R_2 = \text{Sum } V_{2k} / \text{Sum } E_{2k} \quad \text{(B-2)}$$

The summations in these relations are over all exposure conditions designated by k, which may represent, for example, driver age brackets, alcohol involvement, time of day, highway type, travel speed, etc. It is now helpful to introduce the exposure distribution frequencies:

$$F_{1k} = E_{1k} \text{Sum } E_{1k} \quad \text{(B-3)}$$

$$F_{2k} = E_{2k} \text{Sum } E_{2k} \quad \text{(B-4)}$$

Note that the sum of all F_{1k} or all F_{2k} values equals unity.

The use of these equations in (B-1) and (B-2) yields:

$$R_1 = \text{Sum } (F_{1k} R_{1k}) \quad \text{(B-5)}$$

$$R_2 = \text{Sum } (F_{2k} R_{2k}) \quad \text{(B-6)}$$

where the risks R_{1k} and R_{2k} are defined by Equation (1) in the main text for j = 1 and 2, respectively, and for each value of k that is of interest. Subscript i, i.e., the accident category, is dropped here for simplicity; however, the analysis is equally valid for any given or for all accident categories. Equations (B-5) and (B-6), which are fully equivalent to (B-1) and (B-2), are more informative. They show that, in each case 1 or 2, the aggregated risk is the sum of risks corresponding to individual exposure conditions, with each such risk weighted by the frequency of occurrence of the corresponding exposure condition.

When risks R_1 and R_2 are determined under aggregated exposure conditions, i.e., by Equations (B-1) and (B-2), any difference between them may be not entirely due to risk differentials under specific exposure conditions. As shown in equations (B-5) and (B-6), differences between R_1 and R_2 may arise from differences between R_{1k} and

R_{2k}, or from differences between F_{1k} and F_{2k}, or from both sources.

A numerical example will clarify these points. Let subscripts 1 and 2 represent two different vehicle types and subscripts a and b represent two different exposure conditions, say urban and rural travel. Furthermore, suppose the data we are dealing with are:

$F_{1a} = 90\%$, $F_{1b} = 10\%$; $F_{2a} = 10\%$, $F_{2b} = 90\%$

for the frequencies of occurrence of the exposure and:

$R_{1a} = 3$, $R_{1b} = 1$; $R_{2a} = 5$, $R_{2b} = 2$

for the individual risks, in accidents per unit exposure. The risks R_1 and R_2, integrated over both exposure conditions for each vehicle type, are: $R_1 = 2.8$ and $R_2 = 2.3$.

This answer may be fine if we wish to compare the risks of vehicle categories 1 and 2 under their recorded exposure conditions. However, this answer is absurd if it is meant to be a risk comparison under exposure conditions assumed to be fairly similar. It is absurd because R_{1a} is lower than R_{2a} and R_{1b} is lower than R_{2b} so R_1 is also expected to be lower than R_2, but it is not. This very substantial distortion is introduced because the frequencies of occurrence of exposure categories differ significantly between vehicle types 1 and 2.

Whenever risk calculations and comparisons, vehicle category 1 versus 2, are made over aggregated exposure conditions, it is essential as a minimum to determine and review the frequency distributions of exposure conditions for each of the vehicle categories 1 and 2. If these distributions are fairly similar, the possibility of distorted results is minimized. However, if the distributions differ substantially, then Equations (B-1) and (B-2) or their equivalent (B-5) and (B-6) as written are inappropriate for risk determinations.

Equations (B-5) and (B-6) may be used but only after an adjustment. The necessary adjustment requires that F_{1k} and F_{2k} must be made identical. This can be done either by retaining F_{1k} in (B-5) but also using the same in (B-6) instead of F_{2k}, or by retaining F_{2k} in (B-6) and also using the same in (B-5) instead of F_{1k}. These two alternatives correspond to risk comparisons either under the exposure conditions of vehicle category 1 all across the board or under those of vehicle category 2 also all across the board. A third alternative may be considered by pooling the exposure conditions of both vehicle categories together and determining a frequency distribution F_k for the pooled populations. For this alternative, the appropriate version of Equations (B-5) and (B-6) is:

$$R_1 = \text{Sum}\,(F_k R_{1k}) \quad \text{(B-7)}$$

$$R_2 = \text{Sum}\,(F_k R_{2k}) \quad \text{(B-8)}$$

Note the risks R_{1k} and R_{2k} must be determined for each exposure category k, and then used in conjunction with the common frequency distribution f_k for the determination of R_1 and R_2. Other alternatives are possible for introducing a common frequency distribution. Which alternative is selected depends on the terms under which we wish to compare risks.

Optimum Luminances and Areas of Rear-Postition Lamps and Stop Lamps

Hans-Joachim Schmidt-Clausen
Technical University Darmstadt, Federal Republic of Germany

Abstract

In static and semidynamic tests, the luminances of stop lamps and rear-position lamps were rated by test persons. Out of these results, the influence of light-intensity, area of the light-emitting surface, and observation distance on the assessment of the luminance is shown.

Introduction

Starting from the measured light-intensities as measured during ECE-type approval in Germany(1), the aging effects of lamps were looked at. These results were the basis for the static and semidynamic tests carried out in the normal traffic situation. The influence of the following parameters was investigated: light-intensity of the lamp, area of the light-emitting surface of the lamp, daytime/nighttime observation, and observation distance. As a criterion, the 9-rating scale was chosen.

Light-Intensities of Lamps

The light distribution of signal lamps is prescribed, for example, in ECE regulations. In Figure 1, a frequency distribution for the axial light-intensity is plotted for stop lamps and rear-turn-signal lamps. The plotted values are results from the test-institute in Germany. These values are gained with a so-called test voltage at the filament lamp, which is also prescribed in the regulation. The values have a normal distribution. The typical values are summarized in Table 1.

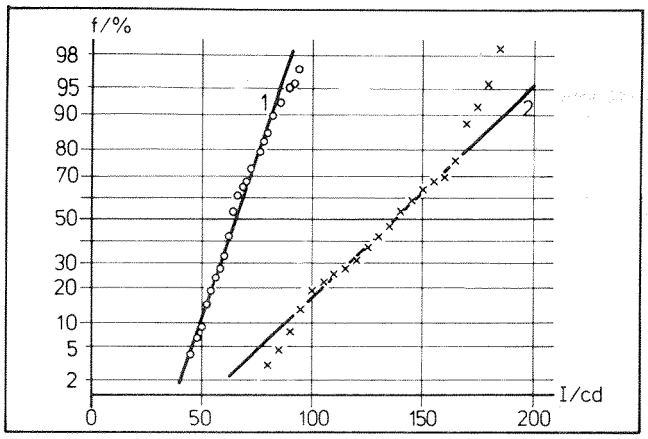

Figure 1. Frequency distribution f of light-intensity I

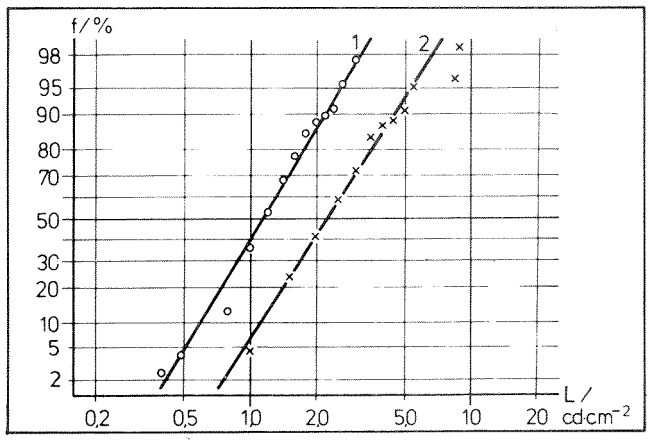

Figure 2. Frequency distribution f of luminous intensities L

Table 1.

Frequency in %	Light-intensities in cp: Stop Lamp	Light-intensities in cp: Rear-Turn-Signal Lamp
.50	65	138
16	53	99
10	49	88

These values of light-intensities were converted to luminance values. The results are plotted in Figure 2 and have a log-normal distribution.

In Table 2, the main values are summarized.

Table 2.

Frequency in %	Luminances in cp/cm²: Stop Lamp	Luminances in cp/cm²: Rear-Turn-Signal Lamp
98	3.2	6.6
50	1.2	2.3
16	0.69	1.3
10	0.59	1.1

These values as shown in Figures 1 and 2 are values measured in the laboratories. Nevertheless, these values may give an impression about the luminances of those two types of lamps.

Light-Intensities of Lamps Mounted on the Car

During a test initiated by the BAST in Germany, the light-intensities of lamps mounted on the car in use were measured(2). Some of the results are shown in the following two figures.

In Figure 3, the results of the stop lamps and rear-turn-signal lamps are plotted; in Figure 4, those for the rear-position lamps always measured with stopped engine. Each curve is represented by roughly 1,200 single measurements. The dots are the mean values as shown in Figure 1 (f = 50 percent). With increasing age, the axial light-intensities of all the described lamps are lowering. For some selected years of construction, the values for light-intensities are summarized in Table 3.

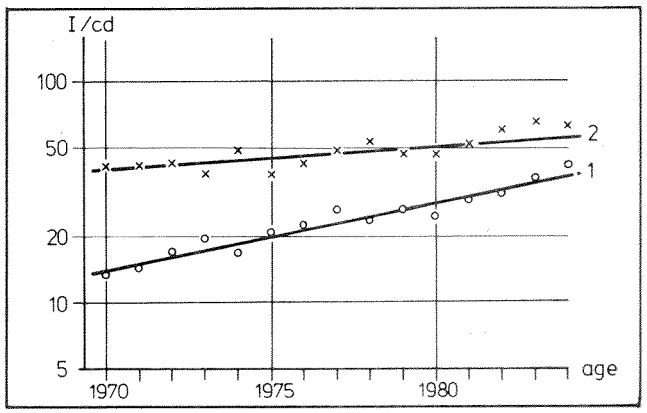

Figure 3. Light-intensity I and age of different lamps

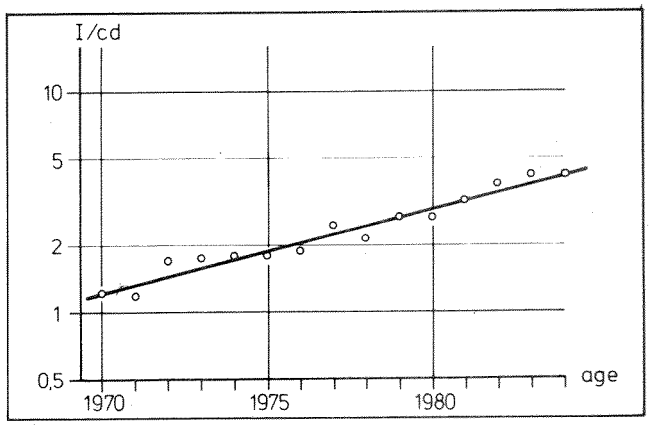

Figure 4. Light-intensity I and age of rear-position lamps

Table 3

Year of Production	Axial Light-Intensity in cp		
	Stop Lamp	Rear-Turn-Signal Lamp	Rear-Position Lamp
84	37	56	4.2
80	28	50	2.9
75	20	45	1.9

Comparing these summarized values with those in Table 1, it can be shown the mean value of the light-intensities of lamps on cars in use is roughly half the value as gained by the type approval. The same reduction will occur when comparing the luminances of the lamps in use and during type approval.

The Tests

The tests were performed statically and semidynamically. In the static test, the test person had to rate the luminance of two lamps while looking on an axial fixation spot. In the semidynamic test, the test person was moving with a car in the direction of the test fixture. At a certain distance, the test person had to rate the luminance. A dynamic test is in preparation at this moment. The areas of the test lamps could be changed between $A = 20cm^2$ and $A = 200cm^2$ in steps. The axial light-intensities of the lamps could be changed between 1cp and 1,000cp while the luminous distribution itself showed a normal curve.

The rating scale is summarized in Table 4.

Table 4

Assessment of the Luminance of Lamps	
Grade	Description
1	Too dark
2	
3	Dark
4	
5	Optimal
6	
7	Bright
8	
9	Too bright

The tests were carried out during daytime and nighttime with 10 emmetropic test persons. About 6,000 tests were conducted. The tests were made on a straight road with a neutral background during daytime and no glaring lights during nighttime. During the nighttime tests, the test persons were adapted to the luminance of a low beam. Because of this restricted kind of test, the results may be somewhat lower than those that will be gained with glare sources, street lighting, and other optical noise, etc.

Evaluation of the Tests

The results of the tests were evaluated using the common statistic method. For the evaluation of the luminances and light-intensities, a log-normal distribution was taken as a basis; for the assessments, a linear-normal distribution was used.

As an example in Figure 5, the assessments of the light-intensities I of stop lamps are plotted. The mean values x and the distribution σ of the results are shown. The regression line of the results as drawn was calculated using common statistic methods.

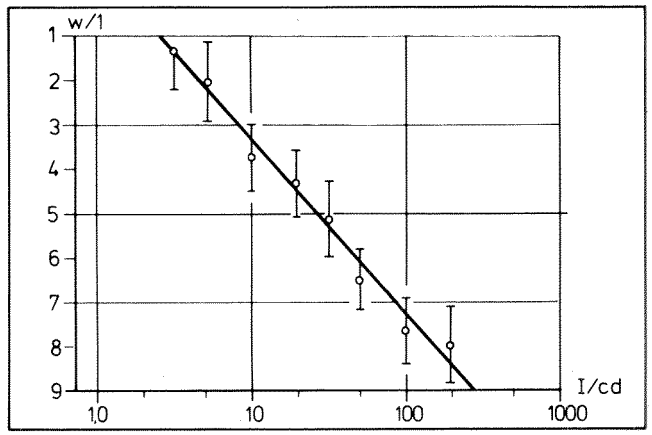

Figure 5. Assessment w of the light-intensity of a stop lamp (size of light-emitting surface of stop lamp: $A = 20cm^2$; time of test: nighttime)

Results of the Tests

Assessment of Light-Intensities

The results of the assessment of the light-intensities of stop lights are plotted in Figure 6 for daytime observation and in Figure 7 for nighttime observation. In both figures, only the results for the areas $A = 20cm^2$ and $A = 200cm^2$ are plotted. For reasons of clarity, the results for the other areas are not shown. The dotted area in both figures represents the area of light-intensities that are permitted after the ECE regulation.

For the assessment "optimal" (w = 5), the results are summarized in Table 5.

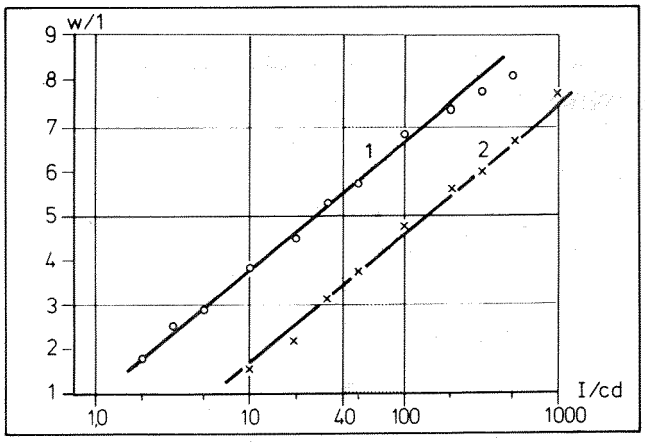

Figure 6. Assessment w of light-intensity I of stop lamps during daytime observation

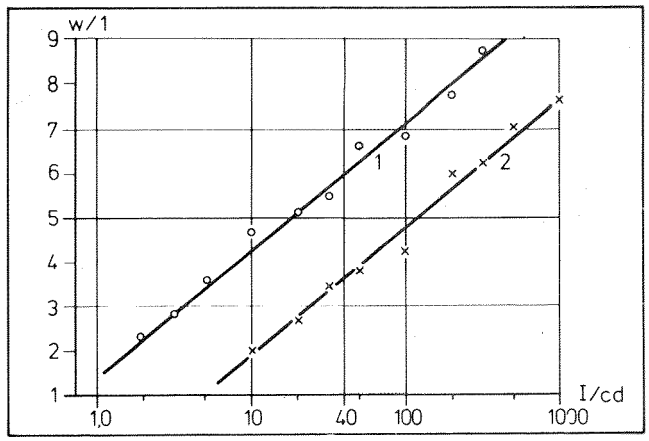

Figure 7. Assessment w of light-intensity I of stop lamps during nighttime observation

Table 5

Observation	Optimal Light-Intensities of Stop Lights in cp Area of the Light-emitting Surface in cm^2	
	20	200
nighttime	18	117
daytime	27	140

Both regression lines in the figures lie somewhat symmetric to the dotted area. In both cases, no optimal luminance can be reached with either the $20cm^2$ area nor the $200cm^2$ area.

For rear-position lamps, the results are plotted for nighttime observation only in Figure 8. The dotted area again describes the limits for the light-intensities after the ECE regulation. The light-intensities for the assessment "optimal" (w = 5) are summarized in Table 6.

Table 6.

Area of the Light-emitting Surface in cm^2	Optimal Light-Intensities of Rear-Position Lights in cp
20	5.2
200	24.3

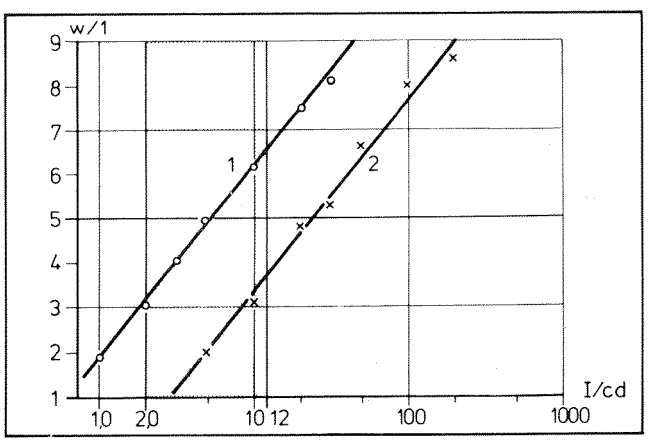

Figure 8. Assessment w of light-intensity I of rear position lamps during nighttime observation

The optimal light-intensity for rear-position lights can be reached with small areas A; for areas A = $200cm^2$, the optimum cannot be reached.

Assessment of the Luminances

For different light-emitting surfaces A, the optimum luminance L of stop lights are plotted in Figure 9. The results are plotted for daytime and nighttime observation. With increasing area A, the luminance is decreasing. The plotted results are somewhat lower than the 50 percent value in Figure 2. These results are valid for neutral backgrounds, no glare source, etc. With these influences, the optimal luminances may be higher than the results in Figure 9.

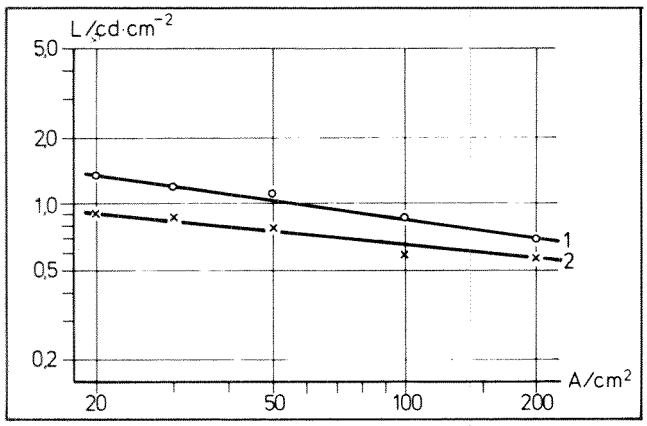

Figure 9. Luminance L and size A of a stop lamp

The results for the rear-position lamp are plotted in Figure 10 with the observation distance as a parameter. An increasing area of the lamp reduces the luminance required for the assessment "optimal." The same effect occurs with decreasing observation distance. Out of the reasons mentioned above, the necessary luminances in the real traffic situation may be higher.

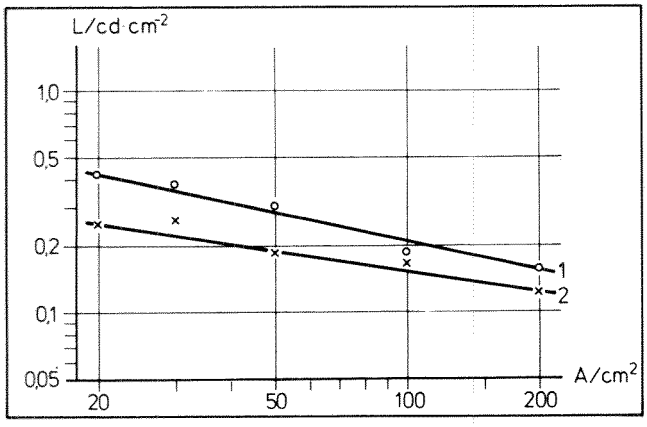

Figure 10. Luminance L and size A of a rear position lamp during nighttime observation

Influence of the Observation Distance on the Assessment

The influence of the observation distance on the assessment of the light-intensity of rear-position lamps can be shown in Figure 11, in which is plotted, with the area of the light-emitting surface A as a parameter, the dependence of the optimum light-intensity I from the observation distance d. With increasing distance d, the light-intensity must also be increased to get optimal high intensity for the lamp. Changing the distance from 25m up to 125m, the light-intensity has to be increased by 60 percent for the small area A and by 30 percent for the large area A.

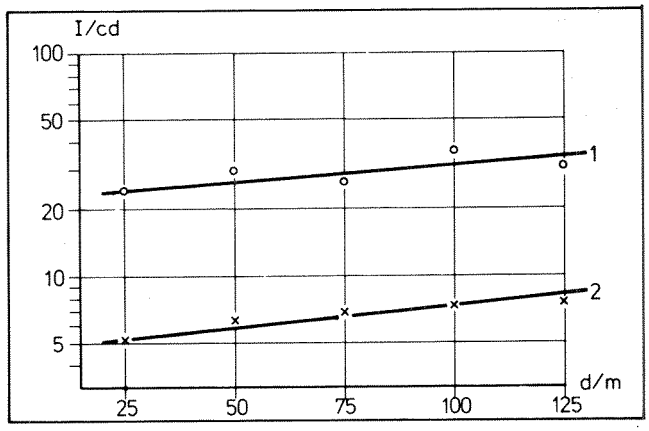

Figure 11. Light-intensity I for rear position lamps and observation distance d

Conclusion

The assessment of the luminances of stop lamps and rear-position lamps indicates that the present ECE regulations more or less fulfill, within certain areas of light-emitting surfaces, the conditions "optimal." It is nevertheless necessary to prove these results by those gained by dynamic tests.

Evaluation of Headlamp Beam Patterns Using the Ford CHESS Program

Michael Perel
U.S. Department of Transportation, National Highway Traffic Safety Administration

Abstract

The Ford CHESS computer program was used to evaluate headlamp performance as a function of various influencing factors such as beam pattern, aim, and overall intensity. The degree to which the model was sensitive to headlamp, driver, and environmental variables was assessed. The results showed that only small increases in performance could be achieved by beam pattern modifications, improved aim, and increased overall intensity. Part of the difficulty in identifying performance improvements was found to be the low sensitivity of the CHESS figure of merit to changes in beam photometrics. Suggestions are made for upgrading the CHESS evaluation methodology to make the performance metrics more sensitive to differences in beam design.

Background

Recent developments in headlamp technology are making new low beam photometrics possible. The National Highway Traffic Safety Administration is interested in developing an evaluation methodology that would provide a means to compare the new beam patterns with each other and with current ones in terms of safety performance. The agency may consider the use of such a methodology to help set minimum performance requirements for headlamp systems.

Currently in the United States, we determine whether a beam is acceptable or not by whether it meets the test point specifications in the Society of Automotive Engineers standards. This approach has a number of limitations, including the difficulty of knowing what the test point values mean in terms of their influence on driver performance. In other words, test point specifications do not quantify the visibility distance or glare hazard potential of the beam. Furthermore, many beam patterns can meet the same test points but may not produce equal performance. If a new pattern is proposed that does not meet the current test point specifications, it is difficult to obtain general agreement on whether it meets minimum safety needs. Another type of problem is that current test point specifications do not permit evaluation of performance of lamps at different mounting heights or of asymmetric lamp systems.

Because of these limitations, NHTSA is exploring the possibility of developing a headlamp evaluation methodology that more directly quantifies safety performance. The performance metric most commonly used to evaluate beam patterns in the past has been target detection distance measured using static or dynamic road tests. One of the problems in conducting these tests is determining what conditions should be used. Parameters that can be varied in such studies include target type, target location, driver characteristics, headlamp aim, and roadway geometry. Because of the many variations possible, a beam that ranks high under certain test conditions might rank low if others were used. The evaluation process becomes even more complicated because there are multiple criteria for evaluating beams. In particular, a beam should provide illumination for target detection and keep glare low for oncoming motorists.

These considerations lead to the question of whether a systems evaluation should be employed that would provide a variety of conditions under which beams should be evaluated and allow tradeoffs to be made among multiple performance criteria. This approach might be thought of as analogous to the current evaluation of vehicle fuel economy where a standardized route is used to evaluate overall fuel economy over a variety of conditions. In the headlight area, this approach is somewhat similar to the Ford CHESS program (Comprehensive Headlamp Environment Systems Simulation)(1). This paper will describe some analyses conducted with CHESS in attempting to better understand whether and how it might serve as a starting point for developing an evaluation methodology. The analyses explored three general areas:

- The effects of various influencing factors on beam performance
- The role of discomfort glare in evaluating performance
- The comparison and evaluation of beam patterns

This paper discusses some of the questions suggested by these analyses that need to be addressed to develop an evaluation methodology and concludes with suggestions for future research.

Description of CHESS

The CHESS program developed by the Ford Motor Company provides a comprehensive method for quantifying headlamp photometric performance. Beam performance is evaluated in terms of a Figure Of Merit (FOM). This FOM is basically the percent of miles driven under

which three criteria for measuring performance are simultaneously met. The three performance measures are right-lane delineation visibility, pedestrian visibility, and discomfort glare. These measures are calculated for a simulated vehicle as it is "driven" over a test route representative of U.S. roadway geometries and environments. In the case of delineation visibility, the performance criterion that must be satisfied is to have visibility for a distance greater than the distance the simulated vehicle travels in 2s—time to steer the car to keep it on the road. Performance is measured based on computation of delineation contrast and comparison to the contrast needed for detection by simulated drivers. For pedestrian detection, performance is measured basically the same way—the criterion is that detection distance must be greater than the car's stopping distance. A driver is considered discomforted if the glare at the eyes is over 10 percent greater than the glare of a baseline U.S. low beam built into the model or when the subjective rating of discomfort based on the DeBoer scale reaches a value of 4 or less. In computing whether or not these criteria are met, the effects of various influencing factors such as aim, target reflectance, and driver visual characteristics are taken into account. In addition, various weightings are used to reflect the relative importance and exposure of the different components in the computation of the FOM.

As an illustration of the representative conditions under which performance is measured, Figure 1 shows how road geometry variables affect angular locations of right-delineation lines, pedestrians, and oncoming drivers. The points on the graphs illustrate where in the beam pattern the critical targets and oncoming vehicles are located. One observation from these figures is that the locations of critical targets sometimes coincide with locations of oncoming drivers—thus, this illustrates the difficulty of making the beam intense enough to detect targets without creating discomfort glare for oncoming drivers.

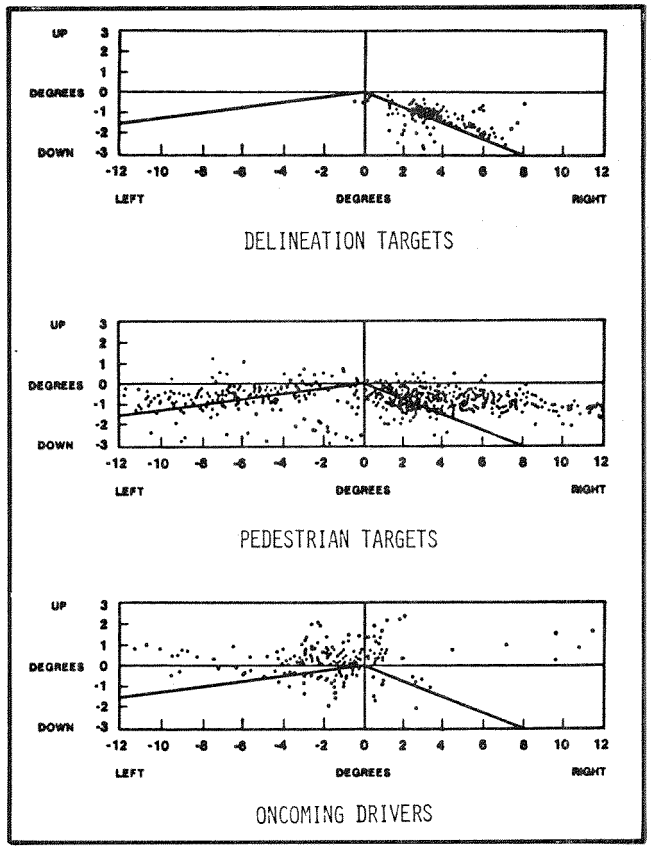

Figure 1. Distribution of angular locations of pedestrian, right-delineation lines, and oncoming drivers

Analysis of Beam Performance

One type of analysis conducted to provide information about the sensitivity of CHESS performance measures was to determine how the metrics varied when values for influencing factors or other components of CHESS were changed. This type of analysis was conducted for a number of CHESS parameters and is summarized in Table 1. It lists the qualitative degree of sensitivity that the performance metrics for a U.S. tungsten low beam have to the various factors listed. For example, the first line is the percent design intensity parameter. This parameter multiplies the overall beam intensity by a given percent. Pedestrian detection had a relatively high sensitivity to this factor, delineation had low sensitivity, drivers discomforted had high sensitivity, and the overall figure of merit shows moderate sensitivity. The delineation detection criterion was not a discriminating measure of performance for any of the factors because the required 2s criterion distance could be met under most encounters.

Another point to note in summarizing these results is that performance varies as a function of the influencing factors. The implications for improving night driving safety with beam pattern modifications is that beam performance cannot be determined in isolation from the various environmental, vehicular, and driver factors that can interact with performance. Because some beam patterns are likely to show greater sensitivity to the effects of some influencing factors than others, the relative ranking of beam performance could be affected by the choice of parameters to include in the evaluation methodology. For this reason, it is also important to reexamine the parameters of CHESS and update those that do not reflect the current driving environment.

The discomfort glare performance measure is important in the CHESS evaluation methodology. The limit of allowable discomfort is a major constraint on lamp intensity. Discomfort glare is determined from geometric consideration by calculating the beam intensity that intersects the oncoming driver's eyes in each meeting

scenario. This intensity level is compared to a criterion value to determine whether or not the driver would be discomforted.

The criterion value is based on the DeBoer rating scale, which was calibrated with a typical U.S. low beam. To calibrate the scale, a typical U.S. tungsten sealed beam was assumed to have acceptable glare. Because this low beam produced discomfort levels of 4 and above (i.e., acceptable glare) on the DeBoer scale, this value was used as the criterion.

Figure 2 shows the results of comparing several real and hypothetical low beams in terms of discomfort glare performance. The headlamps compared include, from left to right: no headlamp; a U.S. tungsten sealed beam; a European sharp cut-off beam; a modified U.S. low beam with overall higher intensity, especially in the lower right-hand quadrant; a hypothetical beam with reduced intensity in the upper left quadrant but higher lower right quadrant intensity; and a hypothetical beam with 40,000cd below horizontal and no intensity above horizontal. The lamps were evaluated under perfect aim and misaim conditions that are representative of the aim of the vehicle fleet in the early 1970's. The mean vertical aim was .75° up with a standard deviation of 1.5°. Mean horizontal aim was .08° right with a standard deviation of .86°.

The results show that, as expected, discomfort glare is an important performance measure in helping to discriminate between beams. The discomfort performance of the ECE beam is noticeably better than the other beams. The 40K beam, because of its high intensity levels, has the worst discomfort. The figure also shows the strong influence of misaim on discomfort. The difference in performance between misaim and perfect aim conditions for the same beam can be as great as the magnitude of the differences between beams. Since misaim is a fact of life for all headlamps, these results emphasize the importance of evaluating beam design under realistic misaim conditions.

An updated survey of headlamp aim of the U.S. fleet has just been completed by Olson(2). The results found that for passenger car model years 1978-1984, the mean vertical aim was .25° down with a standard deviation of 1°. Mean horizontal aim was .04° right with a standard deviation of .78°. An update of the CHESS program

Table 1. Sensitivity of performance measures to input parameters (L = low sensitivity M = moderate H = high

	Pedestrian Detection	Delineation Dection	Drivers Discomfort	FOM
Overall Intensity	H	L	H	M
Mean Vertical Aim	H	L	H	M

Vertical Aim Standard Deviation	M	L	M	M
Mounting Height	M	L	L	L
Beam Pattern	M	L	M	M
Glare Criterion	-	-	H	L
Road Illumination	H	L	L	M
Driver Alertness	M	-	-	L
Pedestrian Size	L	-	-	L

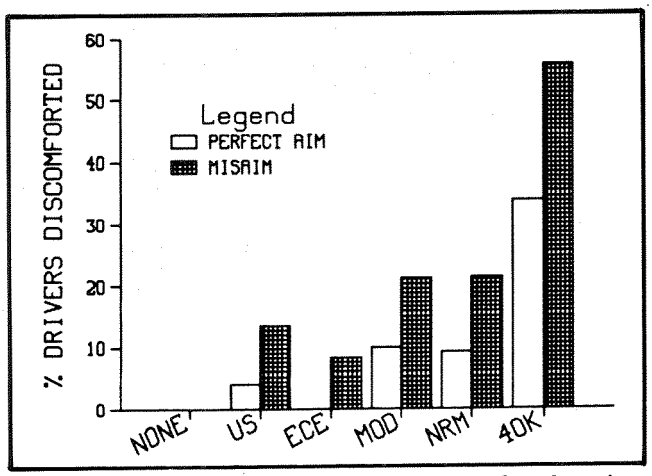

Figure 2. Discomfort glare performance of various low beams

should include these more recent data. Because of the smaller standard deviations of misaim, the more recent data would result in smaller differences between perfect aim and misaim conditions.

Another factor that affects beam performance is the level of glare beyond which drivers would subjectively rate glare as discomforting. This criterion has been studied recently by Olson and Sivak(3). Their results suggest that drivers can accept a higher intensity before they will complain of discomfort than the criterion on which the CHESS program is currently based. This finding is based on measuring glare tolerance under field conditions as opposed to laboratory testing.

The effect on performance when this discomfort glare criterion is changed according to the Michigan results is that the percent drivers discomforted for a U.S. beam pattern decreased to 5 percent from almost 17 percent with the current criterion. However, the overall FOM does not change much. This does not imply that glare is not important but that the current FOM formulation is not a very sensitive metric. It has a narrow range. Also, discomfort glare is weighted considerably less than the pedestrian detection metric in the calculation of the FOM.

The beam patterns discussed above were also compared in terms of percent pedestrians detected and overall FOM. Figure 3 shows pedestrian detection performance under unopposed traffic, unlit roadway conditions. It illustrates that misaim reduces performance slightly. Under these unopposed conditions, misaim down would reduce detection distance; misaim up would increase detection distance. The net effect, as shown in the figure, is a slight decrease in performance. The performance of the ECE beam with its sharper cutoff above horizontal is more sensitive to misaim. The 40K beam appears to be a good performer in this comparison. However, the discomfort glare of this lamp is high. When the various performance measures are combined over the entire

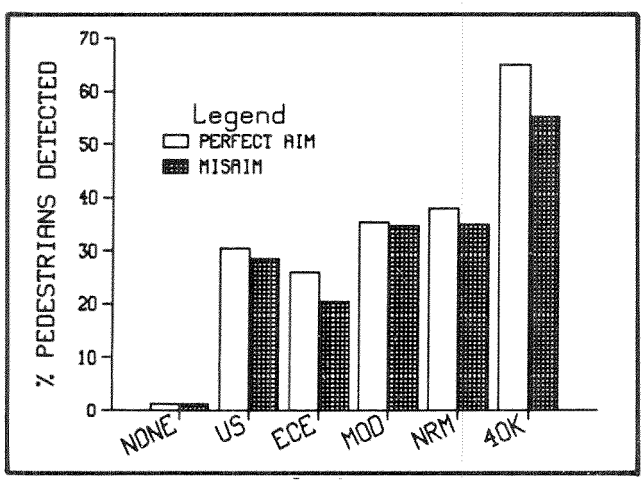

Figure 3. Pedestrian detection performance of various low beams

simulated test route to compute the FOM (Figure 4), the performance of the 40K lamp is not greatly different from the other beams. Misaim results in further reduction in the 40K lamp performance.

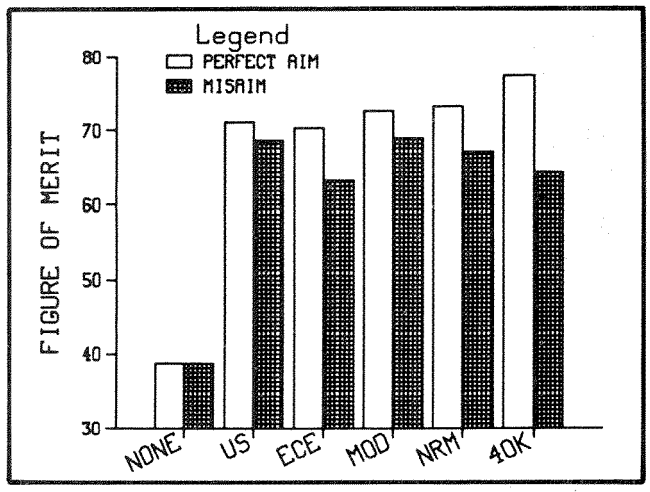

Figure 4. Merit for various low beams

None of the lamps showed any major differences when evaluated by the FOM. Larger differences among beam patterns were found with the individual performance measures than the overall FOM. Part of the reason for the lack of sensitivity of the FOM to different beam patterns is that some criteria are met by all beams and thus do not discriminate. For example, the percent delineation detected was always very high and not much different for different beam patterns. Also, the effects of the various weighting and influencing factors may wash out beam pattern differences. A beam may provide good performance under some conditions but poor performance under others. The net effect is that it is difficult to improve the overall FOM score, which takes all conditions into account. Even if we had a more sensitive FOM, there is the question of whether a major low beam improvement is possible. The inverse square law and log response of the eye mean that a large intensity is needed to gain even a small increase in detection distance. As described on a previous chart, some critical target locations coincide with oncoming drivers' eyes, further increasing the difficulty of satisfying all criteria. Finally, misaim reduces the effectiveness of beam performance.

Another observation to make from Figure 4 is that when there are no headlamps, the FOM is almost 40. In large part, this is due to delineation, and pedestrian targets can be seen from the ambient illumination and fixed roadway lighting. Thus, the CHESS program can evaluate the broader aspects of nighttime driving visibility, not just beam patterns.

Conclusion

It is difficult to identify means to make major improvements in low beam headlamp performance using CHESS. Only relatively small increases in performance could be measured due to changes in beam patterns. Small improvements in performance were also shown by modifying the various factors that interact with photometrics to upgrade performance. Although it is conceivable that other beam patterns could be envisioned that have increased performance potential, major improvements are still considered unlikely because of the underlying constraints on beam performance incorporated in CHESS. As mentioned above, these include the large increase in intensity needed for a relatively small increase in detection distance and the limits on intensity due to discomfort glare concerns. It is also possible that performance improvements are difficult to identify because of limitations in the program structure and formulation. For example, because the FOM score has a very narrow range as a function of beam pattern, performance changes due to beam modifications are difficult to detect. It may also be difficult to identify improvements because of inappropriate assumptions related to the performance criteria, test scenarios, and weighting factors used in the program calculations.

In developing a headlamp evaluation methodology using a CHESS-type approach, problems can arise in deciding which performance criteria are relevant, how to measure performance, what type of driving environment to simulate, and how to compute a performance metric. To resolve these dilemmas, a number of actions are recommended to make the tool more sensitive to safety performance differences in beam photometrics.

The performance criteria form the central basis for the evaluation methodology. It is important they reflect the safety performance required of headlamps. The criteria used in CHESS should be reviewed to make certain they reflect safety needs. Changes that might add to the safety relevance of the criteria include (1) modifying the delineation detection criterion to be a more sensitive metric, (2) adding discomfort glare from following vehicles, and (3) adding a sign detection/reading performance. The criterion level for discomfort glare needs to be reexamined and a consensus developed to determine the maximum values that could be permitted.

Once performance criteria have been identified, the methodologies and equations for computing performance need to be determined. Although some work had been performed to calibrate the formulation used to compute target detection distance and discomfort glare, additional calibration is desirable to consider a broader range of driving conditions and drivers. This type of calibration would serve as a check on the validity of the methods for evaluating performance.

Because the original CHESS development is over 10 years old, the data used to describe the influencing factors related to the driver, vehicle, and environment need to be reassessed and updated. The driving scenarios that best represent safety critical conditions should be identified, the factors that interact with beam photometrics to influence performance reviewed, and the weightings to determine the relative significance of these factors and scenarios reassessed.

Finally, a reevaluation is needed of the method for utilizing the performance metrics to arrive at a value for overall lamp performance. Consideration should be given to alternative means to compute performance that might provide greater sensitivity to beam differences. For example, the use of individual performance metrics such as pedestrians detected, or drivers discomforted, might show the relative safety benefits of the beams more directly than the FOM. Another measure that would help focus on the safety performance of beams and increase the sensitivity of the FOM to beam differences is one that gives increased weights to nonilluminated roads, curves, and other worst case conditions. With such changes, it may be possible to provide a more sensitive and safety-related evaluation of beam performance.

A Study of Laser Radar

Hiroshi Kawata,
Hiroshi Endo, and
Yoshiyuki Eto
Nissan Motor Co., Ltd.

Abstract

Various radar systems have been proposed as collision avoidance sensors for automatic braking and warning applications. Practical use of laser radar systems is near with the introduction of high power, high reliability laser diodes.

Utilizing these new devices, a laser radar system has been adapted for measuring the distance to objects in its path. It was first shown that reflectors on the rear of the automobile possess high reflectivity and sharp directivity. Given these characteristics, a compact laser radar system was tested that employed 12W laser diodes and PIN photodiodes.

The maximum range of approximately 100m was obtained. Furthermore, the ability to discriminate other vehicles from roadside objects was achieved by detecting discontinuity in measured distance data through a microprocessor. These results show that the performance of laser radar is comparable to that of microwave radar. Considering the cost and size of the radar systems, laser radar would appear to be the more practical of the two.

Introduction

Microwave, laser, and acoustic-based radar systems that can be applied to vehicles have been proposed. Radar systems that can detect the distance of the preceding vehicles or obstacles on a highway are limited to microwave and laser-based radar systems, as they require long detection ranges. Development of microwave radar has been carried out for some time, but it is not yet practical due to its large size, high cost, etc.

On the other hand, the development of opto-electronics such as laser diodes has increased the probability of utilization, since laser radar systems can be constructed at a lower cost, while assuring higher performance than microwave radar systems.

As a fundamental experiment, reflective characteristics of the rear of a vehicle were measured. A prospect detection range of about 100m was obtained with laser power, which is nonhazardous to the naked eye. The authors have tried to construct a cheap, small-size, and practical laser radar system with a detection range exceeding 100m.

Effects of adverse weather conditions were expected, so a waterdrop and mud detector and wiper were installed on the window of a laser radar head.

A microprocessor discriminates vehicles from roadside objects by detecting their range and the relative velocity of the detected objects. Thus, the laser radar system was tested to insure its application as a sensor in collision avoidance systems or in automatic headway control systems.

This paper describes the structure and performance of the laser radar system and gives test results gained on actual roads with curves and hills and ranges in adverse weather conditions.

Laser Radar Equation

The geometry of laser radar is shown in Figure 1. A short pulse laser beam is transmitted with the divergence angle γ_0. The transmitted beam is reflected by the target, then the reflected beam diverges with the angle Φ_0 and is focused onto a detector such as photodiode. The received signal power is given by expression (1). Detector is followed by an amplifier. The range to target is given by the time difference between transmitted and received laser beams.

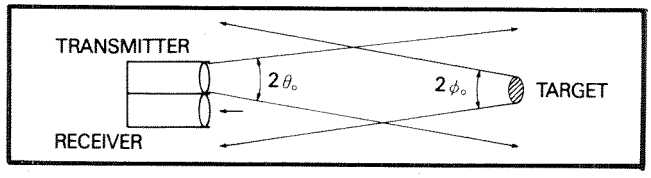

Figure 1. Geometry of laser radar

$$(1) \qquad P_r = \frac{P_t \cdot K \cdot A_t \cdot A_r \cdot T_r}{\pi^2 \, R^4 \, \theta_0^2 \, \Phi_0^2} \, e^{2\sigma R}$$

where

P_t	:	transmitted laser power
K	:	target reflectivity
A_t	:	area of target
A_r	:	receiver area
T_r	:	receiving optics transmission
R	:	range to target
Φ_0	:	transmitter half-angle divergence
Φ_0	:	reflected beam half-angle divergence
σ	:	atmospheric attenuation coefficient

Reflective Characteristics of a Vehicle

Reflective characteristics of the rear of the vehicle have been measured using a simple laser radar. As shown in Figure 2, two reflex reflectors have high reflectivity; other parts do not. Furthermore, reflex reflectors have sharp directivity; beam divergence is about 30mrad. This is very desirable in laser radar systems.

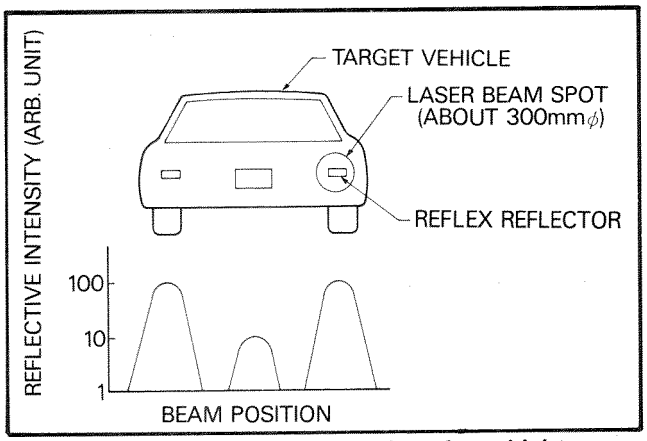

Figure 2. Reflective characteristics of a vehicle

Laser Power and Safety Aspects(1,2)

According to the IEC standard, the maximum permissible exposure value for a repetitive laser beam with a pulse width of 50ns, wavelength 900nm, is about 0.6W. Given the wheel-motion interlock system, a safety range of 1m should not pose a problem. Supposing transmitter beam divergence to be 60mrad (full angle), the diameter is 60mm at 1m range. The pupil diameter is about 7mm, so, assuming a uniform beam, the total laser power is given by:

$$P_0 \left(\frac{7}{60}\right) \leqq 0.6 \text{ (W)}$$

$$P_0 \leqq 44 \text{ (W)}$$

Actually, a uniform beam cannot be obtained, so P_0 must be less than 44W.

Laser Radar System Design

System Composition

A laser radar system is composed of a laser radar head, a display unit, and a microprocessor unit among other parts. The laser radar head is composed of a transmitter, a receiver, and a range-detecting circuit; a waterdrop and mud detector and wiper can be installed. The laser radar head provides range signals. The display unit receives the range signals and displays the range.

Range signals and vehicle velocity signals are provided for the microprocessor.

The system composition is shown in Figure 3.

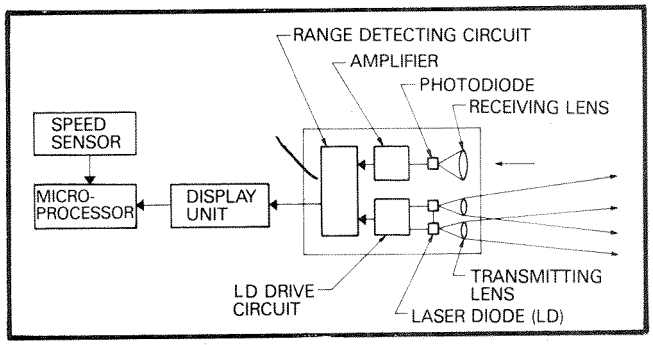

Figure 3. System composition

Transmitter

To get a wide, long detection area, two laser diodes (LD) are provided in the transmitter. Each laser diode can provide 12W peak output power.

The LD drive circuit requires high response to achieve high-range accuracy. Waveforms of drive current and laser pulse are shown in Figure 4.

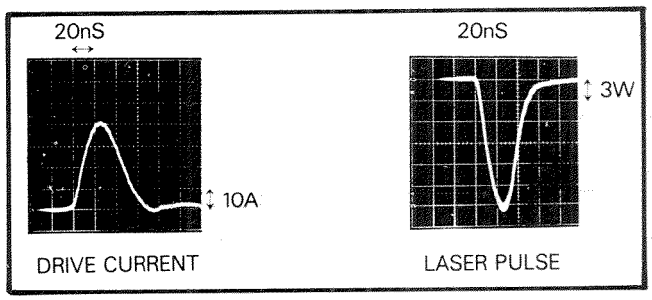

Figure 4. Waveforms of LD drive current and laser pulse

Laser beams from two laser diodes are transmitted through lenses toward the front. One laser beam has a half-intensity, full-angle divergence of 60mrad. Another laser beam has a half-intensity, full-angle divergence of 30 × 10mrad.

Irradiance distribution of the combined laser beams is shown in Figure 5. Distribution depends mainly on the characteristics of the laser diodes; it is difficult to obtain uniform distribution.

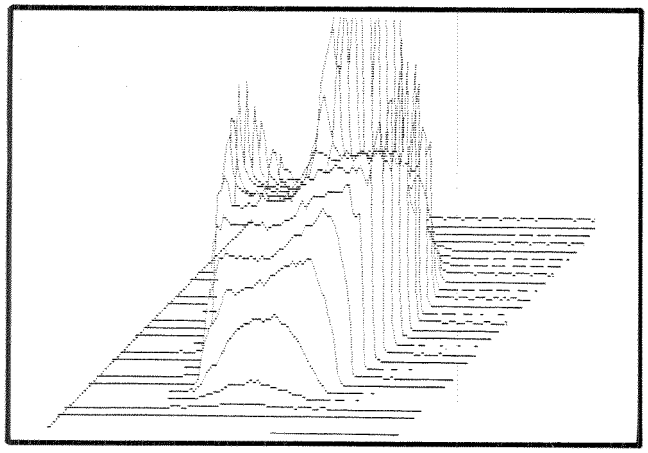

Figure 5. Irradiance distribution of laser beams

Receiver

The receiver is composed of optical parts and a signal amplifier. The structure is shown in Figure 6. Fresnel lens was chosen as a receiving lens because it covers a large area, is lightweight, and is thin. This lens is designed with a short focal length to make the laser radar head small.

The lens plate consists of two lenses, whose size is 60 × 60mm; the focal length is 40mm, respectively. Consequently, two PIN photodiodes are provided on the focal points.

Optical filters consist of infra-red filter (IR filter) and a honeycomb. An acryl-based plate is used both as an IR filter and as a fresnel lens. A honeycomb is used so as not to admit sunlight scattered by the fresnel lenses.

The signal amplifier is composed of an amplifier and an STC (sensitivity time controller). An STC is used to reject the signals reflected from fog, rain, road, etc., at close range.

Performance of the Laser Radar

Characteristics of the Laser Radar

Fundamental performance of the laser radar is shown in Table 1. A photograph of the laser radar head is shown in Figure 7.

Detection Range for a Vehicle

Detection range was measured with a passenger car as the target with two 50 × 40mm reflectors. The results are shown in Figure 8. The lane width of the highway in Japan is about 3.5m, so the vehicle in front can be detected with high reliability on a straightaway.

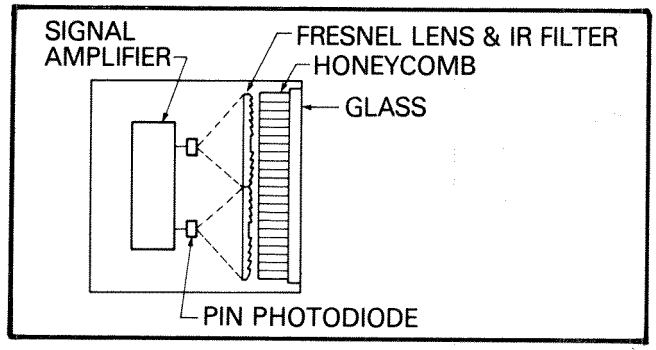

Figure 6. Receiver structure

Table 1. Characteristics of the laser radar head

Item	Description
Size	$180_W \times 80_H \times 150_L$ mm
Laser power	18 W (peak)
Beam divergence angle (full-angle)	60 mrad.
Pulse repetition cycle	6 kHz
Detecting range	about 120 m
Range resolution	1 m
Error of range	about ±2 m
Data output repetition cycle	15 ~ 30 ms
Drive voltage	10 ~ 16 V
Drive current	0.7 A

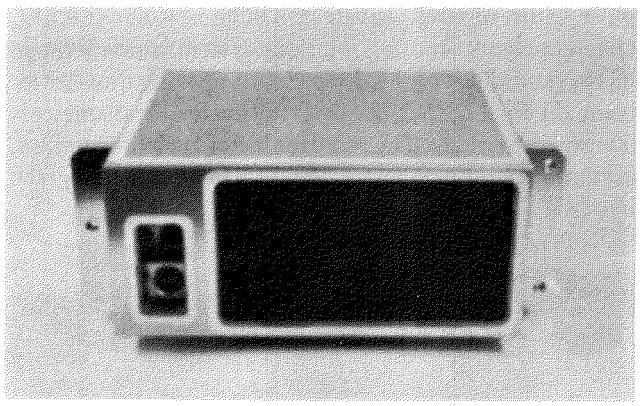

Figure 7. Laser radar head

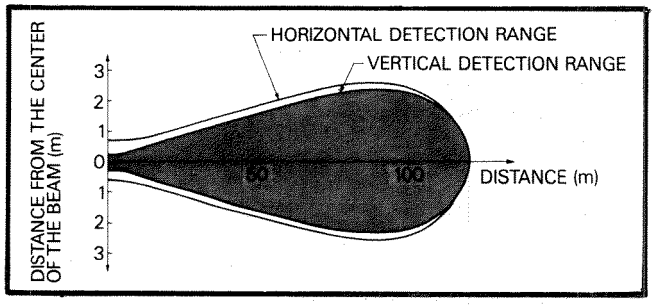

Figure 8. Detection range

Dispersion of Maximum Detection Range

Maximum detection range varies widely, as the reflected beam from the preceding vehicle is mainly from reflectors, where reflected laser power varies with their size and surface cleanliness. Results obtained on a highway are shown in Figure 9. Most of the vehicles are passenger cars or trucks. In the case of passenger cars, dispersion is relatively small. However, in the case of trucks, it is large since some trucks have muddy reflectors or large reflectors.

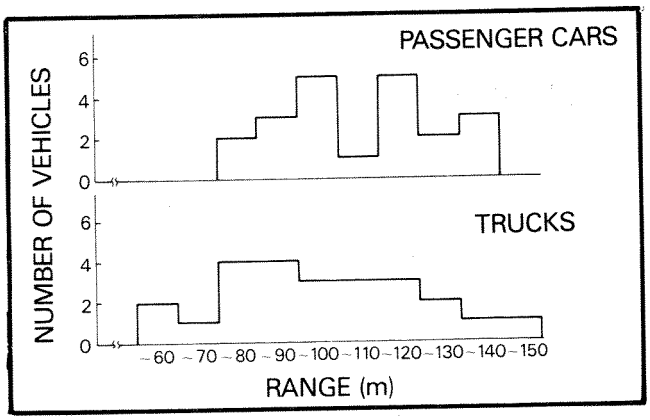

Figure 9. Dispersion of maximum detection range

Range Restriction Due to Curves and Hills

On actual roads, detection range is restricted by curves or hills. For example, in curves of a radius of 300m, maximum range is about 25m. Hills also impose range restriction; however, it is not so severe as in curves. In either case, maximum range is insufficient.

Weather Effects

It was confirmed experimentally that detection ranges in fog, rain, snow, and sunlight are restricted.

In rain, detection range is reduced by approximately a factor of two, from its clear-air value. This is caused by waterdrops on the transmitter, receiver, reflectors of the vehicles in front, and in the air, moreover, by the splashing of the vehicle in front. Based on the amount of water splashed, the detection range is sometimes reduced by approximately a factor of three. It is possible to remove waterdrops by use of a wiper, such that detection range increases about 20 percent from nonwiper values. However, in heavy rain, the wiper is not so useful. When it is raining, the transmitted laser beam is reflected by the rain. Moreover, the transmitted laser beam is scattered on the window of the transmitter and then reflected from the near-range road. An STC is necessary to sift out such useless signals.

In fog, one problem is that a transmitted laser beam is scattered and then detected by the receiver. This is also solved by an STC. Another problem is that the laser beam is attenuated by fog. The detected signal level in fog is shown in Figure 10. When the range of view is less than 100m, detection range is reduced by more than a factor of two.

There are only a few restrictions in light snow because the reflected laser beam from the snow is rejected by an STC. However, in heavy snow, it is impossible to sift out the signals from the snow; then random distance data are obtained.

Sunlight is detected by a photodiode and decreases the signal-to-noise ratio (S/N). Consequently, it causes error of range and, in the worst cases, blinding occurs. As a laser radar is designed by taking account of sunlight and noise, it operates normally under usual conditions. However, in cases when the sun is within 10° of the axis of the laser beam, the laser radar becomes blind.

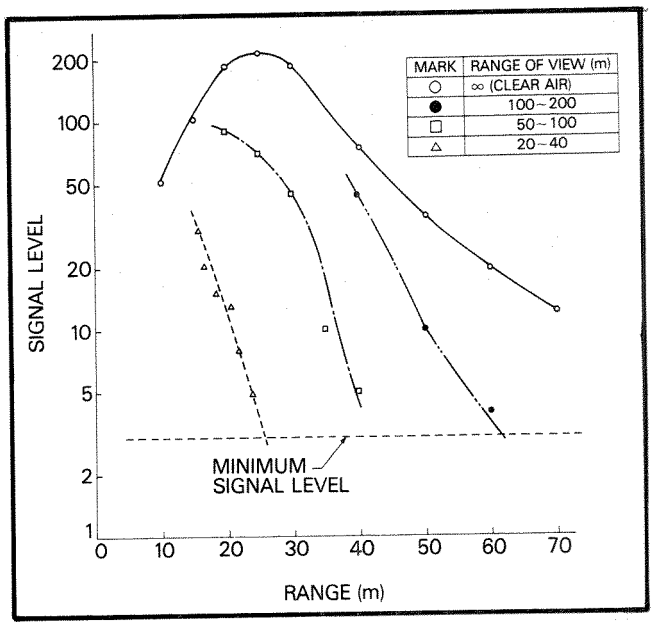

Figure 10. Signal level in fog

Window Cleaning System

As a laser radar head is provided in the front end, it is sometimes exposed to rain, snow, or muddy water. To keep the window of the laser radar head clean, a waterdrops and mud detector and a wiper are installed. The structure of the detector is shown in Figure 11.

Some of the transmitted laser beam is scattered by waterdrops or mud on the window, and the laser beam incident into the optical fiber is detected by a photodiode and then amplified. Although the detection area is limited on the path of the transmitted laser beam, the detector operates very well under ordinary adverse weather conditions. In light rain, the wiper can remove waterdrops and maintain good performance.

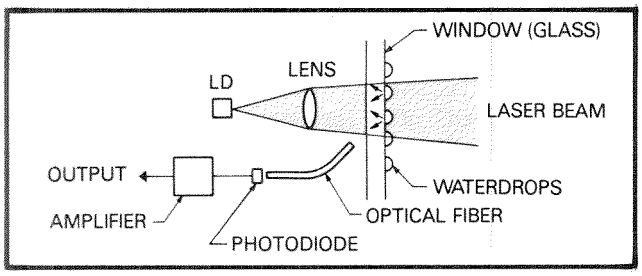

Figure 11. Structure of waterdrops and mud detector

Ranges for Other Targets

The laser radar detects many kinds of targets: roadside reflectors, guardrails, trees, roadside signs, etc. (see Figure 12). Reflectors and roadside signs have high reflectivity and ranges as long as those of vehicles are obtained. Guardrails on a highway are seldom detected. The detection range for a person is about 40m.

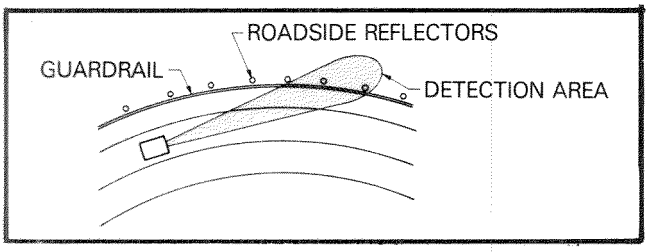

Figure 12. Roadside objects

Discrimination

Some examples of distance data on real roads are shown in Figure 13. Figure 13(a) shows data wherein a vehicle is detected on a straight road and roadside reflectors on curves. Figure 13(b) shows data when another vehicle intrudes between the preceding vehicle. Moving vehicles can be discriminated from other targets by detecting relative velocity and discontinuity in distance data. Hazard level is determined by detecting distance and relative velocity. However, lane discrimination(3,4) of the target is impossible.

Comparative Evaluation of Laser and Microwave Radar

Table 2 shows a comparative evaluation of laser and microwave radar. There is little difference in performance, but, totally evaluated, laser radar seems to be superior to microwave radar.

Conclusion

Laser radar has a detection range of approximately 100m; the capacity for discrimination between moving vehicles and roadside objects is possible. This performance is comparable with that of microwave radar. Totally evaluated, laser radar is more practical than microwave radar.

It is inevitable that the detection range of laser radar will be restricted in adverse weather conditions. Detection ranges are improved by use of a wiper; however, the original performance level cannot be obtained.

To put the laser radar system into practical use, lane discrimination of the targets and improvement in the detection ranges, especially in adverse weather conditions, must be achieved.

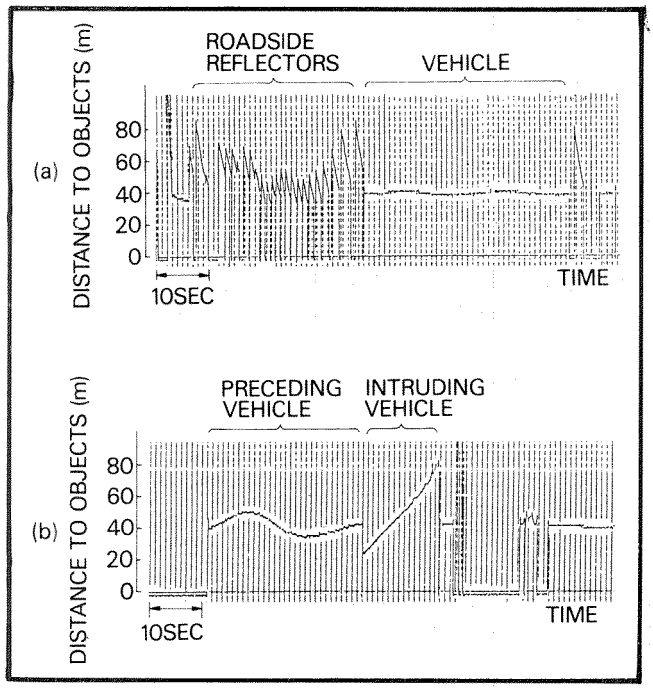

Figure 13. Distance data on real roads

Table 2. Comparative evaluation of laser and microwave radar

Item	Laser Radar	Microwave Radar (60 GHz)
Maximum range	about 100 m	←
Resolution	1 m	←
Operation in adverse weather conditions	poor	good
Cost	reasonable	expensive
Others	Poor detection range for low reflective targets Easy beam control	Poor target discrimination

Car Controls for Physically Handicapped Drivers

Christine M. Haslegrave*
Motor Industry Research Association

Abstract

Many physically handicapped drivers have difficulties in using ordinary car controls, and modifications need to be made to their vehicles. A review of the types of adaptations and equipment that are available for this in Europe has identified the principal aspects that need to be considered in their design. For safety and ease of use, it is important to match the characteristics of a control conversion to the driver's capabilities, taking into account the location and mode of operation of the control, together with the operating forces and the range of movement. Many of these adaptations are highly individual, and it is also important to encourage innovation and flexibility in design to increase the possibilities for severely disabled people to obtain the mobility accepted as the norm by the rest of the population.

Modern technology permits the use of sophisticated control systems, and a high degree of power assistance can be provided on steering and brakes. This raises problems such as determining the appropriate degree of feedback or "feel" on the steering wheel for drivers who have little strength in their arms. More research is needed into drivers' responses using these types of controls. In more radical conversions, such as remote steering, there may be a choice of steering characteristic, and this also needs further study.

*Now at The University of Nottingham, Department of Production Engineering and Production Management

Introduction

Physically handicapped people often need modifications to their cars to make access easier and to allow them to operate the controls safely. With recent developments in technology, many severely disabled people are now able to drive, and some conversions are highly sophisticated. In practice, the control conversions range in complexity from the simple relocation of switches to a full conversion of steering for foot operation, and possibly to the combination of all controls on a single arm-operated unit. Often the controls have to be individually tailored to the driver's needs, and conversions are typically carried out by small specialist firms. However, some of the most common adaptation equipment (such as hand-operated brake and accelerator) may be manufactured in a standard form in relatively large numbers.

A review of the control conversions used by disabled drivers in Europe was carried out in 1984, with the aim of identifying all types of control conversions that are available as well as the technical developments and research that may change their design in the future. Information was collected on the regulations and testing procedures that are applied to car adaptations in the different countries(1).

From the information obtained in various countries, it seems probable that approximately 0.5 percent of drivers are physically handicapped, and an earlier study(2) estimated that about 0.2 percent of drivers would be likely to require adaptations to their cars. In Britain, this would correspond to 70,000 drivers under 65 years of age. The numbers are relatively small compared with the total market for production cars, one reason why most special equipment is added after a production car is sold. Another reason is the diversity of handicaps, which make it unlikely a single car design could be produced suitable for even a large proportion of handicapped drivers.

The physical handicaps with the most effect on the driving task are shown in Table 1. The degree of disability arising from a particular impairment is very variable even for two people with the same medical diagnosis. In addition, some people have multiple disabilities, causing multiple handicaps. It is not a simple matter to list car conversions suitable for different types of disability. A driver with a single leg disability will probably be able to drive a car with automatic transmission, perhaps in the case of a right leg disability having the brake and accelerator pedals moved to the other side of the footwell. Similarly, a driver with a single arm disability can probably drive an ordinary car with automatic transmission, although he may find the steering easier if a knob or spinner is fitted on the steering wheel. Other more complicated conversions will need to be chosen in relation to the needs and capabilities of the individual driver.

Table 1. Principle groups of impairments affecting the driving task

- Limb disabilities which may be the loss of a limb, restricted movement of joints, or muscular impairment impairment affecting one or more limbs
- Spinal disabilities and size or reach limitations (such as dwarfism) that may affect the ability to reach the controls, or to bend or twist
- General weakness that may affect the strength needed to operate ordinary controls, or may affect walking ability and ease of getting into and out of the car
- Lack of coordination

Current Range of Control Adaptations

A wide range of equipment is now available for disabled drivers, but the cost of conversion is a critical factor that may limit the possibilities for an individual driver. Many conversions are adaptations of the ordinary foot-operated brake and/or accelerator to hand operation for drivers with leg disabilities, while a few vehicles must be controlled completely by foot operation when the driver has lost the use of both arms. Tetraplegic drivers and others with severe weakness may require very complex conversions to give a high degree of power assistance.

It is worth mentioning that in any conversion, the first consideration is the driver should have a stable seating posture (using suitable supports and restraints if necessary) with a good view of the road. This may necessitate modifications to the car seating, and sometimes to the structure of the car if the driver has a rigidly extended leg or is unable to bend his spine to adopt an ordinary seated posture. Modifications may be made to help the driver get in and out of the vehicle more easily, but these are outside the scope of this paper, which is confined to a discussion of primary control equipment.

Control conversions in Europe are usually carried out by small firms, many doing individual conversions for their customers rather than using a standardised design of control. However, several of the larger firms produce kits (usually sets of hand controls) that can be supplied to other firms, agents, or local garages. A few conversion firms specialise in a particular type of control (such as foot steering or power-assisted steering systems). In general, the vehicle manufacturers are not directly involved in conversions, which are carried out after purchase of the vehicle. Some manufacturers have organised special model specifications for customers, and a very few are more closely involved in the development of new conversion equipment and may provide a service offering approved conversions.

Brake and Accelerator Controls

The most common type of adaptation is the conversion of both brake and accelerator to hand operation, often using mechanical linkages that operate on the original pedals in the car.

In many conversions, the brake and accelerator functions are combined in a single or split lever, usually installed just under the steering wheel. The levers are normally pushed downward (axial to the steering column) to brake and upward toward the wheel to accelerate. There are some exceptions where the control may be moved radially around the wheel.

A wide variety of hand-operated controls is found, but they fall broadly into the following types:

- Push/pull levers
  - — Segment grip
  - — Ring
  - — Bar
- Rotary "twist grip"
- Electric potentiometer

Two examples are illustrated in Figure 1, which shows a bar-type lever passing below the steering wheel, and in Figure 2 which shows an accelerator ring. This is connected to the accelerator pedal by a rod passing through the centre of the steering column and operated by a light pressure of thumb or palm of the hand. The brake is operated by a different type of control.

Shoulder- and knee-operated controls have also been specially developed for individual drivers. In principle, these are similar to the hand-operated controls.

In every direct brake design found in Europe, mechanical linkages were constructed of rigid rods. Cable linkages were used only in a few designs of accelerator control. The majority of hand-control conversions are purely mechanical, but power assistance can be added to brakes, often using hydraulic servo systems.

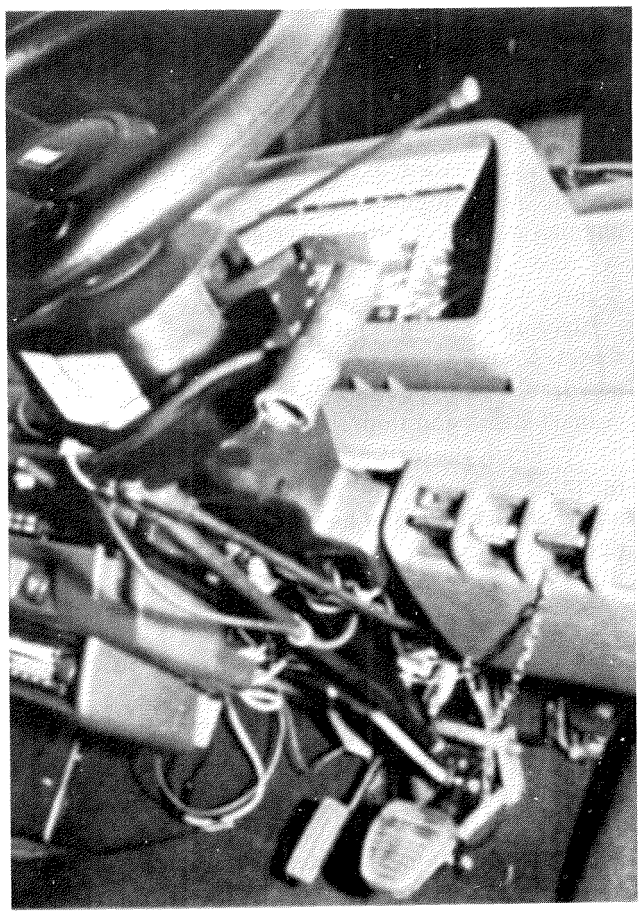

Figure 1. Bar-type hand operated brake/accelerator control

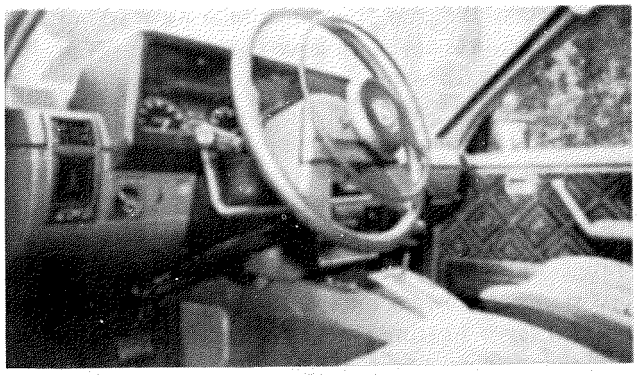

Figure 2. Accelerator ring

One conversion in Sweden is operated by compressed air, with compressors installed to act directly on the foot pedal or hand control. An electronic accelerator has been developed in France and is combined in a single control with a hydraulic brake system.

Steering

The simplest and most widespread steering aid is a knob or spinner fitted to the existing steering wheel. This is needed by anyone steering with only one hand, but may also be helpful for someone with a weak grip. Sometimes the handgrip on the spinner is moulded to fit the driver's hand or arm, and a switch panel is sometimes incorporated with the steering knob to operate minor controls.

More complex conversions to the steering system are normally made to give additional power assistance, to bring the wheel within reach, or to adapt it to foot steering.

Power-Assisted Steering

If a driver cannot choose a car with a power steering option, it is sometimes possible for a conversion firm to fit a power unit that has been designed for a different car within the car manufacturer's range, and some firms can increase the degree of power assistance of an existing system, for example by reducing effort via ratio modification. It would be of great benefit to disabled people if car manufacturers could make power steering options available on a wider range of small and less expensive cars.

A company in Britain now designs special hydraulic systems for different models of cars. During the conversion, they are able to measure the customer's steering effort in a static rig and match their steering unit to his strength.

Extended Steering Column

For small people, it is necessary to resite controls within easy reach and perhaps to fit smaller steering wheels. A conversion for someone with short arms may also include moving the steering wheel closer to the driver, and conversions are available with extended steering columns and telescopic or inclinable columns.

Foot Steering

If steering must be operated by foot, four types of systems are available commercially.

Several conversion firms fit a rotating plate system such as that shown in Figure 3. The rotating plate is positioned on the floor pan, and the foot is inserted in a slipper to turn it. It rotates in the same way as the original steering wheel, with a linkage to the car's steering column. The system is tailor-made for each individual to achieve the optimum driving position. In some conversions, the driver does not use a slipper but grips the rim of the plate with his toes or alternatively turns the plate by friction with the sole of his foot.

The second type, System Franz, was developed in Germany and uses a pedalling motion as shown in Figure 4. The pedal is connected to the normal steering system

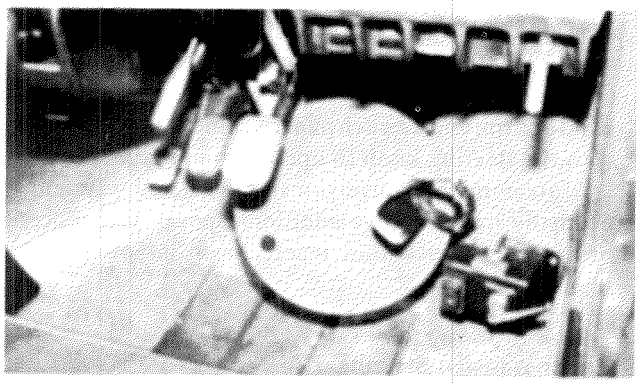

Figure 3. Rotating plate foot steering

Figure 4. System Franz foot steering

through a gear unit and is moved forward to turn right and backward to turn left.

The other two systems suitable for foot steering were designed as remote control systems and are described in the next section.

Obviously, when a driver has lost the use of his arms, many other minor controls will have to be modified when the steering is converted to foot operation. These may be operated by knee, shoulder, or head, as, for example, pushbutton switches that are fitted in the headrest to operate the turn signals.

In some conversions, the original steering wheel may be retained so the car can be driven by able-bodied people. This can be important for maintenance when the car is driven by garage staff.

Remote Steering Controls

Two systems have been developed in Britain that incorporate an operating control remote from the car steering system. These can be positioned virtually anywhere in the car and can be tailored to the individual driver with a suitable mode of operation for his disability. The Malden unit is an electronic control system using a small joystick with a gearbox mounted at the top of the steering column. Three parallel control channels are fitted for safety: two drive motors and potentiometers are fitted to turn the steering wheel, and the third is a reference channel. Three more potentiometers are turned by the gearing that turns the wheel, and their movement is compared with the movement generated by motion of the joystick potentiometer. If a discrepancy is sensed, that channel and motor is disconnected and an alarm sounds. A "reset" facility is provided to allow for temporary failures.

Steering Developments Ltd. has developed hydraulic remote control steering, which has a primary system with a hydraulic pump driven by the engine from a belt off the crankshaft. In addition, there is a backup system, which is an electrically driven hydraulic motor. The control operated by the driver is a lever, which can be placed anywhere in the car but has mostly been fitted on the car door.

Recent Developments

Joystick steering using electronic technology has also been investigated in France and Sweden but has not resulted in commercially available equipment. A team at the University of Birmingham is developing hydraulic joystick controls for small automobiles, while the I.N.S.E.R.M. Biomedical Research Unit at Montpelier has produced a single hydraulic joystick control that operates steering, brake, and accelerator. However, this uses very high technology components and is unlikely to become commercially available in the foreseeable future. In Sweden the Handikappinstitutet is working with Systemteknik to develop a servo system for quadriplegics, which operates steering, brake, and accelerator. It incorporates a hydraulic steering joystick, while the brake and accelerator are operated by a second electro-hydraulic joystick.

The past few years have seen great improvements in steering controls as many companies have introduced a range of modifications to provide additional power assistance. Some car manufacturers have also designed special servo steering units that they market for handicapped drivers. As a result of these developments, steering forces can now be reduced to as low as 4N when using a conventional steering wheel. With remote steering systems, the steering forces are reduced to virtually zero.

Electronic controls are being developed for accelerators and brakes, and more complex hydraulic systems for brakes, which means these functions will be able to be remotely controlled. They can be designed for people with little arm mobility.

Two other new developments have occurred for ancillary controls. One is infra-red sensors, which are used for switch panels and powered access functions (e.g., opening doors). The other is the introduction of voice

control by Kempf Equipements, a great advantage in combination with foot steering for drivers with both arms disabled.

The new electronic technology is on the point of being introduced and can be expected to make a big difference to the design of controls in the next few years. The groups who have the greatest difficulty in driving at present are people with problems of coordination, high tetraplegics, and those with diseases such as multiple sclerosis or muscular dystrophy, which cause severe weakness. They lack the strength to use ordinary controls but are likely to be assisted by powered steering systems or remote steering. The type of control needed but not at present commercially available is a single-handed control that operates all the car functions.

Assessment of the Driver's Requirements

When a handicapped driver chooses a car and has to consider what types of modifications will be needed, usually he will seek advice from the conversion firm or from a driver training or assessment centre. In some countries, licensing authorities and vehicle inspectors may also be involved in determining the most suitable conversion.

In many cases, these conversions are devised by medical or engineering staff who have a knowledge of the options from years of experience. There is considerable liaison between the staff of rehabilitation or assessment centres and engineers in conversion firms, which has resulted in many new developments. Often, the final design of the control system evolves through several trials, making further modifications as necessary to suit the individual driver.

Some centres are now using car simulators (or mock-ups) in which the driver's capabilities can be measured more objectively. One advantage of this is that various control layouts can be tried out quickly and easily to choose the best solution. Performance measurements can then be made using the type of control they anticipate fitting in the car. Typical measurements would be of the forces the driver is able to apply, the range and speed of movement, and the reaction time. The driver's coordination would be assessed, and it might also be necessary to assess endurance for a sustained pressure, as on the accelerator.

However, up to date, there has been little research into the levels of these measures that should be acceptable for the driving task nor into the correlation between measurements made in a simulator and performance on the road. Most research studies have concentrated on measuring the maximum forces that people can apply and on assessing these in relation to control loads in vehicles on the road. Despite this, there is still no consensus among the recommendations made by different organisations—for instance in relation to the maximum operating forces beyond which power assistance will be required.

With the wider availability of power assistance on brakes and (more recently) on steering systems, more emphasis needs to be placed on driver responses and performance using ultra-light and finger-operated controls where steering and braking forces can be virtually zero. With a light joystick control, for instance, the car's response can be very rapid, and the driver gains little feedback from the control. Similarly, servo braking can be very abrupt. Some controls are so sensitive that drivers are constantly making steering corrections, which can be tiring. Additionally, where steering is very light, it is not possible for the driver to relax with his arms resting on the wheel, and he may find this to be tiring.

Further study is needed to find how feedback or "feel" should be built into the system. In discussing this problem in relation to braking, Harden and Tenniswood(3) suggested that artificial feedback might not be the best solution, since the feedback should be a function of the specific vehicle's characteristics and nonlinearities are induced in the brake system by factors such as temperature or brake lining wear. They advocate direct feedback through the servo valve. Nishikawa et al.(4) discussed the provision of feedback in developing a power steering system for Honda.

Microprocessors and electronic control systems now make it feasible to alter the traditional steering response characteristic, and research is needed to investigate the most appropriate characteristics for drivers with various types of handicap. There is little knowledge of the degree of sensitivity or feedback acceptable for able-bodied drivers using the new types of controls, and still less for severely handicapped drivers.

Although car simulators may be useful in studying driver performance with new types of control systems, an assessment of an individual's driving ability should not be based solely on the measured criteria such as force capability and reaction time measured in a simulator. Driving is a very complex task, which cannot be completely reproduced in a simulator, and this is particularly so when reaction times are measured. Most staff involved in assessing potential drivers would agree there is no substitute for a final road test to judge the person's driving performance. However, simulators are being used more widely and have considerable advantages in assessing different options in a conversion and in providing objective measures of force capability that can be matched to control forces measured on the car itself.

Design of Controls

During the study, it was obvious a good deal of flexibility is needed in providing designs suitable for the

individual drivers, who may have very different or complicated handicaps. In many countries, converted vehicles are subjected to a technical appraisal of the control installation, and physically handicapped drivers may also be assessed while driving their converted vehicles. The inspection procedures are chiefly concerned with the suitability of the adaptation for the driver and with his ability to control the car, although they sometimes find problems with poor engineering and with installation by inexperienced fitters.

In no country visited during the study tour are there regulations or codes of practice specifying the design of the controls themselves nor of the installation, although there may be regulations prescribing the modifications or types of controls required for each type of disability. Neither is there any legislation that specifies the operating forces for controls used by handicapped drivers. It is in fact very important to encourage innovation in design in order to increase the possibilities of mobility for very severely disabled people.

However, it is possible to use the experience related by vehicle technical inspectors to promote good design of controls. During discussions with both engineers and medical staff working in this field, various problems or technical points were mentioned that have arisen with controls and/or with their installations. These have been analysed to identify the principal factors that need to be considered in the design of a control conversion, and they are listed in Table 2. They represent a summary of aspects that are important from the points of view of safety and ergonomics and that should be of concern to manufacturers and convertors. The factors fall under four main headings: ergonomics, general safety, engineering, and installation.

Table 2. Principal design factors in control conversions

ERGONOMICS
Mode of operation
Direction of operation
Location and range of movement
Operating force
Response characteristic
Relative positions of controls (separation, clearance)
GENERAL SAFETY
Stability of seating and posture
Provision of duplicate control channels or backup systems
Dangerous projections
ENGINEERING
Type of system (mechanical, hydraulic, pneumatic, electrical)
Interaction between controls in operation
Mechanical linkages (rigid or cable)
Construction techniques
Vehicle environment
Durability
INSTALLATION
Stability and rigidity of fixings and adjustments
Provision of guards or removal of original equipment
Clearance between controls, and between controls and structures
Safety of electrical connections
Facility for an able-bodied person to drive the car
Notice warning that controls have been modified

Ergonomic Factors

The ergonomic factors that need to be considered relate to the positioning and adjustments of the control, as well as to the choice of operating mode and response characteristics most suitable for different types of handicaps.

The detailed design will often need to be matched to the individual driver. Taking mode of operation as an example, a control could be operated in a linear mode, radially around the steering wheel, or in a rotary mode (such as a motorcycle throttle). The most appropriate mode would depend on the driver's disability and strength and particularly on whether certain groups of muscles had sufficient function, degree of coordination, or endurance for sustained applications.

The positioning of the control would depend on the range of movement of the driver's joints, on his mobility, and often on reaction time. Redesign of the layout or mode of operation may be sufficient to increase a driver's reaction time, just by reducing the element of movement or by overcoming difficulties of coordination. One example is a layout (described by an assessment centre as using a "paddle" action) where one foot operates the accelerator and the other the brake. This can nearly halve reaction time.

On the question of direction of operation, there are varying opinions among European organisations. It would generally be accepted, of course, that a brake control should operate forward since the driver's weight will be thrown on the control during heavy braking. However, in a few cases, the driver may need to use a different action because of his disability. Any attempt at standardisation of directions of control operations would therefore need to incorporate some flexibility.

In matching the control conversion to the driver, it is important to consider his capabilities rather than his handicaps. This can be done by determining the strength, mobility, and coordination of each limb in turn to decide which is best suited to operate each control. For example, the ordinary brake pedal in the car requires strength to operate, whereas the accelerator requires little strength but does need position control and sustained operation.

The various controls need to be considered in relation to each other to insure their relative positions are suitable and they are sensibly divided between the driver's limbs having sufficient function, so that the driving task does not overload him. The design solution needs to be tested with the driver himself either in situ or in a mock-up, if necessary making minor modifications, and seating support and posture are an important element in this.

Although emphasis has been placed here on matching the design to the driver's individual requirements, the cost of conversions is perceived by many disabled people as a major barrier to driving. There would therefore be great benefits to be gained by designing low-cost controls, perhaps by designing them to be adjustable or to fit a wider range of car models, or by using modular systems. Although this may not be feasible for the most complex conversions, it should be possible for simpler equipment—for examples, standard sets of hand-operated controls needed by larger numbers of people. If possible, adaptations should be designed to fit any model of car and not be specific to particular models.

General Safety Provisions

The general safety provisions listed are not comprehensive but highlight points where requirements may differ from those in ordinary production cars. A good seating posture is essential and needs to be established before prescribing the types of controls that will be appropriate. It has to be remembered that disabled drivers may be operating closer to the maximum limit of their capabilities than are able-bodied drivers. In the event of an engine failure, for example, the driver may lose power assistance and be unable to steer the car. Additional backup systems may be needed.

The installation of controls differs considerably between car models, requiring brackets and other fixings, often fitted on an ad hoc basis. It is not always possible to avoid encroaching on knee or other impact zones, and protection from sharp projections may then be important.

Engineering Factors

Small companies involved in manufacturing control conversions often do not have access to the sophisticated test facilities used by vehicle manufacturers. Some of the more important engineering factors that they need to take into account are given in Table 2. A few points will be mentioned in more detail.

Policies or requirements for mechanical linkages may differ between European countries. Rigid links were found to be used in virtually all direct brake systems, and in a few countries these are required for direct accelerator systems. Other countries, however, permit cable linkages on accelerator controls.

In installing special or modified control equipment, there is a danger of interaction between the new control and the original systems on the vehicle or between different parts of modified equipment. This may occur in several ways. One example that has been found in accelerator conversions for hand operation is the loss of kick-down when fitted on a vehicle with automatic transmission.

Installation

The method of installation and fixings of the control equipment in the vehicle are just as important as the design of the control unit itself. Many hand-operated controls and other ancillary controls are produced as kits, which can be fitted by people other than the manufacturers. The fixings and range of operation may differ considerably between different models of car.

Since there is an alteration of the original vehicle design, there is again the possibility of an interaction between the modified control and other controls already on the vehicle. At its simplest, the operation of a lever may restrict access to other controls at some positions in its range of travel, or there can be clearance problems between the lever and the bodywork of the car. This might result in the travel not fully covering the range of brake or accelerator operation.

Fixtures must be stable and rigid. For instance, there have been cases of adjustable steering knob fitments that do not have an adequate attachment mechanism and can be pulled away from the steering wheel. In recent car models, the increased use of plastic components and collapsible structures has tended to make installation more difficult.

Some models of car can present particular problems of installation. For example, they may have an angular offset on the steering wheel, which means the clearance between the wheel and a hand-operated control varies as the wheel is rotated. The hand reach to the control therefore varies, and it could present problems in providing sufficient travel to operate fully.

It can be useful to retain the original car equipment in addition to the converted controls. The car may need to be driven by garage mechanics during maintenance or by able-bodied members of the family. Some disabled drivers also like to have the option of using two types of controls, if for instance they are not capable of sustained pressure on an accelerator pedal for long periods of motorway driving, when they may use a hand control.

If there is any danger of a control being operated inadvertently when two types of controls are fitted, a guard should be fitted over the control, or it should be hinged out of the way or made easily removable (for example, by fitting with a wing nut). All of these solutions are frequently used when pedals are moved to the

opposite side of the footwell for left leg operation. This is particularly important for paraplegics who may not be aware of where their feet are placed and for drivers who are subject to muscle spasms.

Conclusion

1. There is now a wide range of control conversions available for production cars in Europe, permitting various modes of operation suitable for drivers with different types of handicap, although there is still need for a system in which all control functions can be operated by a single limb.
2. New techniques are being developed incorporating electronic and hydraulic systems that can provide remote-controlled and ultra-light steering, where the control can be placed in whichever position is most convenient for the driver.
3. Voice control and infra-red sensors have been developed using new technologies for the remote control of nonsafety critical functions.
4. Our knowledge of driver performance and response with the new types of controls is limited. Since it is now possible to alter the conventional control response characteristics, further research needs to be directed to determine suitable levels of feedback and of sensitivity for people with various forms of handicap.
5. The survey of control conversions currently being used in Europe has identified the various aspects of their design (relating to the ergonomics, safety, engineering, and installation) that need to be considered when a conversion is carried out.
6. It is important that designs should not be specified too rigidly. Flexibility is needed to allow for the very individual needs of drivers with different handicaps, and also to encourage innovation to permit larger numbers of severely disabled people to be able to drive.
7. One of the greatest problems perceived by disabled drivers themselves is the expense of the conversions, and there is a need for design of low-cost controls.
8. The main areas in which further study is needed are—
   - The methods of testing and assessment for handicapped drivers and the correlation between simulator measurements and road performance
   - The use of unconventional control characteristics
   - Driving performance with ultra-light steering controls
   - Ways of reducing the cost of controls and conversions

Acknowledgments

The study was carried out by the Ergonomics Department at the Motor Industry Research Association, under contract to the Vehicle Engineering Division of the Transport and Road Research Laboratory on behalf of the Vehicle Standards and Engineering Branch of the Department of Transport.

The Prevention of Bead Dislodgement of Tires and the Importance of Limited Run Flat Capability on Safety

G. Tavazza
Pirelli Coordinamento Pneumatici, Milano, Italy

Tire Failure and Safety

Every motorist quite rightly has the fear of a tire "blowout," especially during cornering. In this case, the cornering force exerted by one of the tires is suddenly reduced, causing a situation in which the vehicle becomes uncontrollable, especially if the tire affected is fitted to the rear axle. Furthermore, as will be seen later, due to the loss of inflation pressure, the beads of the tire will fall into the wheel well, allowing the rim flange to scrape the road and risking the possibility of becoming embedded in any surface irregularities.

Fortunately, modern car tires of tubeless design rarely blow out; instead, when damaged, they tend to lose air slowly, sometimes taking many hours to deflate to pressures significantly lower than those recommended. This phenonenon, in the absence of a good low-pressure warning device, could cause an underinflated tire to go unnoticed by the driver and precipitate a dangerous situation. In fact, should a sharp steering maneuver be executed, especially on an irregular surface, the tire beads could dislodge, giving rise to the identical conditions of a blowout but with the added risk of occurring during an emergency maneuver. It is from these types of incidents that the interest to decrease or eliminate the possibility of bead dislodgement originates.

Another potential danger for the unfortunate motorist is the necessity of immediately changing the damaged tire/wheel and fitting the spare. This, should the incident occur in a tunnel or on a busy road, can be hazardous, in which instance it is advantageous for safety reasons to be able to continue running without difficulty a short distance to arrive in a safer area to park the vehicle. This can only be achieved if no bead dislodgement has occurred and with a tire having a certain run flat performance.

The Bead Dislodgement

Examining the case of a tubeless tire, in conditions of normal use, the bead is maintained on its seating by the internal inflation pressure as shown in Figure 1.

It is accepted the bead core is considered as a ring practically radially inextensible. Thus, as the internal inflation pressure pushes the bead along the conical bead seat until it comes in contact with the flange, the rubber

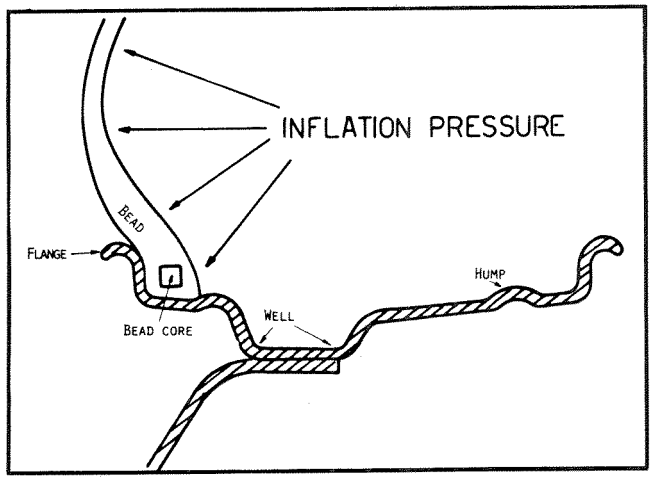

Figure 1. Internal inflation pressure on bead

between the bead core and wheel becomes compressed, giving the high contact pressure that insures the retention of air. This force effectively renders the tire locked to the wheel and capable of transmitting driving and braking torques generated by the most potent vehicles.

During cornering, the road exerts a force on the outer tire (relative to the corner) that tends to push the bead inward toward the center on the wheel as shown in Figure 2. This action can be divided into two components, an axial force that acts at the center of the bead core and an

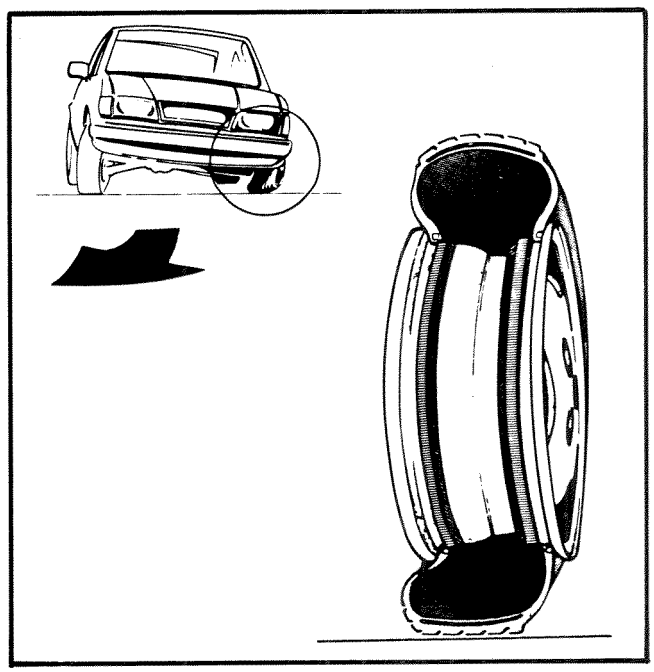

Figure 2. Effect of cornering

overturning moment (see Figure 3) that tends to turn the bead upward and inward. This rotational movement is resisted by the torsional rigidity and radial rigidity of the bead; in fact, the bead blocked from any axial movement by the hump tends to roll around the bead toe, and in doing so raises the center height of the bead core. The axial force, which tends to force the bead along its seat into the wheel well, is opposed solely by the hump. Therefore, since the bead is sufficiently rigid to resist the overturning tendencies (due to design parameters), the axial force becomes the principal cause of bead dislodgement, and the hump becomes the main obstacle to bead dislodgement.

The bead dislodgement is influenced by—

- The overload condition that affects the tire (external relative to the curve) during the cornering maneuver. This depends on suspension geometry and vehicle design.
- The grip afforded by the road surface.
- The violence at which the maneuver is performed.

These ultimate considerations explain why the laboratory tests, both static (U.S. "Push-off" test) and dynamic, are inadequate to predict the road performance of the tire/wheel unit being unable to take into account the sharp increase in load and slip angle of the affected wheel, while alternatively "on road" tests are relatively simple to perform and very realistic.

The most frequently used test is illustrated in Figure 4. The wheel being tested runs each time with the inflation pressure reduced in fixed decrements along a semicircular course at a relatively low speed (to ensure driver safety) but with high lateral acceleration due to small radius of test course (about 1.0G). The bead dislodgement usually occurs immediately after entry into the curve. With normal humps (flat or round), this dislodgement happens typically at inflation pressures of 0.7-1.1Atm.

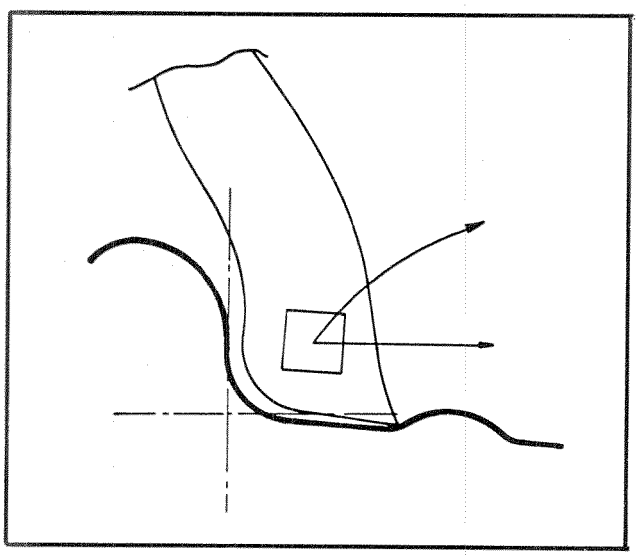

Figure 3. Overturning moment

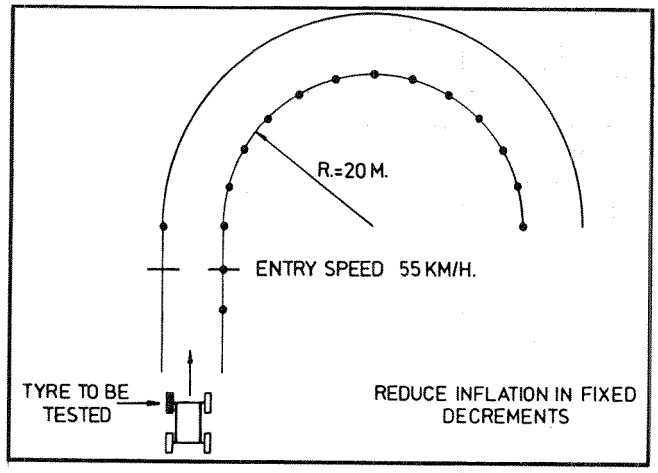

Figure 4. J-Curve roll-off test

Rims and Humps

It is obvious that increasing the diameter of the humps will certainly increase the level of bead retention but will render more difficult the seating of the beads during fitting and also (generally a less serious problem) the removal of the tire from the rim. Additionally, the fitting of tires on rims must be feasible on existing automatic fitting machines, and any variation in a fitting technique that causes an increase in operation time would be totally unacceptable in a mass production environment.

This constraint, with the exception on certain particular applications, excludes all the various solutions of split or multipiece wheels that do not require a well for fitting, systems for closing the well with inserts, or even the use of wheels with retractable pins (instead of humps), which have been used although found to suffer problems of air loss under sporty driving applications.

Other possible solutions require the use of special tires fitted to special wheels upon which, as a rule, it is not possible to mount standard tires. Solutions of this type have never really gained favor in the market since they restrict the vehicle owner to a limited range of tires or otherwise cause him to suffer the financial inconvenience of having to change wheels.

It seems the only acceptable solution is to permit the fitment of standard tires produced by a large range of manufacturers while allowing easy automatic fitting and maintaining the level of bead retention indispensable for safety reasons. This level must permit the driving in a deflated condition at reasonable speeds and lateral forces (e.g., 100Kph in a straight line and lateral acceleration of 0.2g) without bead dislodgement. The mileage attainable in this condition, as we will see later, depends only on the tire and insures the bead retention at the very low inflation pressures that even the most unexperienced motorist cannot fail to notice.

The types of humps most commonly used (Figure 5) are very similar, and unfortunately do not satisfy the criteria requested.

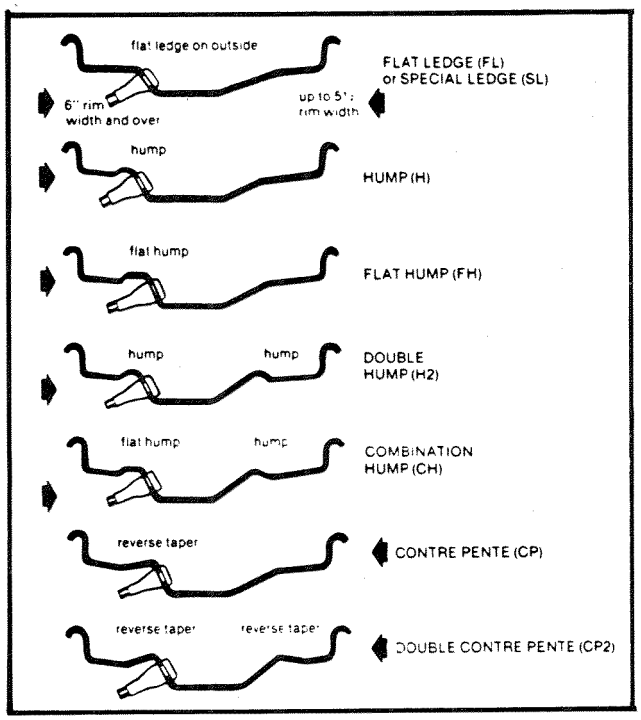

Figure 5. Types of car rims

The Asymmetric Hump Rim

Recently Pirelli and Goodyear have presented a new type of hump design, which significantly increases the level of bead retention, thereby fulfilling the safety factors listed above while satisfying the requirements of ease of fitting and compatibility with other manufacturers of tires.

The working principle is shown schematically in Figure 6. The hump can be considered as made from two rings symmetrically eccentric with respect to the hub and joined together by a straight plane. They are both of equal diameter, approximately equal to that of a standard hump, and the plane that joins the two rings has a variable inclination along the circumference (e.g., it is parallel to the axis of rotation at 90° to the section of Figure 6).

As a result of the inherent flexibility of the tire sidewalls, during the fitting operation the tire is automatically self-centering, as shown in Figure 7, ideally expanding only enough to arrive at the circumferential development of the hump, which, as stated previously, is similar to that of a normal hump. This ideal situation is realized very closely with automatic fitting where, during dome inflation, the tire is pushed simultaneously along the bead circumference.

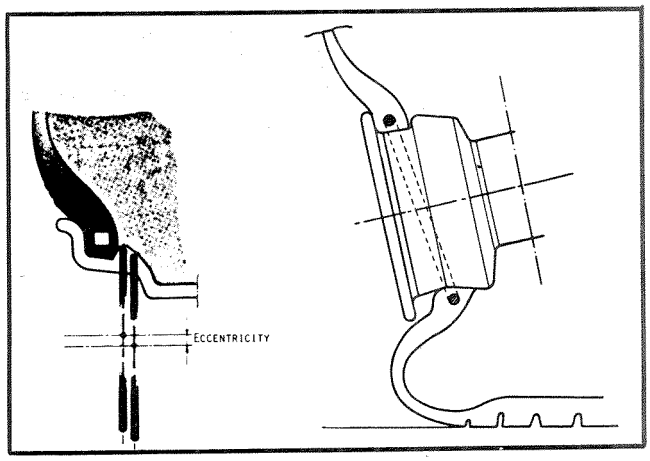

Figure 6. Working principle

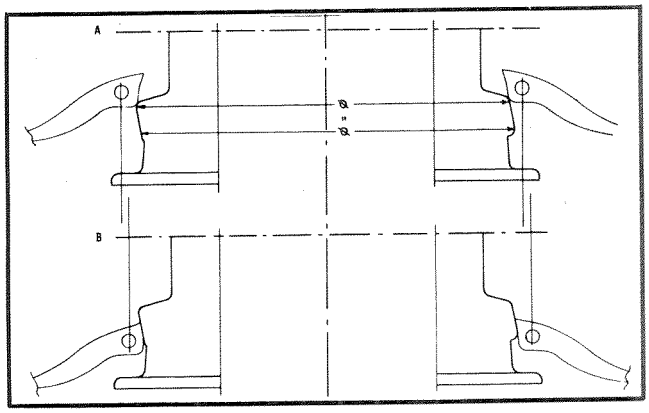

Figure 7. Mounting

During manual fitting, however, inflating through the valve, the increasing internal pressure pushes the tire in an asymmetrical manner, which causes a slight deviation from perfect self-centering. For this reason, the pop-up pressure in this condition can be slightly higher than for normal humps but always remaining within acceptable safe limits of 3-3.5bar.

During the bead dislodgement maneuver, the road applies its force to only a small section of the tire, that corresponding to the footprint area (about 30°). In such conditions, the bead is restricted from moving into the well by a barrier equal to the sum of a normal hump, plus a value of eccentricity (which usually is of the order of 2.5mm). This is far more important than the obstacle represented solely by the hump.

A selection of test results are shown in Tables 1 and 2.

The AH wheels are used as original equipment by four important European vehicle manufacturers and can be constructed in cast light alloy as well as in pressed steel.

Run Flat and Limited Run Flat

As demonstrated, wheels now exist that protect the motorist from the dangers of bead dislodgement; however,

Test description (FMVSS110/Australia design 20)

- Dry straight road
- Vehcile with full road
- At a pre-determined point actuate rapid deflation device
- Bring the vehicle to rest under moderate braking

it remains to establish exactly how many miles a fully deflated (but still with beads in position) tire can continue running to arrive in a safe area where the wheel can be changed.

In the absence of an internal inflation pressure, the load-carrying capacity of the tire is drastically reduced by 80 to 90 percent, the sidewall and bead area come in contact with each other as shown in Figure 8, while the contact area with the road increases notably (three or four times that of the normally inflated tire), tending to lift away from the road surface in the center (C), thus increasing the contact pressure in the shoulder area (D). Occasionally, part of the sidewall comes in contact with the road surface (area B in Figure 8), which results in the relatively soft sidewall rubber compound being abraded away quite rapidly, thus cutting the tire longitudinally in this area. If, due to the geometry of the tire and width of wheel used, this does not occur, the deflated tire becomes

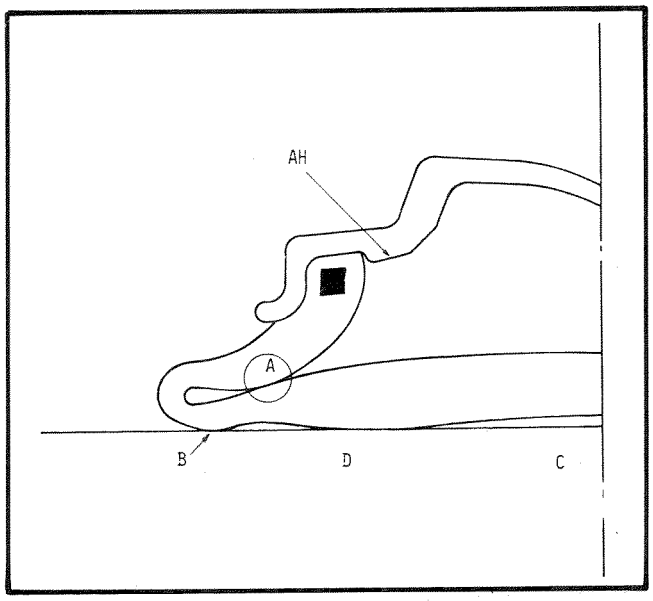

Figure 8. Sidewall and bead contact

subject to immense frictional forces in area (A), during straight running due to longitudinal chafing between the lower bead area and the part in contact with the road (particularly important on driven wheels) and during cornering due to lateral chafing between the tread and the bead.

The result of this friction generates a significant increase in temperature, which causes a rapid degradation in all the mechanical properties of the rubber compounds and temperature-sensitive reinforcing materials.

The tire failure, in the absence of sidewall damage, is seen externally as oblique cuts in the sidewall and internally as abrasion corresponding to zones of contact.

These mechanisms clearly indicate that the distance one can travel on a deflated tire diminishes rapidly with the increase in load, speed, and lateral force of the vehicle, and the situation becomes worse for a driven wheel.

Table 3 indicates a sample of test results. The speeds and lateral accelerations adopted for the tests were chosen to simulate conditions encountered by a motorist with a deflated tire searching for a safe place to change the wheel without jeopardizing the safety of other road users. The tests were all performed with the valve core removed to insure complete deflation of the tire.

It is noted that even in the most favorable conditions of a VR tire with a very low aspect ratio, the mobility afforded prior to the tire's destruction is very low.

The level of mobility of an uninflated tire can be increased in various ways. Excluding the solutions that utilize internal supporting systems necessitating multipiece wheels or the use of spray cans that require stopping the car, the simplest answer is to strengthen the tire sidewalls to obtain a self-supporting tire.

Solutions of this type have been available in the market for several years but without great success, since (prior to the introduction of AH wheels) they required special wheels, were significantly heavier (about 20 percent), and more expensive.

Figure 9 illustrates a section of the Pirelli self-supporting tire of which the weight and performance characteristics are listed in Table 3. In addition to the weight penalty, it also needs stating that it is not easy to tune such a robust tire to the performance comfort and rolling resistance levels currently demanded by modern motor vehicle manufacturers.

However, a run flat mobility of 20 to 30Km should be sufficient for locating a roadside area that would permit a safe wheel change. Tires providing this type of mobility, which we can refer to as limited run flat, have only a moderate increase in weight and consent to a performance almost equal to that of normal tires.

They are not self-supporting, and their run flat performance is obtained using small filters in the sidewalls and carefully choosing the structure materials. Results and characteristics are listed on Table 3.

Summarizing, it can be said that mounted on AH wheels these tires constitute a major step forward in the area of motor vehicle and road safety.

Shuji Shiraishi
Honda R&D Co., Ltd.

Abstract

At past ESV conferences, we have reported on a series of studies on how the driver's control performance is affected by vehicle steering response. These studies showed that a four-wheel steering system can reduce the delay in lateral acceleration response to steering action, which may result in better control performance of the driver.

The present report examines the handling performance of an experimental vehicle fitted with a four-wheel steering system under a wider range of operating conditions. The studies were conducted using mathematical models and simulation of the driver-vehicle system, plus road tests.

The findings indicate that the four-wheel steering system may provide better vehicle handling performance than a conventional two-wheel steering system.

A vehicle incorporating this steering system may exhibit improved accident avoidance capabilities.

Introduction

This paper discusses the handling performance of a motor vehicle equipped with a four-wheel steering system. Vehicle handling performance means the overall steering performance of a driver-vehicle system, which is schematically shown in Figure 1.

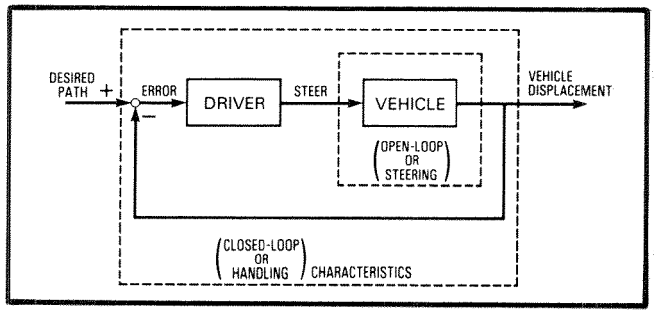

Figure 1. Driver-vehicle system

The open-loop characteristics in Figure 1 represent the steering response characteristics of a vehicle as determined with the input as a steering wheel angle and the output as vehicle motion including lateral displacement. The closed-loop characteristics are part of the "handling performance." This includes the vehicle characteristics, the driver's control performance, and the driver-vehicle closed-loop combination as shown in Figure 1. The system input is a desired course, the error is the deviation from that course, and the output is the actual vehicle path.

Sections 1 and 2 of this paper discuss research efforts to find the difference between the two-wheel and four-wheel steering systems with respect to possible vehicle steering qualities and to identify the effects of such differences on vehicle handling performance based on previous reports(1,2).

This is followed by discussions in Section 3 of computer simulation using a mathematical model of driver's steering action, conducted under a number of typical operating conditions to find vehicle handling performance; road tests to validate the simulation results; and studies based on these experiment findings to estimate the possible effects of the four-wheel steering system on driver's control performance and subjective rating.

Studies on the Handling Performance of Two-Wheel Steering Cars

Many reports are available on methods of evaluating vehicle handling performance using vehicle response parameters. Previously, the authors conducted two series of studies mostly with a lateral motion simulator. In course tracking and evasive lane change tests, it was found that a shorter delay in the phase of vehicle lateral acceleration response to steer inputs would improve the driver-vehicle system performance even if the yaw response gain and phase were kept constant(1,2).

This section first discusses how the delay in the phase of lateral acceleration response to steering action relates to the handling performance of a conventional two-wheel steering car and how this is affected by vehicle speed and design parameters. This analysis uses the two-degree of freedom car equations to calculate the frequency response (see Appendix A).

Response Delay and Vehicle Speed

The calculated effect of vehicle speed on the phase lag in the lateral acceleration response to steering action is shown in Figure 2. The vehicle specifications used in these calculations were modelled after those of a small production car, now on the market in Japan, which is of the same model as the vehicle used for road tests. The frequency bands used in Figure 2 are 0.3Hz and 0.75Hz,

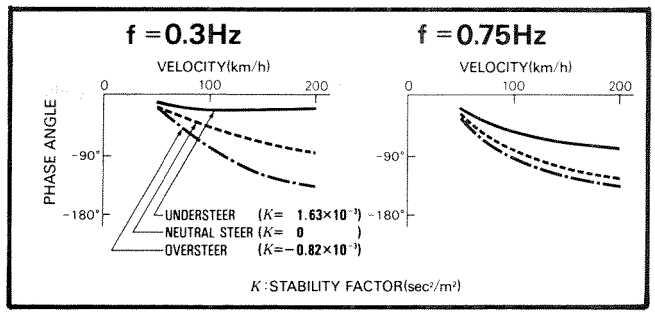

Figure 2. Effect of vehicle velocity on phase angle of lateral acceleration response

which were selected as the most typical regions in the higher and lower portions of a steering frequency range, below 1Hz. This range was selected because the steering frequency during normal driving mostly comes within 1Hz. The vehicle stability factor was alternatively set at three different levels, ranging from slight understeer to slight oversteer (see Appendix B for full details of vehicle specifications and stability factor).

The following characteristics are shown in Figure 2:

- The higher the vehicle speed, the larger the phase lag of lateral acceleration response to steering action.
- The phase delay increases as the stability factor becomes smaller and as the vehicle tends more toward oversteer characteristics.
- Vehicles with understeer characteristics have little phase delay in the lower frequency range.

Techniques To Reduce Response Delay and Their Effects

To study possible means of improving the handling performance of conventional two-wheel steering cars, the basic vehicle design parameters were varied in several ways to determine how much each contributed to the phase delay in lateral acceleration response. The vehicle specifications and typical frequency levels used for this calculation were those of the preceding section. The stability factor of the vehicle used as a reference standard was varied to three different levels, as in Figure 2. The vehicle speed was set at 110km/h (see Figure 3).

Reduction of Response Delay Relative to Vehicle Speed

To quantitatively determine the possible effects of a four-wheel steering car in terms of steering frequency range, the following paragraphs calculate the delay in the phase of lateral acceleration response to steering action from a frequency response equation for an example four-wheel steering car (see Appendix A).

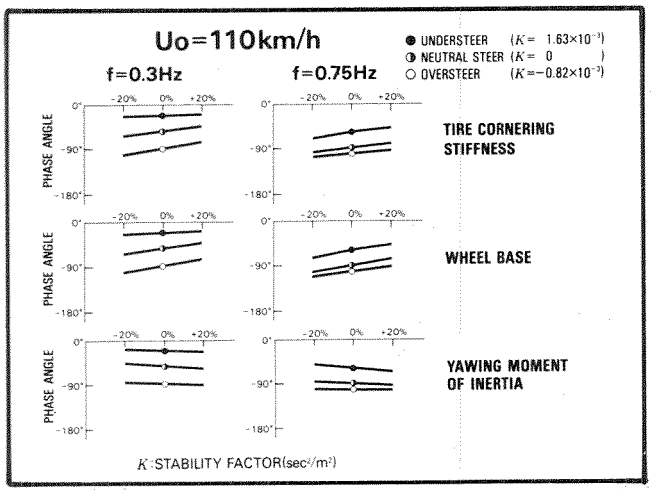

Figure 3. Effect of vehicle design parameter on phase angle of lateral acceleration response

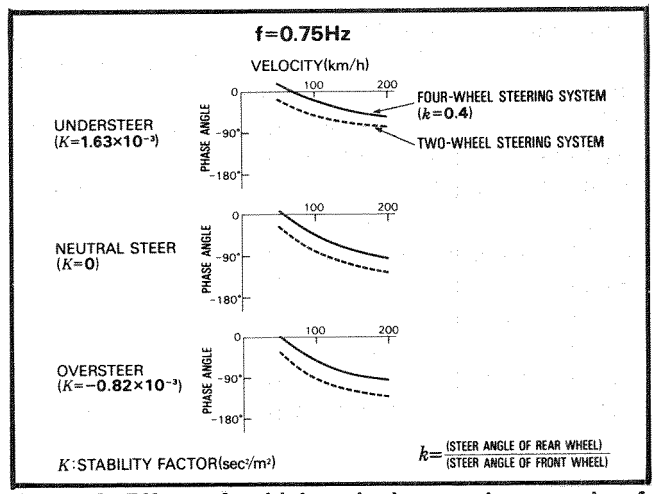

Figure 4. Effect of vehicle velocity on phase angle of lateral acceleration response by steer angle ratio of rear to front wheel

Figure 4 shows the delay in the phase of lateral acceleration at the frequency of 0.75Hz, relative to vehicle speed, for a four-wheel steering car with the same parameters and the same steady-state response gain as a two-wheel steering car.

The ratio of the rear-wheel steering angle to that of the front wheels κ was set at 0.4 level, for comparison with the two-wheel steering system. The steering angle ratio κ is considered positive when the rear wheels are steering in the same direction as the front wheels. The vehicle stability factor was set at the three different levels of Figure 2.

A. Effects of tires
   The cornering stiffness of both the front and rear tires was varied by ± 20 percent.
B. Effects of basic specifications
   The wheel base was varied ± 20 percent.
   The yawing moment of inertia was varied ± 20 percent.

The results of the calculation are as follows:

- The delay in the phase of lateral acceleration response to steering action becomes shorter as the cornering stiffness increases, as the wheel base becomes longer, and as the yawing moment of inertia decreases.
- These percentage changes in cornering stiffness and wheel base contribute almost in the same degree to the phase delay, producing an effect of around ± 10° of lag.
- The contribution of this change in yawing moment of inertia reaches its height—an effect of around ± 8°—when the vehicle has an understeer trend in the higher frequency range.

These findings indicate that the existing two-wheel steering cars can have the following trends in steering characteristics: Typical small production cars with understeer can show a longer delay in the phase of lateral acceleration response to steering action, particularly in the higher frequency range, as they run faster. The phase delay may be reduced only about 10° even if the vehicle design parameters are changed as much as some 20 percent.

This implies that in normal production cars, the improvement of vehicle handling performance may usefully involve research efforts to properly control the phase delay in lateral acceleration response in the higher frequency range. Therefore, only the typical value of 0.75Hz in the higher steering frequency range will be used in further discussion on this subject.

Reduction of Response Delay by Four-Wheel Steering System

We have reported at previous ESV conferences that the delay in the phase of lateral acceleration response to steering action may be reduced by a four-wheel steering system designed to steer the rear wheels in the same direction as the front wheels. Our reports also suggested that reduction of such a phase delay within a proper range might improve the control performance of driver-vehicle systems(1,2).

This section discusses the possible improvement of lateral acceleration response through the use of a four-wheel steering system with particular emphasis on the effects of vehicle speed variation and the steer angle ratio of rear to front wheel.

Effects of Four-Wheel Steering System

The four-wheel steering system may have the following effects: When the steering wheel is turned, a conventional two-wheel steering car places the front wheels at a slip angle in the initial stage, which gives the front wheels a

cornering force. This becomes lateral force and yawing moment for the vehicle, making it turn its heading while moving it sideways. Then a slip angle occurs between the vehicle heading and the velocity direction. This places the rear wheels at a corresponding slip angle, giving them a cornering force. Thus, the rear wheels lag a little in contributing to the lateral motion of the vehicle. The result is a delay in lateral acceleration response to steering action.

With a four-wheel steering system, on the other hand, the rear wheels take part from the first in producing a lateral force for the vehicle. Therefore, it can provide the vehicle with a quicker lateral acceleration response than the conventional two-wheel steering system.

The analytical findings are as follows:

- The four-wheel steering system can provide a shorter delay in the lateral acceleration response in any speed range whether the vehicle has understeer, neutral steer, or oversteer characteristics.
- In the higher steering frequency range, it reduces the phase delay by as much as 30° in all speed ranges. This favorable effect grows stronger as the vehicle tends more toward oversteer characteristics.

Effects of Steer Angle Ratio of Rear to Front Wheel on Phase Delay

Figure 5 shows the effects of the steer angle ratio of rear to front wheel κ noted above on the phase delay at 110km/h.

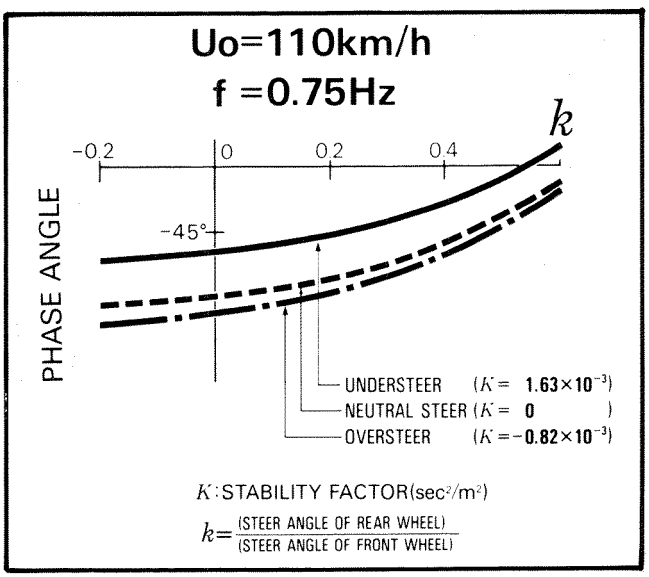

Figure 5. Effect of steer angle ratio of rear to front wheel on phase angle of lateral acceleration response

Variations in the steer angle ratio κ are significant in this higher frequency range. The phase delay decreases remarkably as the value of κ increases.

The discussions in Sections 1 and 2 may be summarized as follows:

The four-wheel steering system becomes more effective in reducing the delay in the phase of lateral acceleration as the rear-wheel steer amplitude more closely matches the front. The analyses showed that steering the rear wheels at a ratio of 0.4 to the front is about three times more effective in reducing the phase delay than a selected design parameter change. In course tracking and lane change tests, as shown previously in (1) and (2), reduction of the phase delay in lateral acceleration response may help improve vehicle handling performance. This suggests that the four-wheel steering system may provide motor vehicles with better handling performance in some driving tasks.

Effects Of Four-Wheel Steering System

This section examines the handling performance of a vehicle fitted with the four-wheel steering system using a variety of assumed operating tasks and conditions likely to occur on the road. The aim is to identify more clearly the effects of the new steering system.

Method of Study

Computer simulation with mathematical models of the driver-vehicle system was used to examine the effects of the four-wheel steering system under a wide variety of operating conditions. The simulation findings were then confirmed by road tests.

The tasks evaluating the closed-loop characteristics may be broadly divided into course tracking and course changing. The first step was to evaluate the stability of the driver-vehicle systems. Our attention was then turned to the subjects of road irregularity and lateral wind sensitivity to assess the course tracking, followed by the lane changing performance as typical of course changing tasks.

Evaluating Conditions

Table 1 shows the subjects, methods, and parameters of evaluation.

Simulation Models

For comparison with the four-wheel steering system, a two-wheel (bicycle) model as used in the preceding sections was selected for the vehicle, and a simple preview predictor model was used for driver control. Major

Table 1. Evaluating conditions

Subject	Evaluating Method and Parameters

	Settlement of steering patterns and vehicle motion	Settlement of steering patterns and vehicle motion

details of the driver's mathematical model used in the simulation are given below and in Appendix A.

Mathematical model

Vehicle: Bicycle model

Driver: Preview predictor model (see Reference 3)

Control parameters

1) Preview distance —L

2) Control gain —h (steering wheel angle relative to the deviation of driver's sight point from the desired course)

3) Time delay —τ (time lag between the perception of such deviation and the start of steering action)

Analytically, the driver looks at a point L meters ahead of the vehicle, finds the deviation of that point from the desired course, and turns the steering wheel for correction with the control gain h after the time delay τ seconds.

Road Tests

A test driver operated an experimental vehicle that had the steer angle ratio of rear to front wheel set at κ = 0.4. The vehicle specifications and operating conditions for the test car were identical with those for the simulation.

Driver-Vehicle System Stability

The first step in the evaluation was to analyze the stability of the driver-vehicle system.

Given a transfer function for each of the driver and vehicle, the transfer function for the driver-vehicle system can be obtained. The closed-loop system stability can be evaluated from the resulting characteristic equation (see Appendix A).

Figure 6 shows the stable range for the driver parameters preview distance L and control gain h with the time delay τ fixed at 0.2s. The results are sensitive to the time delay selected. Generally, the closed-loop response time can range from 0.15 to 0.8s, with typical values in the range of 0.25 to 0.45s(5). A nominal value of 0.2s was chosen for all the analyses based on assumed operating conditions for evasive maneuvers.

For analysis purposes, the steer angle ratio of rear to front wheel κ was set at three different levels from 0 to 0.4. As in the previous calculations, the ratio of steering wheel angle to the front-wheel steering angle η was adjusted to make the steady-state gain equal to that of the two-wheel steering car. The analysis was made at 110km/h.

Figure 6 gives the following findings:

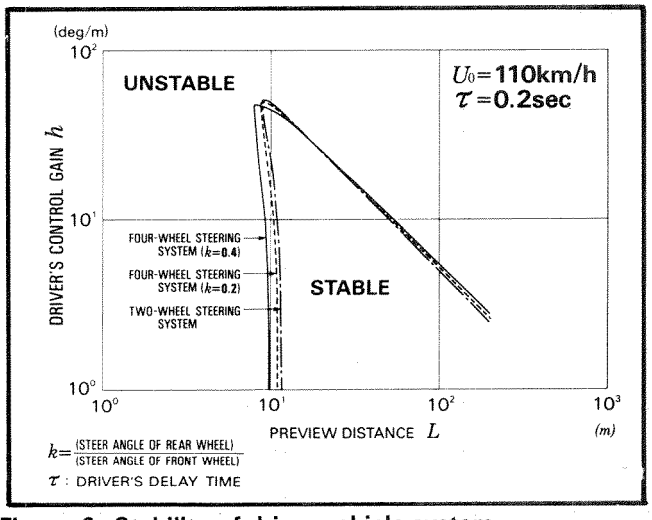

Figure 6. Stability of driver-vehicle system

- The preview distance L has a minimum value that depends on the driver time delay and vehicle speed. The four-wheel steering vehicle shows a slightly smaller minimum value of the preview distance L and, therefore, a wider range of calculated closed-loop stability than the two-wheel steering car.
- As the preview distance L becomes longer, the driver's control gain has to be made smaller to insure stability.
- The maximum value of control gain for a given length of preview distance L is little affected by the steer angle ratio of rear to front wheel κ

Sensitivity to Road Irregularity and Other External Disturbances During Straight-Ahead Driving

This section examines the driver's control action and vehicle motion when an external, lateral force is applied at random to the front and rear axles of a vehicle running straight ahead. The mathematical model of the driver described above is used.

The external disturbance used in the calculation had sufficient force to put the vehicle one full lane width (3.5m) off the desired course and give it a 1° yaw angle, after 15s, if no steering action was taken. Another feature of the external disturbance was good repeatability. The steering power spectral density was adjusted to the same level as in the road tests.

Figure 7 shows the steering and vehicle behavior when the steer angle ratio of rear to front wheel κ was varied while the driver's control gain h and preview distance L were kept constant at 5° / m and 100m, respectively. The vehicle speed was set at 110km/h. The findings are as follows.

The larger the steer angle ratio of rear to front wheel κ the less the vehicle moves sideways.

The root mean square (rms) values of steering angle, heading angle, and lateral displacement were selected as parameters for evaluating the performance of the driver-vehicle system when receiving an external disturbance. These values were divided by the rms values at κ = 0 (corresponding to the two-wheel steering car) and then made nondimensional. The results are given in Figure 8.

The four-wheel steering system does not differ appreciably from the two-wheel system in steering angle or heading angle until the steer angle ratio of rear to front wheel approaches 0.4. At κ = 0.4, the vehicle lateral deviation decreases to less than half that of the two-wheel steering system.

The most effective value of κ ıor coping with an external force is probably about 0.4. The way the vehicle lateral deviation changes relative to the level of κ is consistent with the objective and subjective ratings

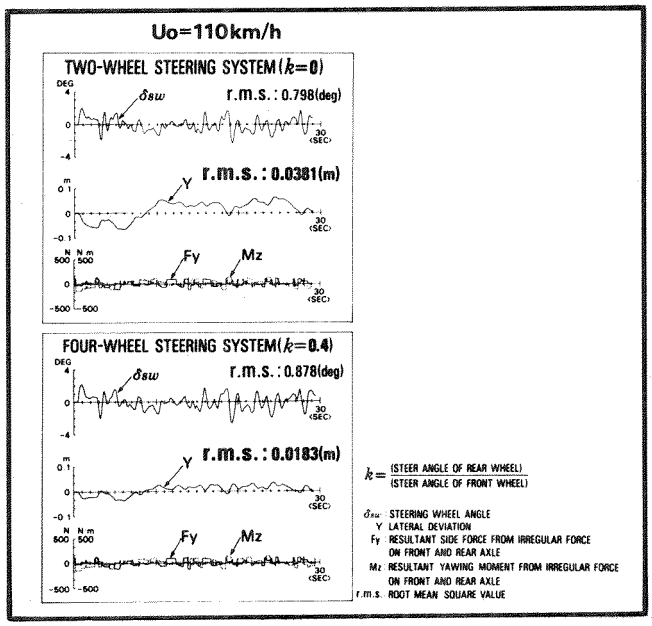

Figure 7. Maneuver on road irregularity sensitivity

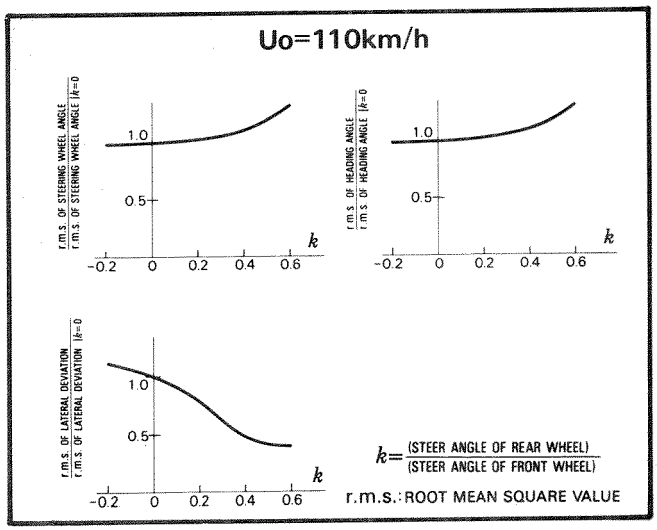

Figure 8. Effect of steer angle ratio of rear to front wheel on road irregularity sensitivity

measured in a lateral motion simulator with random course tracking tests. This was reported at previous ESV conferences (see (2) and Figure 9).

Figure 10 compares the steering power spectral densities of the four-wheel and two-wheel steering cars. In this comparison, the driver's control gain was adjusted to keep the rms value for the lateral deviation of the four-wheel steering vehicle (at κ = 0.4) virtually equal to that for the two-wheel steering car.

In the higher frequency range, the four-wheel steering car has a lower steering power spectral density amplitude than the two-wheel steering car. The power spectral density of the former reaches a peak at about 0.75Hz, and the four-wheel steering system efficiently reduces the required steering wheel amplitude at frequencies above 0.4Hz.

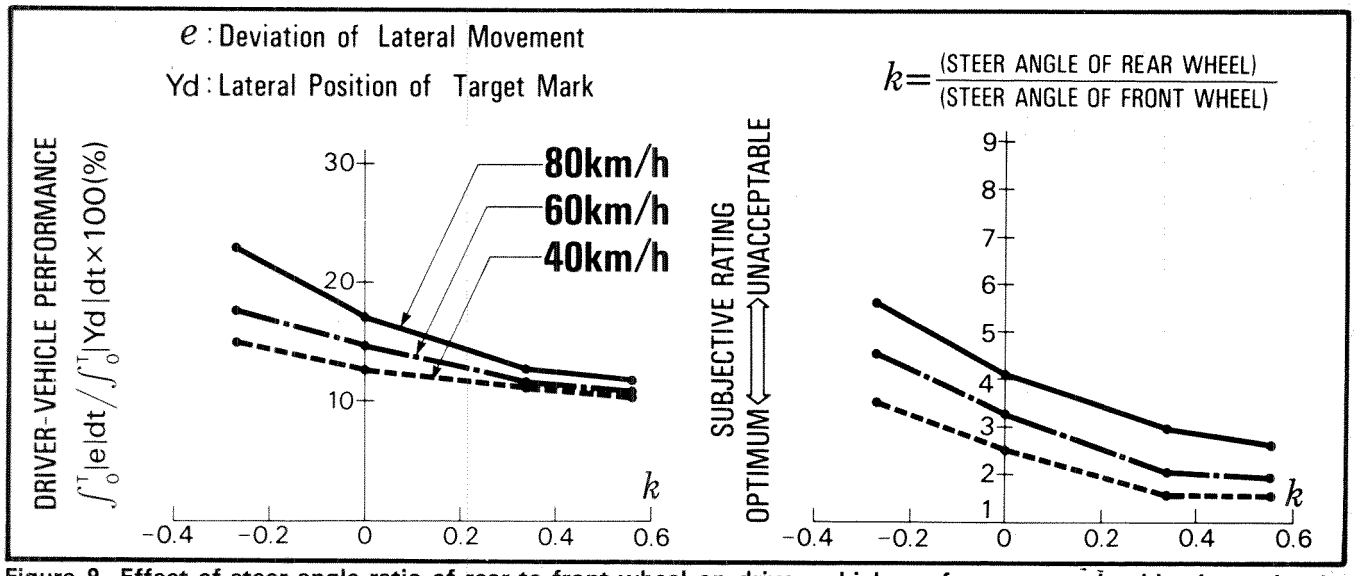

Figure 9. Effect of steer angle ratio of rear to front wheel on driver-vehicle performance and subjective rating in course tracking test

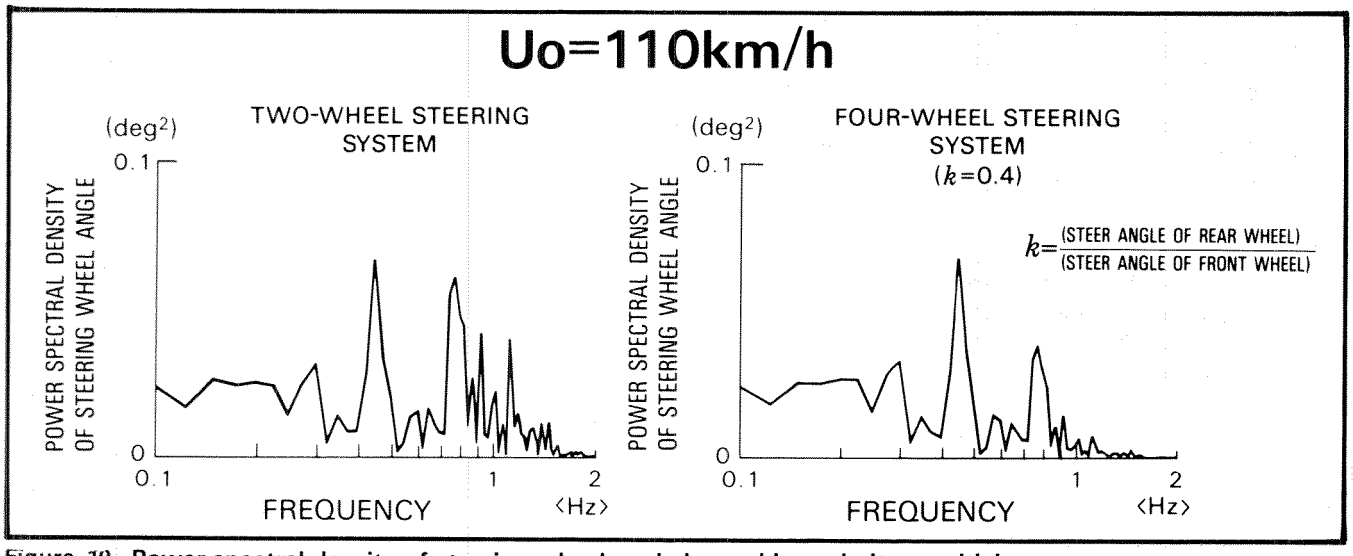

Figure 10. Power spectral density of steering wheel angle in road irregularity sensitivity

In the course tracking tests conducted on a lateral motion simulator, discussed in (2), two steering frequency ranges were considered. One was the frequency range for following the desired course, and the other related to corrective steering needed when the initial steering action failed to keep the vehicle on the desired course. The second frequency range had a peak around 0.7Hz. It was found that the amplitude of this peak was lower for the four-wheel steering car(2).

The simulation findings indicate that the four-wheel steering car requires less corrective steering to maintain the vehicle back on course.

The effects of the steer angle ratio of rear to front wheel and stability factor on the rms steering wheel angle, heading angle, and lateral deviation (see Figure 11) were investigated, i.e.,

- Vehicle lateral deviation is affected more by the steer angle ratio κ than by the stability factor K.
- But the steering wheel angle and heading angle are affected more significantly by the stability factor than by the ratio κ, if it is kept below about 0.4.

This means that use of the four-wheel steering system for vehicles with understeer characteristics should reduce the steering wheel angle, heading angle, and lateral deviation.

Lateral Wind Sensitivity

The difference between the closed-loop behavior of the four-wheel and two-wheel steering cars was calculated in

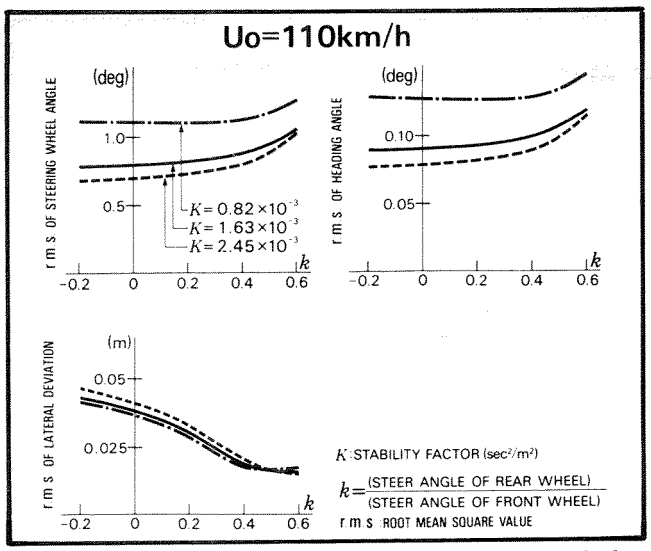

Figure 11. Effect of stability factor on road irregularity sensitivity

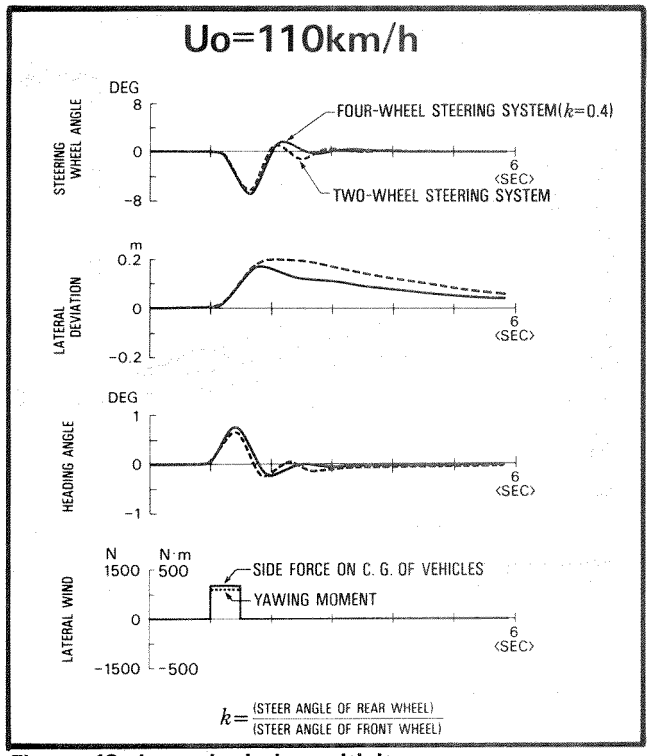

Figure 12. Lateral wind sensitivity

the presence of an external force and moment corresponding to a lateral wind. The external force and moment were made roughly equal to those a test vehicle would receive while running at 110km/h through a 15m-long lateral wind pulse with a strength of 22.5m/s.

Figure 12 compares the two-wheel steering car and the four-wheel steering car with its steer angle ratio of rear to front wheel κ set at 0.4.

The analyses show that the steering and heading angle damp faster with the four-wheel steering car.

The maximum lateral displacement of the four-wheel steering vehicle is about 20 percent less than that of the two-wheel steering vehicle. The four-wheel steering car is also some 30 percent lower than the two-wheel steering car in the cumulative value of lateral deviation—the results of integrating the lateral deviation up to the point where steering settles down.

Figure 13 shows the effects of the steer angle ratio of rear to front wheel on the maximum lateral deviation and heading angle after the closed-loop driver-vehicle is exposed to a simulated lateral wind.

The maximum heading angle becomes larger as the steer angle ratio of rear to front wheel κ increases, while the maximum closed-loop lateral deviation decreases as the value of κ increases.

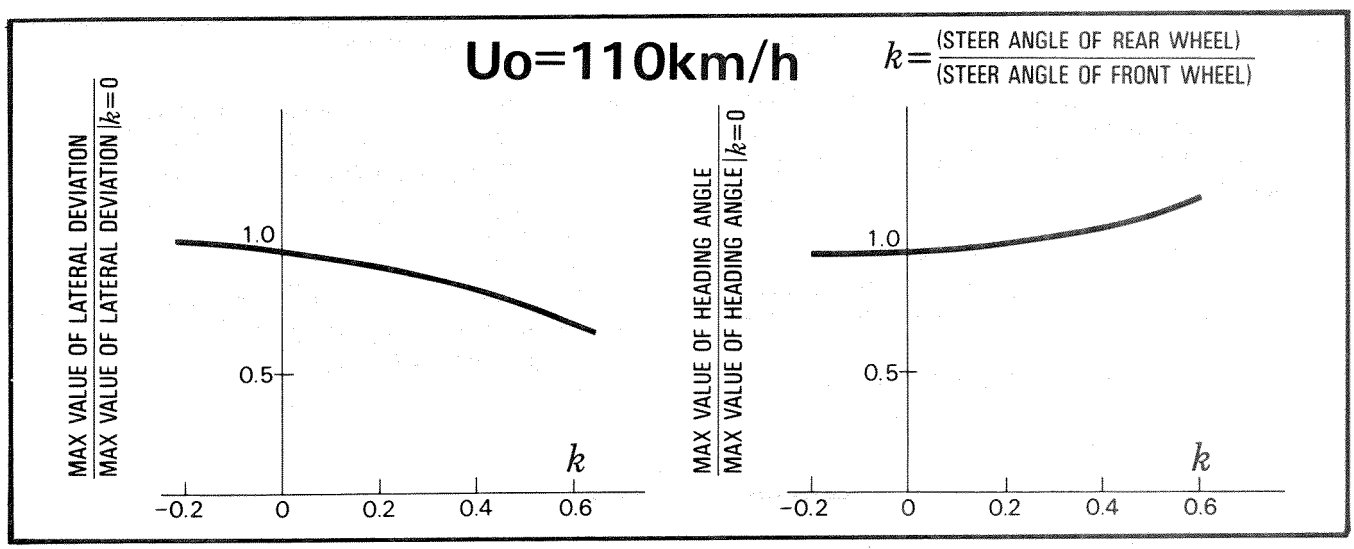

Figure 13. Effect of steer angle ratio of rear to front wheel on lateral wind sensitivity

Lane Change

Maneuverability to Pass Through Courses Marked by Traffic Cones

An attempt was made to analyze the range of driver's control parameters by which the vehicle could pass through using a simple closed-loop, driver model. In this simulation, the driver preview distance L and control gain h were varied for both the two-wheel steering car and the four-wheel steering car (at κ = 0.4). The time delay was set at 0.2.

The maneuverability was determined by whether the vehicles operated with the above driver control model could run successfully through the lane change courses, the width of which was marked by traffic cones as shown in Figure 14. A target line was used to define the course, and the vehicles were required to go through the courses without touching any of the cones. The vehicle dimensions for this calculation were fitted to the overall length and width of the test vehicles, and the vehicle speed was set at 110km/h.

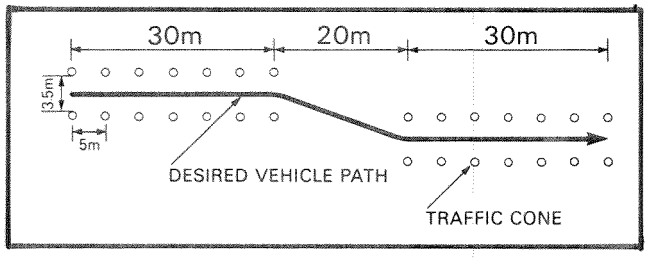

Figure 14. Course layout for lane change test

Figure 15 presents a diagram prepared by plotting the regions of successful lane change courses for the two vehicles on top of the stable ranges of driver control shown in Figure 6.

These results of computer modeling for the assumed driver time delay and vehicle speed are as follows:

- The two-wheel steering vehicle cannot change lanes successfully in a stable range of control at this speed. In other words, its motion after running through the course correctly cannot be stabilized unless the driver model control parameters change right after the lane change is over.
- The four-wheel steering vehicle, on the other hand, can change lanes using the stable range of control for the assumed conditions. These parameters enable the driver-vehicle model to go on without changing control parameters and stably run through the desired course.
- Although the steady-state response gains of the two vehicles are set equal, the four-wheel steering car requires a smaller amount of the driver control gain to run through the desired course.

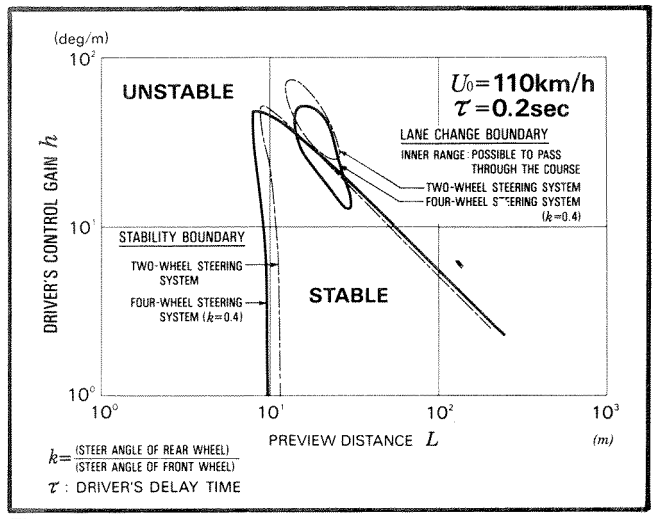

Figure 15. Task performance and stability in driver-vehicle system

Steering and Vehicle Behavior

For a lane change, from a driver control standpoint, the most desirable values of driver model parameters are probably the least control gain h and the longest preview distance L. The two vehicles can be compared in the lane change to find the difference between the systems in steering and behavior. Possibly, less control gain h and longer distance L within the stable range-parameters selected cause the driver-vehicle system to remain most stable.

The analytical findings are given in Figure 16.

The steering wheel angle, lateral acceleration, yaw velocity, and roll angle of the four-wheel steering vehicle are all less than those of the two-wheel steering car. In addition, they damp more rapidly.

Figure 16 gives the results of road tests, which show the same tendency as noted above.

Conclusion

The open-loop and closed-loop characteristics of the four-wheel steering system were analyzed by computer simulation. The results may be summarized as follows:

(1.) Open-loop characteristics of the vehicle. The four-wheel steering configuration reduces the phase lag of lateral acceleration when the rear wheels are steered in the direction of the front wheels. Steering the rear wheels at a ratio of 0.4 to the front wheels is about three times more effective in reducing this phase delay than, say, a 20 percent change in the design parameters of the conventional two-wheel steering system.

(2.) Driver-vehicle system stability. The four-wheel steering system permits the driver model preview distance to be reduced, compared with the two-

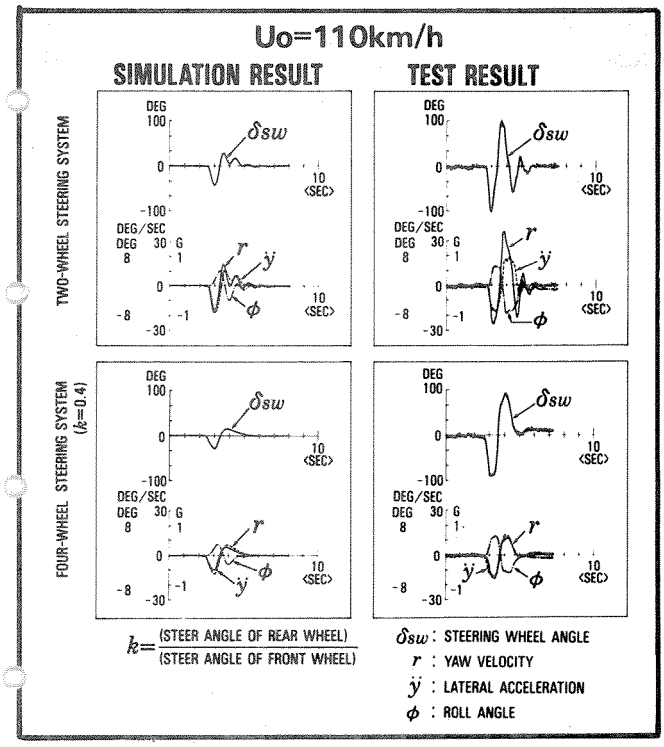

Figure 16. Lane Change Maneuver

wheel steering system. In addition, the maximum value of driver control gain for the new system does not depend on the steer angle ratio of rear to front wheel. This suggests that the new steering system might provide a slightly wider range of stability for driver-vehicle systems than the conventional two-wheel steering system.

(3.) Sensitivity to road irregularity and other external disturbances. When the steer angle ratio of rear to front wheel is set at about 0.4, the four-wheel steering system allows the corrective steering of the driver model to be reduced by about 30 percent, when countering road irregularity or other external disturbances during course tracking driving. For good lateral deviation performance, the range of steer angle ratio is up to 0.4 or so, and ratios above this level produce little effect. This trend is consistent with previous studies conducted with a lateral motion simulator.

(4.) Lateral wind sensitivity. When affected by a lateral wind, the lateral response of the four-wheel steering car damps more quickly, closed-loop. The larger the steer angle ratio, the less the lateral deviation.

(5.) Lane change. For the assumed driver model, the conventional two-wheel steering car cannot accomplish the lane change with a stable range of control parameters. However, the four-wheel steering car can follow the prescribed lane change using a stable range of model parameters.

The computed behavior of the four-wheel steering car is moderate and settles down quickly following the maneuver.

In summary, the new steering system, designed to steer the rear wheels in the same direction as the front wheels, improves the calculated control performance of the driver-vehicle system under a wide variety of operating conditions. It may provide a significant contribution to the area of active safety devices for motor vehicles in the years to come.

Appendix A
Mathematical Models

Model of a Vehicle Equipped with a Four-Wheel Steering System

Equations of Vehicle Motion

With the forward vehicle velocity given as U_o (= constant) and vehicle slip angle given as β (= small), equations of vehicle motion with 2 degrees of freedom in a coordinate system fixed to the vehicle center of gravity can be expressed as follows (see Reference (1):

$$\begin{bmatrix} I\,\dot{r} \\ m\,\dot{\beta} \end{bmatrix} = \begin{bmatrix} -\dfrac{C_f\,a^2+C_r\,b^2}{U_o} & C_r\,b-C_f\,a \\ -m+\dfrac{C_r\,b-C_f\,a}{U_o^2} & -\dfrac{C_f+C_r}{U_o} \end{bmatrix} \cdot \begin{bmatrix} r \\ \beta \end{bmatrix} + \begin{bmatrix} C_f\,a & -C_r\,b \\ \dfrac{C_f}{U_o} & \dfrac{C_r}{U_o} \end{bmatrix} \cdot \begin{bmatrix} \delta_f \\ \delta_r \end{bmatrix} \quad (1)$$

The definition of the symbols used in the equation is given in the nomenclature at the end of the appendixes.

Transfer Function for Steering Response

The right and left members of Equation (1) may be Laplace-transformed by using the relations:

$$\delta_{sw} = n\,\delta_f \quad (2)$$

$$\delta_r = k\,\delta_f \quad (3)$$

$$\ddot{y} = U_o\,(\dot{\beta}+r) \quad (4)$$

Then the transfer functions for yaw velocity response and lateral acceleration response to steering δsw can be expressed respectively as follows:

$$(5)\quad \frac{r(S)}{\delta sw(S)} = G^{r}_{\delta sw}(S) = G^{r}_{\delta sw}(O)\cdot \frac{1+Tr\,S}{1+\frac{2\zeta}{\omega n}\,S+\frac{1}{\omega n^2}\,S^2}$$

$$(6)\quad \frac{\dot{y}(S)}{\delta sw(S)} = G^{\dot{y}}_{\delta sw}(S) = G^{\dot{y}}_{\delta sw}(O)\cdot \frac{1+\frac{2\zeta'}{\omega'n}\,S+\frac{1}{\omega'^2_n}\,S^2}{1+\frac{2\zeta}{\omega n}\,S+\frac{1}{\omega n^2}\,S^2}$$

The coefficients for different terms of these transfer functions are:

$$(7)\quad G^{r}_{\delta sw}(O) = \frac{1-k}{n}\cdot\frac{Uo}{\ell\,(1+K\,Uo^2)} \qquad (7)$$

$$(8)\quad G^{\dot{y}}_{\delta sw}(O) = \frac{1-k}{n}\cdot\frac{Uo^2}{\ell\,(1+K\,Uo^2)} \qquad (8)$$

$$(9)\quad \omega n^2 = \frac{Cf\,Cr\,\ell^2\,(1+K\,Uo^2)}{m\,I\,Uo^2}$$

$$(10)\quad \zeta^2 = \frac{\{(Cf\,a^2+Cr\,b^2)\,m+(Cf+Cr)\,I\}^2}{4m\,I\,Cf\,Cr\,\ell^2\,(1+K\,Uo^2)}$$

$$(11)\quad Tr = \frac{m\,(Cf\,a-k\,Cr\,b)}{(1-k)\,Cf\,Cr\,\ell}\,Uo$$

$$(12)\quad \omega'^2_n = \frac{(1-k)\,Cf\,Cr\,\ell}{(Cf+k\,Cr)\,I}$$

$$(13)\quad \zeta'^2 = \frac{(b+k\,a)^2\,Cf\,Cr\,\ell}{4\,(1-k)\,(Cf+k\,Cr)\,I}\cdot\frac{1}{Uo^2}$$

$$(14)\quad K = \frac{Cr\,b-Cf\,a}{Cf\,Cr\,\ell^2}\,m$$

Where

$G^{r}_{\delta sw}(O)$: Steady-state gain in yaw velocity response to steering

$G^{\dot{y}}_{\delta sw}(O)$: Steady-state gain in lateral acceleration response to steering

ωn : Natural frequency of lateral motion

ζ : Damping ratio of lateral motion

Tr : Time constant (for lead) of yaw velocity

K : Vehicle stability factor.

Equations of Vehicle Motion in Ground-Fixed Coordinate System

This section derives vehicle transfer functions in a ground-fixed coordinate system o-XY, which are useful for an analysis of driver-vehicle system stability as discussed in the next section.

From Figure A-1, the following equation may be obtained:

$$\dot{Y} = Uo\,\sin(\beta+\psi) \qquad (15)$$

$$\ddot{Y} = Uo\,(\dot{\beta}+r)\,\cos(\beta+\psi) \qquad (16)$$

If vehicle motion is limited to small lateral perturbations, while running straight ahead at a constant velocity, then small angle approximations can be used, i.e.:

$$\ddot{Y} = Uo\,(\dot{\beta}+r) \qquad (17)$$

$$\dot{\psi} = r \qquad (18)$$

The right side of Equation (17) conforms with Equation (4).

Hence:

$$G^{Y}_{\delta sw}(S) = \frac{1}{S^2}\,G^{\ddot{y}}_{\delta sw}(S) = \frac{1}{S^2}\,G^{\ddot{y}}_{\delta sw}(S) \qquad (19)$$

$$G^{\psi}_{\delta sw}(S) = \frac{1}{S}\,G^{r}_{\delta sw}(S) \qquad (20)$$

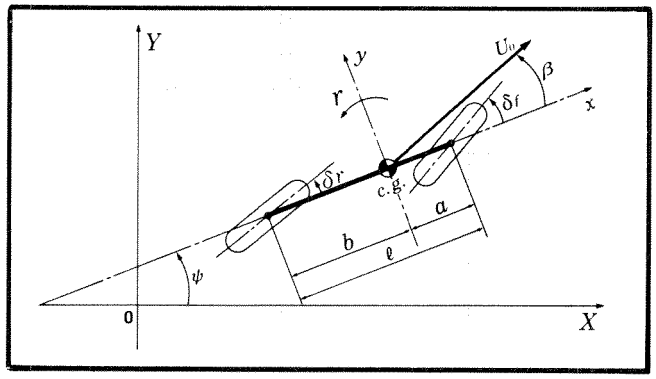

Figure A-1. Bicycle model of four-wheel steering vehicle

Analytical Model of the Driver-Vehicle System

Mathematical Model for the Driver

To analyze the handling performance of the four-wheel steering system, this paper uses a driver model, called the "preview predictor model" (see Reference (3)).

As is apparent from Equation (19), lateral vehicle position has the qualities of second-order integration. Accordingly, differential as well as proportional behavior are needed to stably control the vehicle using the driver's feedback control action. Determination of vehicle lateral deviation requires second-order integration, while the heading angle assumes characteristics similar to first-order integration as indicated in Equation (15). Typically, a motor vehicle can be easily controlled by detecting and controlling these two phenomena. This is the basic idea on which this mathematical model of drivers has been established.

As shown in Figure A-2, a driver as the mathematical model described above looks at a point L meters ahead of the vehicle, and after finding the error ε of that point from the desired course, feeds back such information to the steering wheel angle at a given gain h. It is assumed there is a delay time τ between the detection of such error and an initiating steering action.

Hence:

$$\delta sw(t)=h\ \varepsilon(t-\tau) \tag{21}$$

With the right and left members Laplace-transformed, the transfer function $G^{\delta sw}(S)$ becomes:

$$G_{\varepsilon}^{\delta sw}(S)=\frac{\delta sw(S)}{\varepsilon(S)}=h\ e^{-\tau s} \tag{22}$$

Assuming that τ is small, it follows:

$$\simeq h\ (1-\tau\ S) \tag{23}$$

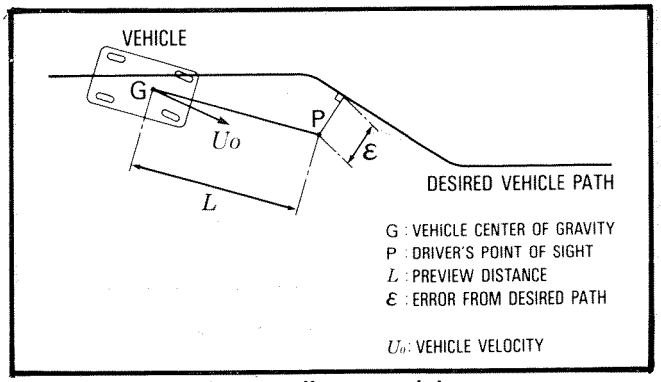

Figure A-2. Preview predictor model

With the lateral position of the desired course given as Yc, the error ε may be expressed as follows:

$$\psi \ll 1$$

$$\varepsilon \simeq Y+L\psi-Yc \tag{24}$$

The time-domain computer simulation uses Equation (21) instead of Equation (24).

Equations (23) and (24) are used in linearizing the driver-vehicle system for stability analysis, as discussed in the next subsection.

Stability Analysis of the Driver-Vehicle System

The block diagram of the driver-vehicle model discussed here is similar to Figure A-3.

From the diagram:

$$Yc(S)=\varepsilon(S)+\delta sw(S)\cdot\{G_{\delta sw}^{Y}(S)+L\ G_{\delta sw}^{\psi}(S)\} \tag{25}$$

$$Y(S)=\delta sw(S)\cdot G_{\delta sw}^{Y}(S) \tag{26}$$

$$\frac{Y(S)}{Yc(S)}=\frac{G_{\varepsilon}^{\delta sw}(S)\cdot G_{\delta sw}^{Y}(S)}{1+G_{\varepsilon}^{\delta sw}(S)\cdot\{G_{\delta sw}^{Y}(S)+L\ G_{\delta sw}^{\psi}(S)\}}$$

The characteristic equation for the driver-vehicle system as described in (27) above with the desired course as input and the lateral displacement of the vehicle as output can be expressed as follows:

$$F(S)=1+G_{\varepsilon}^{\delta sw}(S)\cdot\{G_{\delta sw}^{Y}(S)+L\ G_{\delta sw}^{\psi}(S)\}=0 \tag{27}$$

If Equations (19), (20), (23) are substituted for the appropriate terms of Equation (28), a polynomial of S raised to the fourth power can be obtained:

$$F(S)=a_0 S^4+a_1 S^3+a_2 S^2+a_3 S+a_4=0 \tag{28}$$

Where

$$a_0=n\ m\ I \tag{29}$$

$$a_1=\frac{n}{Uo}\{(C_f a^2+Cr\ b^2)\ m+(C_f+Cr)\ I\}- \tag{30}$$

$$\tau\ h\ \{(C_f+k\ Cr)\ I+L\ (C_f\ a-k\ Cr\ b)\ m\} \tag{31}$$

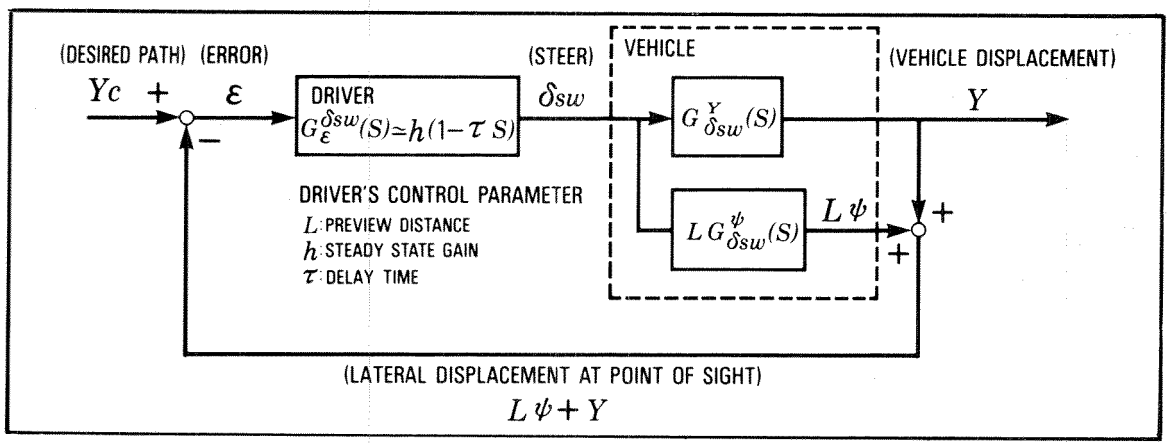

Figure A-3. Driver-vehicle system using preview predictor model

(32) $$a_2 = n\,C_f\,C_r\,\ell^2\,\frac{(1+K\,U_o^2)}{U_o^2}$$

$$h\,\{(C_f+k\,C_r)\,I+L\,(C_f\,a-k\,C_r\,b)\,m\}$$

$$-\,\tau\,h\,\frac{C_f\,C_r\,\ell}{U_o}\,\{b+k\,a+L\,(1-k)\}$$

(33) $$a_3 = h\,\frac{C_f\,C_r\,\ell}{U_o}\,\{b+k\,a+L\,(1-k)\}$$

$$-\,h\,\tau\,(1-k)\,C_f\,C_r\,\ell$$

(34) $$a_4 = h\,(1-k)\,C_f\,C_r\,\ell$$

To keep this system asymptotically stable, all roots of Equation (29) must be found in the left-half plane.

Two methods are available for identifying the stable ranges of driver's control parameters L, h, and τ; one is to directly solve Equation (29), and the other is to find such ranges from coefficients α_0, α_1, α_2, α_3 and α_4.

The second method includes a techniquts αeorem. A primary test on this particular method found that all coefficients of Equation (29) must be positive. From:

$$a_3 > 0$$

The following relation can be derived:

$$L > \tau\,U_o - \frac{b+k\,a}{1-k} \tag{35}$$

This means that the preview distance the driver has to look out ahead has a minimum value that depends on vehicle velocity and driver time delay and that a four-wheel steering system helps reduce the minimum possible preview distance, L.

Nomenclature

- a : Distance from front axle to center of gravity (C. G) of vehicle.
- b : Distance from rear axle to C. G.
- ℓ : Wheel base $(a+b)$.
- m : Vehicle mass.
- I : Yawing moment of inertia.
- n : Steer angle ratio of steering wheel to front wheel.
- k : Steer angle ratio of rear to front wheel.
- C_f : Front tires' cornering stiffness.
- C_r : Rear tires' cornering stiffness.
- U_o : Vehicle forward velocity.
- δ_{sw} : Steering wheel angle.
- δ_f : Steer angle of front wheel.
- δ_r : Steer angle of rear wheel.
- K : Stability factor.
- (X,Y) : Earth-fixed axis system.
- (x,y) : Vehicle-fixed axis system.
- ψ : Heading angle.
- β : Vehicle sideslip angle.
- r : Yaw velocity.
- $\dot{y}$: Lateral acceleration.

Maneuverability and New Suspension for Four-Wheel Drive Vehicles

Minoru Otake,
Shingo Obayashi,
Midori Kubota, and
Yoshiaki Nozawa
Subaru Engineering Division, Fuji Heavy Industries, Ltd.

Abstract

Four-wheel drive vehicles have recently become widely used for their enhanced safety in a variety of road conditions on the highway and snowy, wet, and gravel-covered roads.

It is well known that four-wheel drive vehicles are superior in maneuverability to two-wheel drive vehicles. We have attempted to explain this superiority by theoretical as well as experimental methods.

This paper deals with the theoretical approach in determining the difference in movements between two-wheel and four-wheel drive vehicles during cornering with varying tire-to-road-surface friction coefficients and wheel loads. Experiments were carried out on paved and snowy roads using the two types of vehicles. As a result, it has been verified quantitatively that the four-wheel drive vehicle provides higher stability with greater variations in friction coefficients and wheel loads, though the difference is only marginal under a steady state.

This paper also reports on the new suspension system developed to implement enhanced characteristic levels of a normal passenger car (vibration, ride comfort, steering stability and control, etc.) without sacrificing the unique features of the four-wheel drive system.

Introduction

The four-wheel drive vehicle, with its greater traction than two-wheel drive vehicles, was developed mainly for off-road use, but in recent years the four-wheel drive has been adopted for normal passenger cars as well. It insures safe driving not only on the snowy and unsurfaced roads but also on highways(1).

For maneuverability, however, conventional analysis based on experiments on flat roads with constant coefficient of friction is unsatisfactory for proving that the four-wheel drive vehicle is safer than two-wheel drive vehicles. We, therefore, have analyzed the movements of front-wheel, rear-wheel, and four-wheel drive vehicles with varying coefficients of road friction and wheel loads to compare and report on the safety of these types of vehicles.

This paper also reports on the practical pneumatic suspension system with height control that has been developed to insure not only a safer and more comfortable ride under high-speed cruising on the highway and on long drives, but the best performance of the four-wheel drive when used off the road.

Maneuverability Characteristics of Four-Wheel Drive Vehicles

Driving and Braking Characteristics

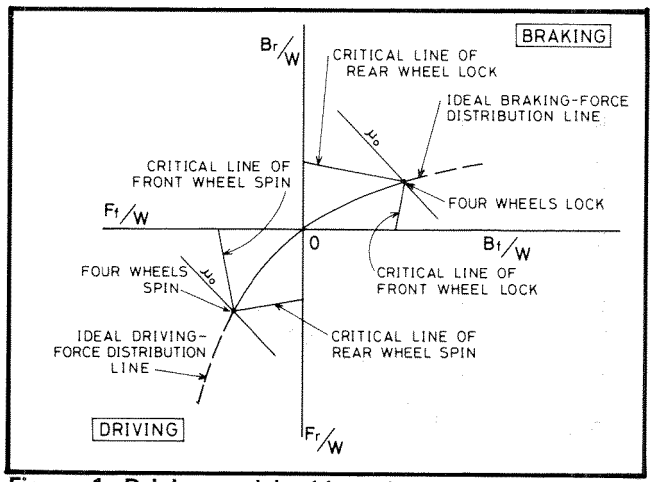

Figure 1. Driving and braking characteristics of four-wheel drive

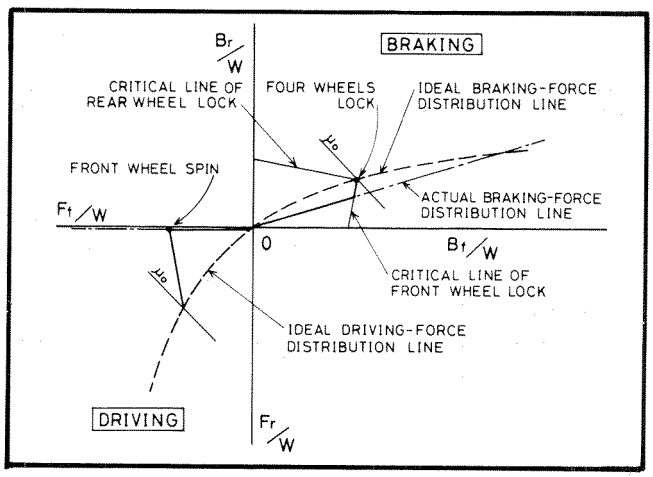

Figure 2. Driving and braking characteristics of four-wheel drive

Where:

- $B_{f\text{-}r}$: Braking-force of front and rear wheels (per wheel)
- $F_{f\text{-}r}$: Driving-force of front and rear wheels (per wheel)
- W : Vehicle weight
- μ_o : Maximum friction coefficient between tire and road surfaces

Figures 1 and 2 show driving and braking characteristics of automobiles. The four-wheel drive vehicle, in which both the front and rear wheels are connected directly to the transmission, traces theoretically an ideal braking-force distribution line during braking, insuring maximum performance regardless of road surface conditions. Though front tires cannot be steered in the two-wheel drive system while they are locked up, the four-wheel drive system allows the control of steering until all four wheels are locked, thus enhancing safety. Figure 3 shows the results of experiment.

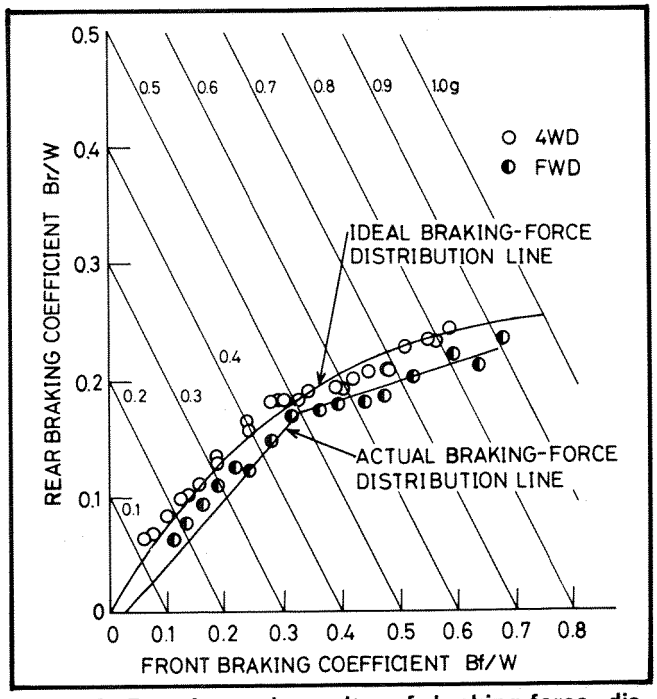

Figure 3. Experimental results of braking-force distribution

The four-wheel drive shows an ideal driving-force distribution line during driving and insures maximum traction at all times. When the equivalent traction is used in two-wheel and four-wheel drive vehicles, the four-wheel drive vehicle uses less traction per wheel, allowing greater use of cornering force.

Figure 4 shows the maximum friction coefficient (between tire and road surfaces) to maximum acceleration diagram (μ_o - α_{max} diagram) for four-wheel, front-wheel, and rear-wheel drive vehicles as obtained by calculation, from which we know the four-wheel drive vehicle is superior in its ability to transmit driving force.

Simulation Model with Three Degrees of Freedom

Figure 5 shows a two-wheel model with three degrees of freedom in a vehicle, simplified for making an analysis.

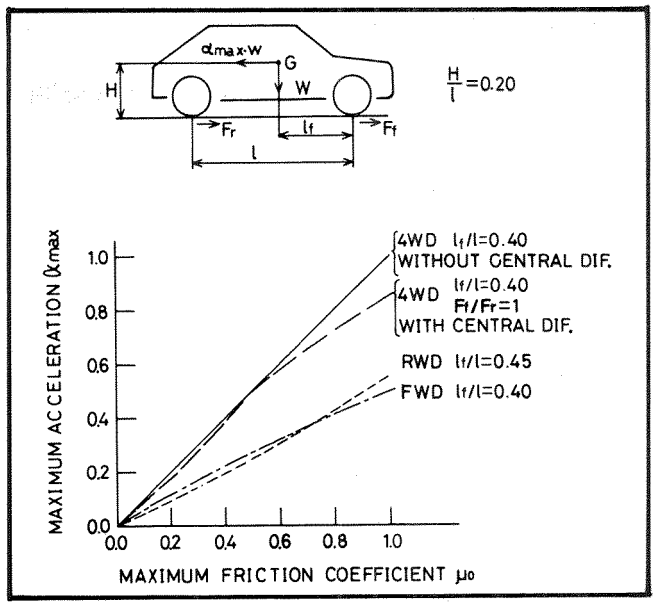

Figure 4. Maximum friction coefficient to maximum acceleration diagram

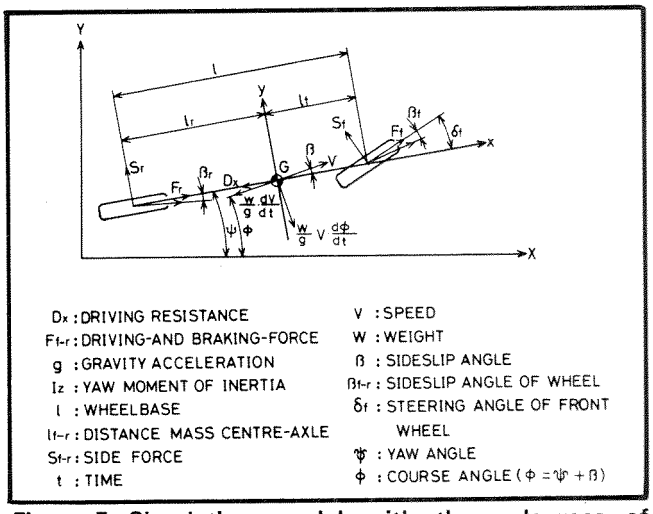

Figure 5. Simulation model with three degrees of freedom

Equations of equilibrium for vehicle longitudinal force, lateral force, and yawing moment are as follows:

Longitudinal force

$$-Dx - \left\{\left(\frac{dV}{dt}\right) - V\left(\frac{d\phi}{dt}\right)\beta\right\}\frac{W}{g} + F_f \cos\delta_f - S_f \sin\delta_f + F_r = 0 \quad (1)$$

Lateral force

$$-\left\{\left(\frac{dV}{dt}\right)\beta + V\left(\frac{d\phi}{dt}\right)\right\}\frac{W}{g} + F_f \sin\delta_f + S_f \cos\delta_f + Sr = 0 \quad (2)$$

Yawing moment

$$-I_z\left(\frac{d^2\psi}{dt^2}\right) + (F_f \sin\delta_f + S_f \cos\delta_f)\,\ell_f - S_r\,\ell_r = 0 \quad (3)$$

By applying the concept of friction circle, the relationship between tire driving and braking force $F_{f\text{-}r}$ and side force $S_{f\text{-}r}$ can be simplified as follows:

$$S_{f\text{-}r} = f_c(\mu_o \cdot L_{f\text{-}r}) \times \sqrt{1 - \left(\frac{f_{f\text{-}r}}{2} / \mu L_{f\text{-}r}\right)^2} \times 2\beta_{f\text{-}r} \quad (4)$$

Where:

- μ_o : Maximum friction coefficient between tire and road surfaces
- μ : Friction coefficient between tire and road surfaces
- $L_{f\text{-}r}$: Vertical load on front and rear wheels (per wheel)
- $f_c(\mu_o \cdot L_{f\text{-}r})$: Side force per given slip angle

From these equations, it is learned that more marked differences exist in vehicle movement between different drive systems with greater driving resistance D_x, driving force $F_{f\text{-}r}$, and wheel vertical load $L_{f\text{-}r}$, and a smaller maximum friction coefficient μ_o: the four-wheel drive system is superior in driving stability. These factors correspond, respectively, to driving on snow- and gravel-covered roads, hill climbing, and high-speed cruising on wet roads.

Figure 6 indicates simulation results of vehicle behavior when turning with a fixed steering angle and varying friction coefficients on road surfaces μ_o. It shows that the rear-wheel drive demonstrates the most drastic change in yaw velocity and a stronger tendency toward spin.

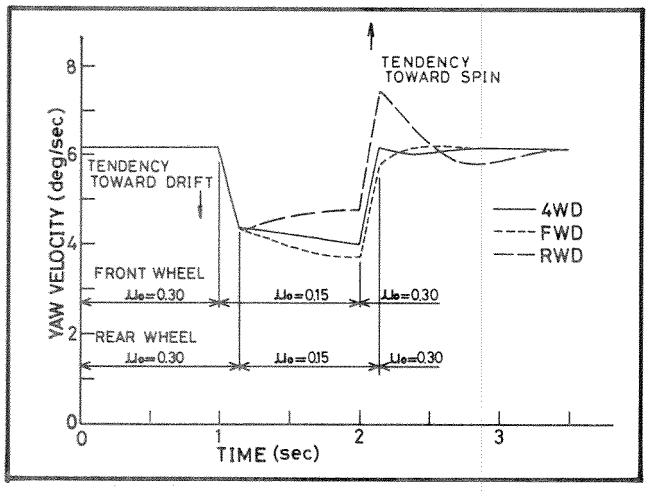

Figure 6. Theoretical simulation of vehicle behavior during turning with varying μ_o values

The front-wheel drive has greater change in yaw velocity and shows a strong drift tendency. The four-wheel drive, on the other hand, has the least change in yaw velocity, showing excellent driving stability.

The same is also true in Figure 7, which simulates vehicle behavior during turning with a fixed steering angle but varying wheel vertical loads.

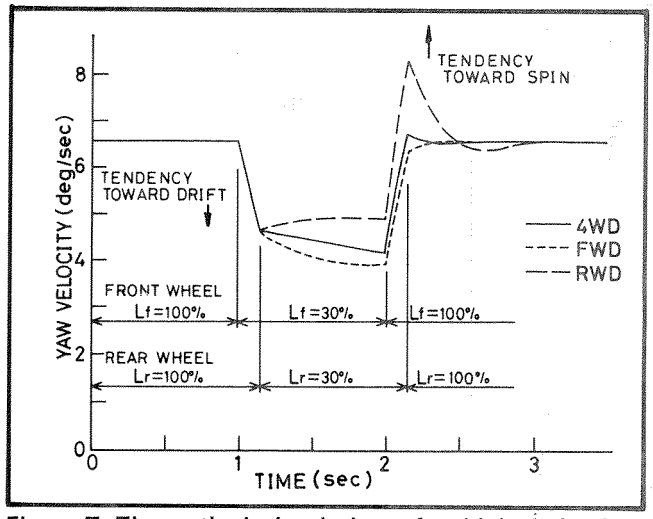

Figure 7. Theoretical simulation of vehicle behavior during turning with varying $L_{f\text{-}r}$ values

Actual Maneuverability Examples

Looking at differences in vehicle behavior between actual four-wheel and two-wheel drive vehicles when they make a steady state cornering and move up and down a snowy hill, the following are seen:

Steady State Cornering

Figure 8 shows the results of steady state cornering made by a vehicle allowing selection of either front-wheel or four-wheel drive mode, cornered in both modes. The test was conducted on both wet and dry surfaces. In both cases, the four-wheel drive has a slightly higher limit of adhesion and tends to have reduced understeer near the limit, the difference between front-wheel and four-wheel drive being marginal. This is because for a flat, smooth surface, there is no change of friction coefficient (μ_o), and there is little driving resistance.

Driving on Snowy Roads

Figure 9 shows measurements of frequency of various steering-wheel angles, steering efforts, and lateral accelerations occurring for a vehicle driven in both front-wheel and four-wheel drive modes. The vehicle was driven on a test course of approximately 5km by one driver to hold the same road impression. Maximum vehicle speed was held to the same level on a straight course.

The figure reveals that the four-wheel drive has a smaller frequency in the region of relatively small levels of steering-wheel angle, steering effort, and lateral acceleration. This indicates that the four-wheel drive tends to stay on course better, requiring little correction of steering angles along a straight line, which insures safer

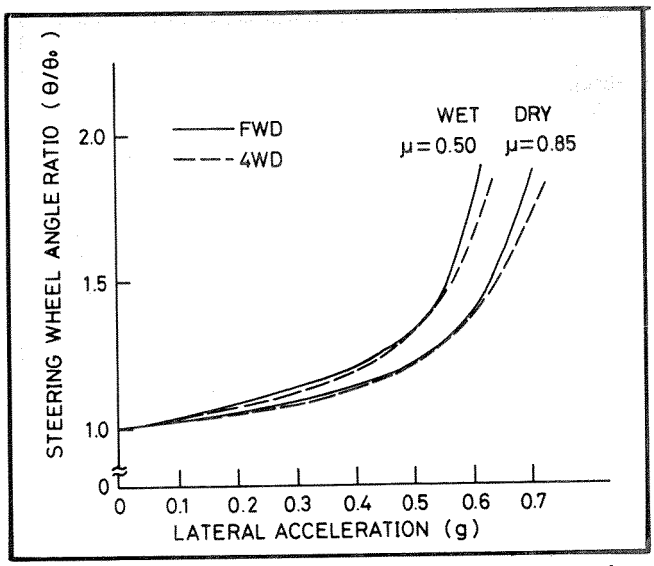

Figure 8. Experimental results of steady state cornering

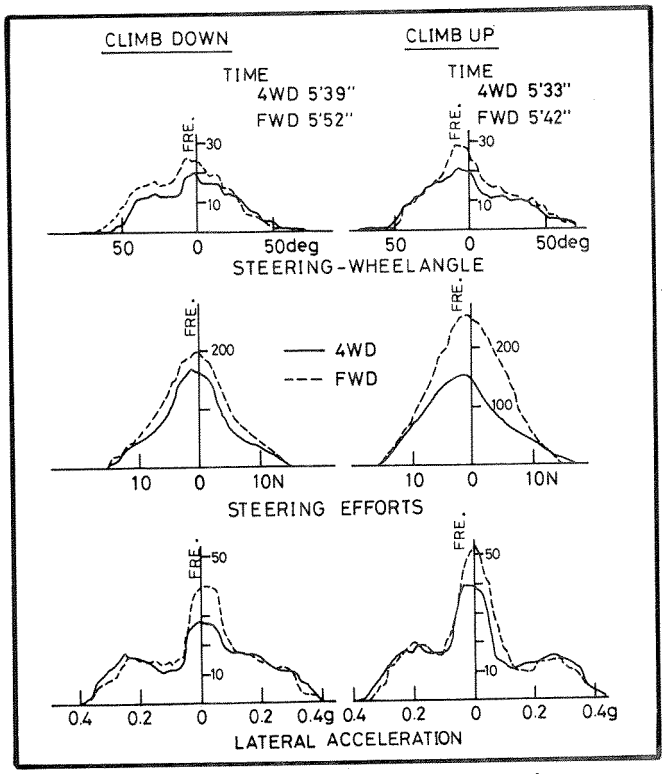

Figure 9. Experimental results of snowy roads

driving. This tendency is especially true with steering-wheel angle and steering effort when the vehicle climbs a hill, which demonstrates that the greater the driving force the more noticeable the difference between the two drive systems.

A closer examination of the results of lateral acceleration measurements shows that the four-wheel drive has a greater frequency in higher acceleration regions, as compared with the front-wheel drive, which means it is easier to handle during cornering. This agrees with the subjective evaluation results, and the four-wheel drive required shorter time than the two-wheel drive despite the fact that the vehicle was driven at the same maximum speed and driver's road impression.

Suspension System of Four-Wheel Drive Vehicles

Requirements for the Suspension System on Four-Wheel Drive Vehicles

On-Road

It is important to consider passenger comfort as well as noise characteristics, in addition to driving stability at high speeds, to insure a safe, comfortable ride on the road. These factors help to reduce fatigue of passengers. Thus, the requirements are—

- Height of vehicle center of gravity should be low.
- Sufficient suspension stroke should be provided at all times regardless of pay load.
- Spring and damper damping characteristics should be insured according to operating conditions.
- Transmission of vibration from unsprung weight should be minimized.

Off-Road

Generally speaking, off-road driving limit depends not only on traction but also on grounding and bottoming characteristics, the important factors to take into account for the suspension system on a four-wheel drive vehicle.

Excessive road shocks imparted to the vehicle body increase driver fatigue, affect driving stability, and lead to body damage. Requirements therefore include—

- Sufficient road clearance should be provided, unaffected by varying load weight.
- Sufficient suspension stroke should be provided regardless of load weight.
- Spring rate should be increased in proportion to increased load weight.
- The damper damping force should be kept at an adequately high level.

As can be observed above, design requirements for a suspension system for both on-road and off-road use tend to contradict each other in many respects.

Subaru Pneumatic Suspension System with Height Control

Outline of the System

To eliminate conflict between the requirements, we have equipped the system with several novel functions as follows:

(1) Level control that selects height at either normal or high in a range of 30mm at the front and 35mm in the rear, thereby insuring road clearance as well as low center of gravity
(2) Automatic load leveling that maintains vehicle height at a predetermined value regardless of load weight, thereby insuring sufficient suspension stroke as well as road clearance
(3) Replacement of conventional metal springs by air-spring assemblies, not only to improve the vibration damping characteristics from the unsprung weight but also to help make possible the automatic load leveling mentioned above
(4) Displacement-dependent variable damping force that improves ride comfort and stability on the road as well as driving ability off the road

Figure 10 shows the configuration of the Subaru Pneumatic Suspension System with Height Control. The system consists of the following components:

- Pneumatic springs: A rolling-diaphragm-type air spring is installed outboard the damper. This, combined with automatic load leveling, allows setting of a low spring rate for improved ride comfort. The spring rate can also be increased in proportion to load, which improves road stability with a heavy load, as well as bottoming characteristics. Should there be an air leak, the built-in bump stopper rubber comes into play to allow continued driving.

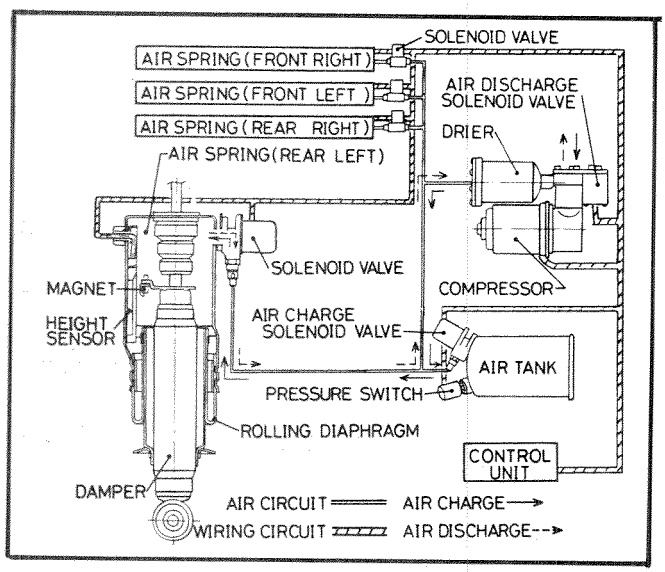

Figure 10. System diagram

- Variable damping force: Figure 11 shows the variable damping force mechanism; Figure 12 shows an example of damping force characteristics.
- Height sensor: A sensor is installed in each of the four air springs and detects suspension stroke within close tolerances, offering a means of precisely determining vehicle conditions.
- Compressor and drier: The compressor, drier, and exhaust solenoid valve are integrated into one unit. As a safety feature, the solenoid valve acts as a relief valve when delivery pressure of the

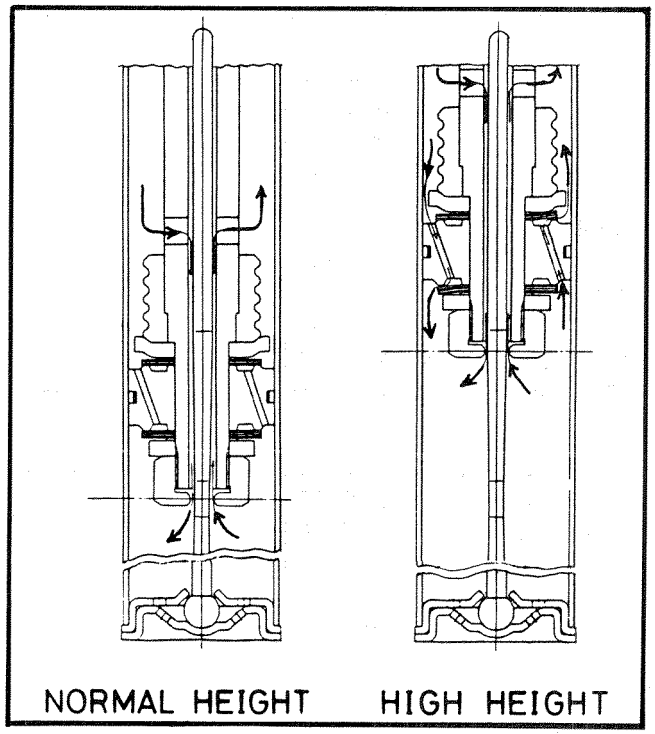

Figure 11. Variable damping force mechanism

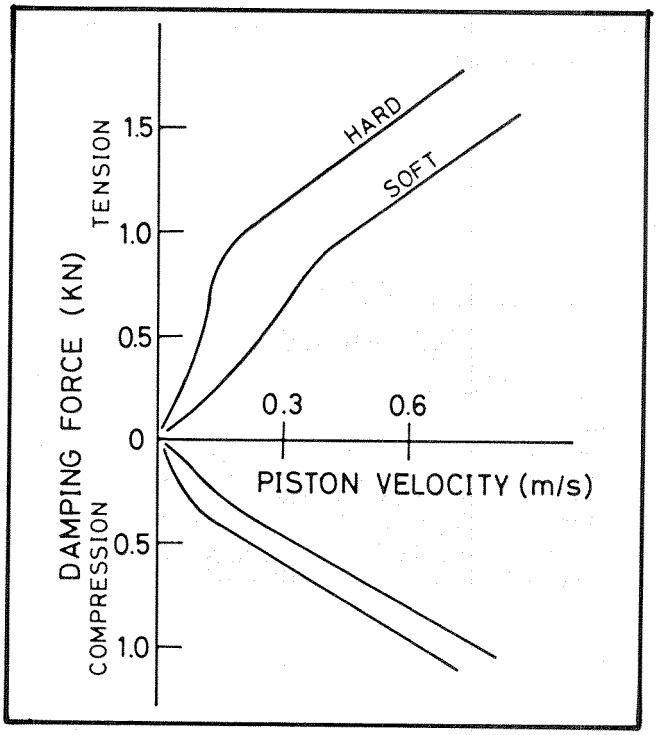

Figure 12. Damping force characteristics

compressor becomes excessive in certain unusual conditions.

- Control unit: Using a single-chip microcomputer, it enables optimum control of air springs by analyzing height-sensor and vehicle-speed signals. Figure 13 is a block diagram of the control logic.

Height Selection—The height selection switch allows the driver to select either the high or normal height, as shown in Figure 14. When vehicle speed exceeds a predetermined level while driving in high level, normal height is automatically selected to lower the center of gravity, improving driving stability at higher speeds.

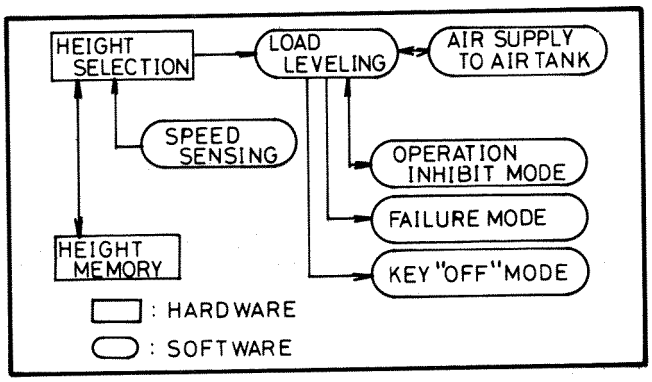

Figure 13. Block diagram of the control logic

Load Leveling—Load leveling maintains vehicle height at a predetermined level regardless of load weight. The function is activated when the height sensor transmits a signal indicating variations in car height for time duration, as shown in Table 1. It is not activated, however, when "a wheel rides on road bump," "a wheel comes off track to a lower level," or "body roll" (see Figure 15). This prevents stability and control from being deviated to right and left.

If an error occurs in the system, an indicator light flashes to warn the driver of incorrect operation, and the relevant control functions are deactivated.

Performance Evaluation

On-Road—Road stability at high speeds is improved by low vehicle height and constant vehicle position regardless of pay load and aerodynamic lift. In particular, the subjective evaluation has proved that the pneumatic suspension is extremely effective in keeping the vehicle on straight course at 100km/h or over.

The new suspension also insures good ride comfort. For example, there is little rapid pitching, such as choppy ride (see Figure 16) or vibration around 5Hz, and vibration is drastically reduced over 20Hz (see Figure 17). Noise characteristic has also been improved, as shown in Figure 18, by effectively damping or road noise.

Off-Road—When used off the road, the vehicle with the new suspension in high mode offers a wide 195mm road

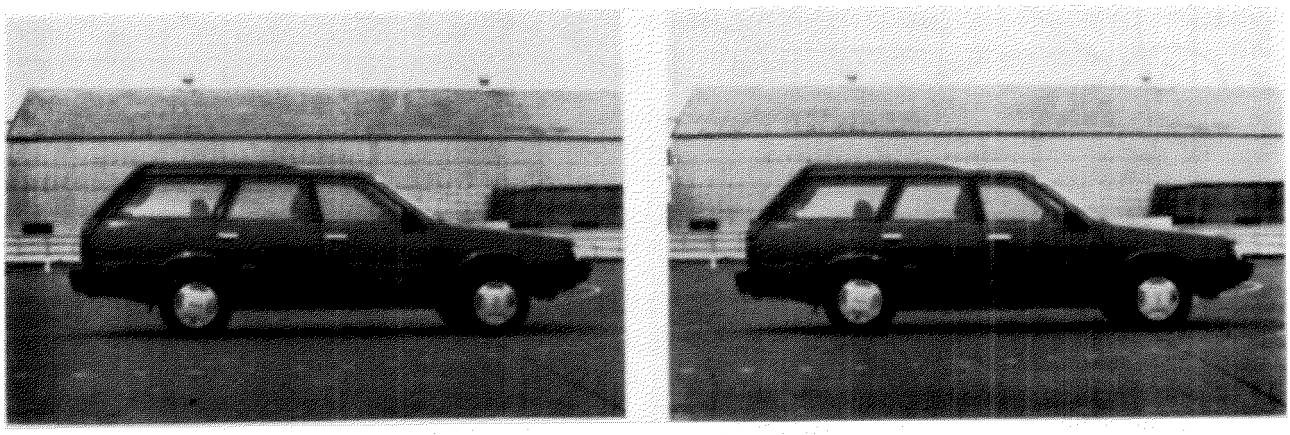

Figure 14. External view

Table 1. Time constant of height sensor signal.

Vehicle Conditions	Time Constant
Within 2 sec after ignition switch on	0.5 sec
During stationary	10 sec
Within 1 min after starting a vehicle	15 sec
1 min or more after starting a vehicle	60 sec

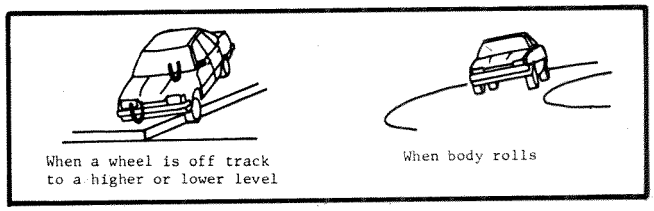

Figure 15. Examples of operation inhibit pattern

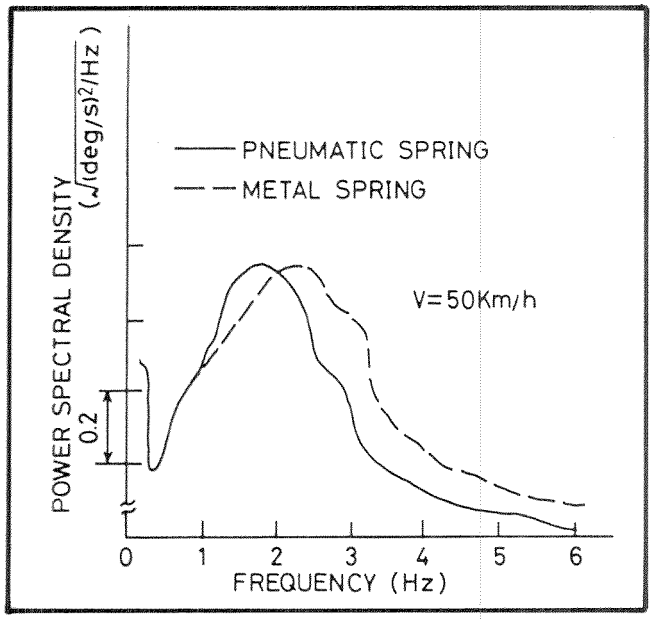

Figure 16. Body pitch rate

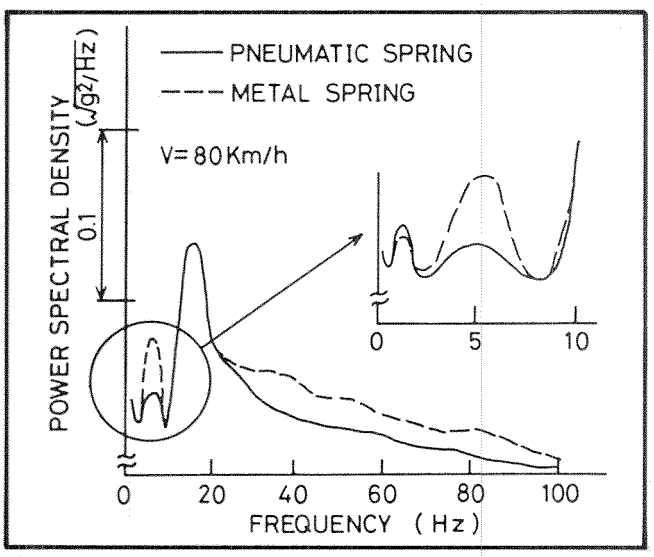

Figure 17. Vertical body vibration on Belgian road

clearance, and automatic load leveling has minimized bottoming regardless of load weight (see Figure 19). This improves driving ability as well as ride comfort on rough roads.

Conclusion

The four-wheel drive vehicle, because of its more stabilized motion on the highways and snowy and unsurfaced roads than the two-wheel drive vehicle, can insure a safer ride. By combining the four-wheel drive with the electronically controlled pneumatic suspension, sufficient stability, when used under a wider range of conditions including off-road, can be achieved together

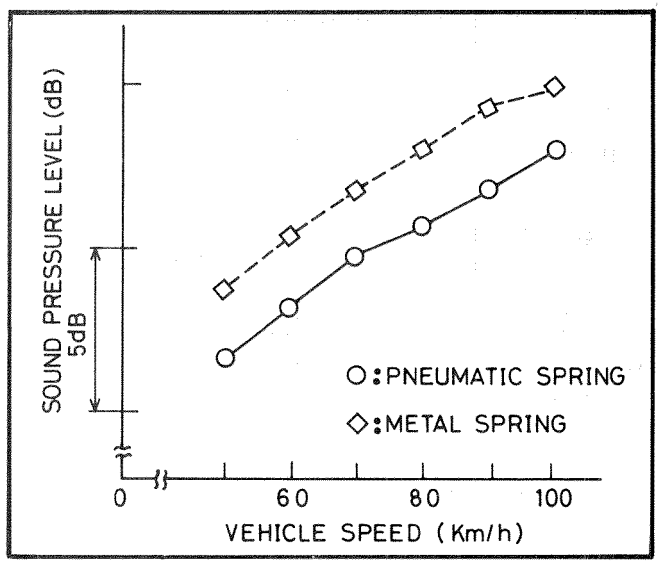

Figure 18. Interior noise

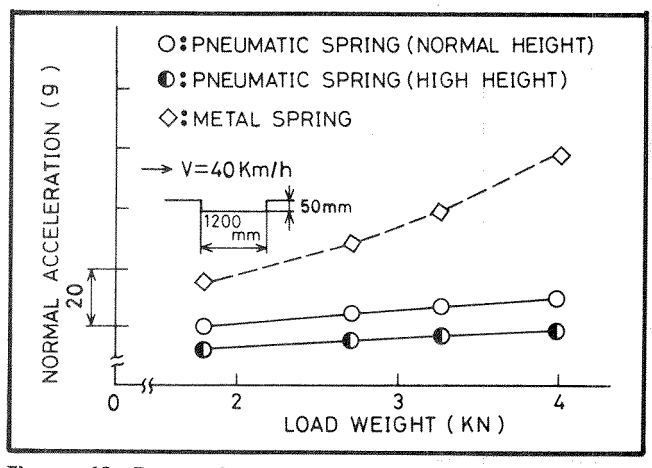

Figure 19. Bottoming characteristics

with excellent ride comfort. The combination, we believe, will provide a safer ride from both the vehicle maneuverability and human comfort viewpoints.

Behavior of a Vehicle During Turning

Y. Vermont
Renault

Introduction

Doing things in such a way that the driver of a car is always in control of his vehicle, whatever the circumstances, is one of the goals that Regie Renault has set regarding safety:

- The behavior of the vehicle must always be consistent with the instantaneous orders given by the driver, whether he is braking, accelerating, or lifting his foot off the accelerator (a point that will be the object of this paper).
- The vehicle must inform its driver when it is nearing the point of limit.

It is easy to understand that a driver will very possibly leave the road if he takes a curve too fast. Family cars do not benefit from aerodynamic ground effects and cannot tackle a turn, without running substantial risk, at a speed greater than that producing transverse acceleration of 1g (9.81m/s2).

The natural reaction of a driver who realizes he is taking a turn too fast is to lift his foot off the accelerator and then, in some cases, to brake. Without particular technical precautions being taken, the vehicle is quite likely to skid head-to-tail.

The manufacturer, when drawing up the specifications for the axle assemblies of a car, specifies the steering geometry stresses that will improve coherence between the driver's action and the response of the vehicle. Therefore, we think we can improve car-driving safety.

The purpose of this study is to help understand—

- Why a vehicle begins a head-to-tail skid
- How the manufacturer can correct this phenomenon

Using the calculation results of a mathematical model representing the transitory behavior of a vehicle, we shall see how, by adjusting the running gear, the limit at which a car begins a head-to-tail skid can be pushed back.

The first part of this paper will be devoted to the attitude assumed by the vehicle with respect to its trajectory at stabilized speeds. In this way, we will bring in different notions needed to understand the transitory behavior of the car:

- Rigidity of the overall drift of the axle assemblies and tires
- The steering angles induced by the vehicle roll attitude
- Under- and over-steering behavior (angular dynamic)
- Behavior of the tire under load

To characterize the probable transitory stage of a car when the foot is lifted, we shall compare two static-dynamic states of the vehicle:

- Just before the foot is lifted
- The second just after, when the deceleration of the car creates longitudinal load transfers proportional to its deceleration

To maintain the trajectory, the driver must correct the angle set by the steering wheel. The greater this angle, the less stable the car will be and the higher the chances of head-to-tail skidding. If we modify the parameters defining the axle assemblies it becomes possible to have the overall rigidity of each of the axle assemblies sets evolve favorably. Although this rigidity is basically caused by the tires, it is, in fact, the evolution of the deviation between the front and rear axle rigidity that governs this behavior. The car manufacturer's margin maneuver is approximately of the same order of magnitude.

These first results were confirmed by simulations using a vehicle transitory model. This model integrates a tire model designed by Mr. Ratti, engineer at Regie Renault.

Static-Dynamic Balance of a Vehicle Turning on a Circle

Definition of Tire Drift Rigidity

If a side force is applied to a tire, the tire drifts through an angle δ. For a small angle δ, the drift and force F are in proportion to one another, so we can define a drift rigidity as $F = D \times \delta$. The drift rigidity is an increasing function of the vertical load applied to the tires.

Definition of Angular Dynamic

The angular dynamic defines the under- or over-steering behavior of the car. The test currently performed to test the under- or over-steering performance of a car is as follows. A 50m circle is traced on the ground. The test driver has to follow this line while accelerating. If he is obliged to increase the steering wheel angle, the vehicle under-steers; otherwise, it over-steers. Family car manufacturers seek to design under-steering cars. The increase of the steering angle at the steering wheel as the transverse acceleration speed increases is a natural driver reflex. In addition, it is a stability criteria for the car.

The angular dynamic of a car is the supplementary angle through which the steering wheel must be turned to keep the car on the same trajectory when transverse acceleration increases at the rate of lm/s2. A positive

angle means that the car under-steers; a negative angle means that it over-steers. The angular dynamic can be expressed either at the road wheel or at the steering wheel, through the application of the steering demultiplication ratio N.

$Ds = N \times Dr$

Let us assume a car is running at a speed V on a circle with a radius R.

- M : weight of vehicle
- M1 : weight on front axle
- M2 : weight on rear axle
- l : wheelbase
- l1 : distance from center of gravity to front axle
- l2 : distance from center of gravity to rear axle
- γt : transverse acceleration
- Ψp : vehicle yaw speed
- Y1 : transverse force on ground at front axle
- Y2 : transverse force on ground at rear axle
- D1 : front tire drift rigidity
- D2 : rear tire drift rigidity
- δ : body center of gravity drift angle
- $\delta 1$: front axle drift angle
- $\delta 2$: rear axle drift angle
- r : circle radius
- α : angle on steering wheel (expressed at road wheel)

General equations of dynamic:

$$(M1 + M2) \times \gamma t = Y1 + Y2$$

$$0 = Y1 \times l1 - Y2 \times l2$$

$$Y1 = M1 \times \gamma t$$

$$Y2 = M2 \times \gamma t$$

Tire balance equations:

$$Y1 = D1 \times \delta 11$$

$$Y2 = D2 \times \delta 12$$

Kinematic relations:

$$V \times (\alpha + \delta 1) = V \times \delta g + l1 \times \psi p$$

$$V \times \delta 2 = V \times \delta g - l2 \times \psi p$$

$$\psi p = V / R$$

$$\gamma t = V \times V / R$$

$$\alpha = l / R + \delta 2 - \delta 1$$

Finally, the angular dynamic equals the difference of the respective drift angle of the rear axle and front axle when the vehicle, traveling at a stabilized speed, is subjected to transverse acceleration of 1m/s2.

$Dr = (\delta 2 - \delta 1) / \gamma t$

If the axle drift is due only to the rigidity of the tire drift, the angular dynamic assumes a very simple expression:

$Dr = (M2/D2 - M1/D1)$

Static-Dynamic Balance of a Vehicle Traveling Around a Circle—Vehicle Attitude with Respect to Trajectory

Let us assume the vehicle is running at a stabilized speed around the circle. If the rear axle does not drift, the attitude of the vehicle on its trajectory would be in conformity with the following diagram. The center of the circle on which the vehicle is moving would be exactly in line with the rear axle. From the trace obtained, it also becomes obvious that it is essential the inner wheel turns more during turning than the outer wheel.

Because the tires drift, the attitude of the turning vehicle will conform with the following diagram. The projection from the center of the circle is now ahead of the rear axle.

Behavior of a Vehicle When the Foot Is Lifted

Static-Dynamic Approach

Let us assume the car is moving at a steady rate over a circle with radius R. Because the vehicle is understeering, the driver must turn the steering wheel (as equivalent to the road wheel), in the light of the above, through:

$\alpha v = (l/R) + (V \times V/R) \times DR$

$DR = M2/D2 - M1/D1$

Lifting the foot instantaneously results in longitudinal load transfers linked with the deceleration of the car. The drift rigidities of the axle assemblies (which as seen above depend on the vertical load supported by them) will be modified. D2 will decrease; D1 will increase. To remain on the same trajectory, the driver must decrease the angle to which the steering wheel is turned.

Stability Criterion

As a stability criterion for the car when the foot is lifted, we shall select the difference of the angle on the

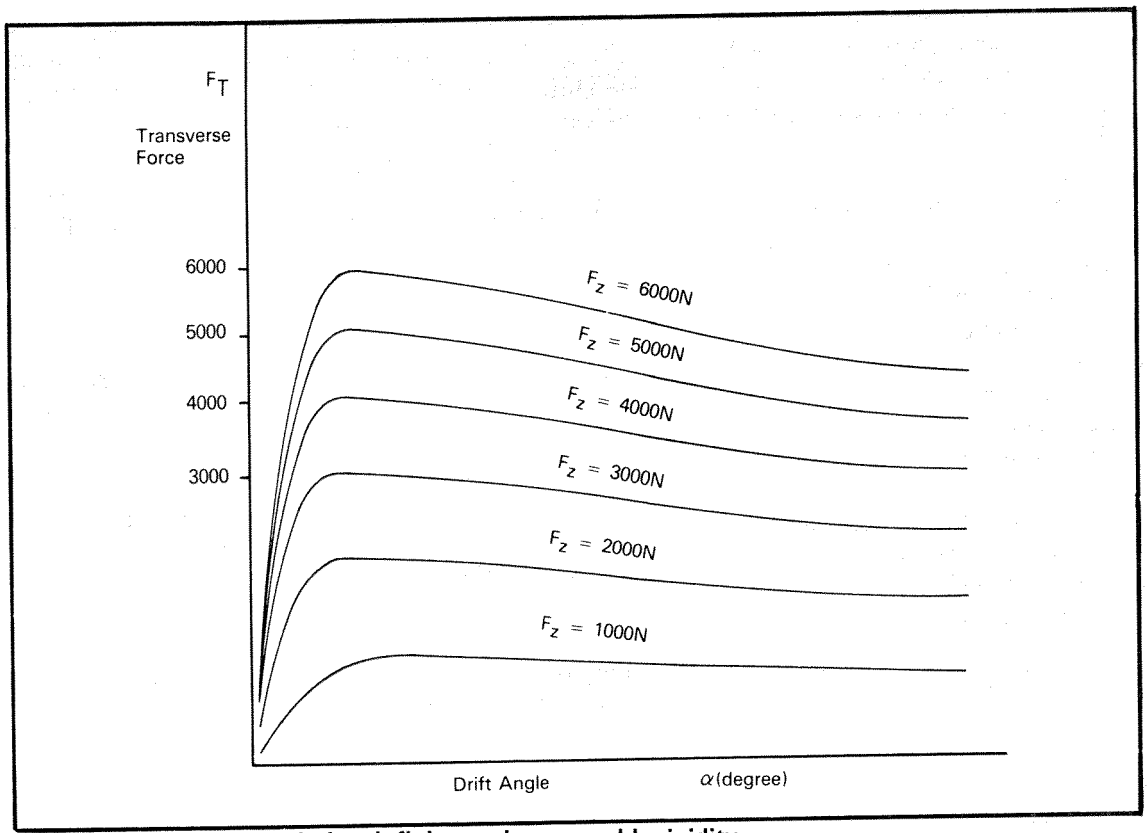

Figure 1. Vehicle on circle, infinite axle assemble rigidity

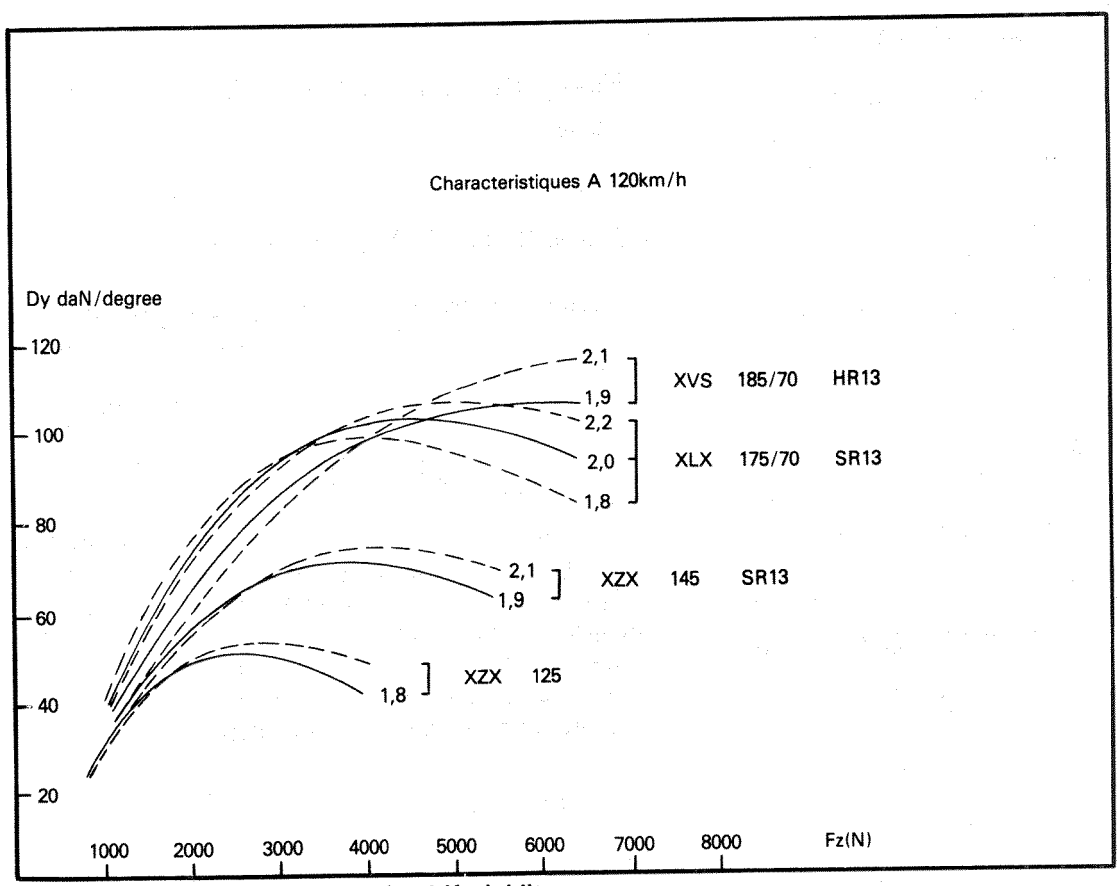

Figure 2. Vehicle on circle, low tire drift rigidity

steering wheel as required by the driver to keep to the same trajectory: the lesser the angle, the more the vehicle will be stable.

The calculation results are presented differently; in reality, we are comparing the two static-dynamic attitudes of the car before the foot is lifted and after it is lifted.

Vehicle without adjustment of running gear.

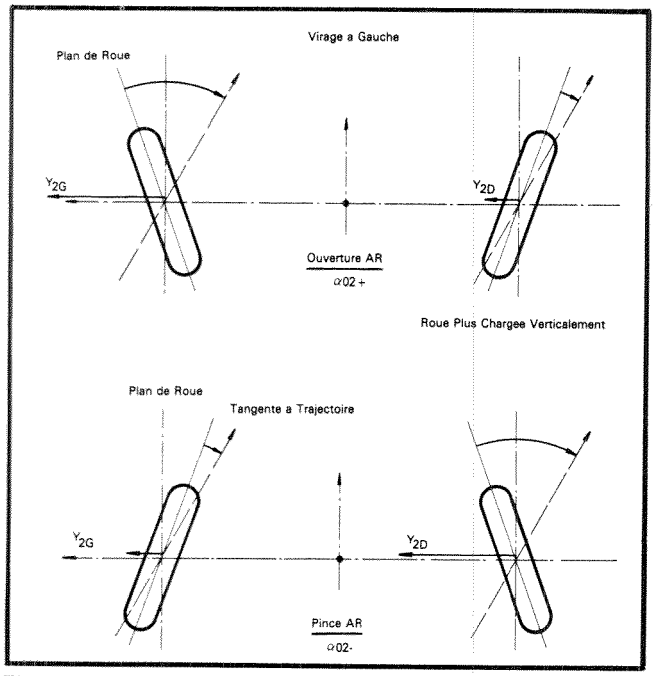

Figure 3. Two static-dynamic attitudes before and after lifting the foot (tire effect only)

Adjustment of Induced Steering Angle

If the drift rigidity of the axle assembly depends only on the tire, the automobile manufacturer would be unable to improve matters. If, effectively, the drift rigidity of the axle assembly is basically caused by the tires, the variation of the drift rigidity of a tire can be counterbalanced by a purely kinematic modification of wheel-steering angles.

We have a measuring system with which we can evaluate the steering angle of a vehicle's wheels under different stresses. On this apparatus, it is possible to impose a roll angle on the vehicle. It has been found the plane of the wheel turns in proportion to the roll angle assumed by the car.

For a given car attitude, the induced steering angles are a linear function of the roll angle. This leads to the notion of steering angles induced by roll:

eps = αir(z) / ϑ
αir : wheel steering angle
eps : induced steering coefficient
ϑ : vehicle roll (γt = λm/s^2)
z : vehicle trim

The coefficient eps depends on the car trim. The induced steering angles modify the under-steering behavior of the car. Therefore, it is normal they appear in the angular-dynamic formula:

DR = M2 / D2 - M1 / D1 + (eps2 - epsl) × ϑ

epsl: steering angle induced at front wheels
eps2: steering angle induced at rear wheels

taking into account that the sign conventions for the under-steering angles are negative at the front but positive at the rear. Controlling the wheel steering angles induced by vehicle roll forms part of the axle specifications.

Let us consider how they can be used to improve the behavior of the vehicle.

The order of magnitude if the desirable variation of the induced steering angles is not compatible with the customary kinematics of the running gear.

Therefore, we shall use another phenomenon to improve the vehicle.

Adjustment of Toe-In or Toe-Out of Axle Assembly

If we consult the technical specifications of manufacturers relative to adjusting the alignment of axle assembly, we will come to the surprising conclusion that perfect alignment is never sought after.

example of R9: 10ft toe-out at the front
30ft toe-in at the rear

As a general rule, vehicles are adjusted with toe-out at the front and toe-in at the rear.

Let us consider axle assembly adjusted with toe-in. When the car runs in a straight line, the tires drift by an angle equal to the toe-in imposed on the axle assembly and therefore develop substantial internal forces of up to 300N for a 30min wheel toe-in.

When a car rolls, the transverse forces on the ground are picked up by each wheel of the axle assembly in proportion to the rigidity of the drift of each tire. Increasing the toe-in of axle assembly is, in fact, equivalent to increasing the transverse force picked up by the outer wheel that is most heavily loaded, i.e., the wheel of the axle assembly with the greatest drift rigidity. Accordingly, the drift rigidity of the axle assembly can be increased by changing its adjustment toward a toe-in (if the axle assembly is adjusted for toe-out, then the rigidity will drop).

Adjustment of Anti-Roll Distribution

The choice of the anti-roll distribution governs the distribution of the transverse loads transfers between the front and rear running gear of the vehicle when it begins to roll. If the drift rigidity of the tire were proportional to

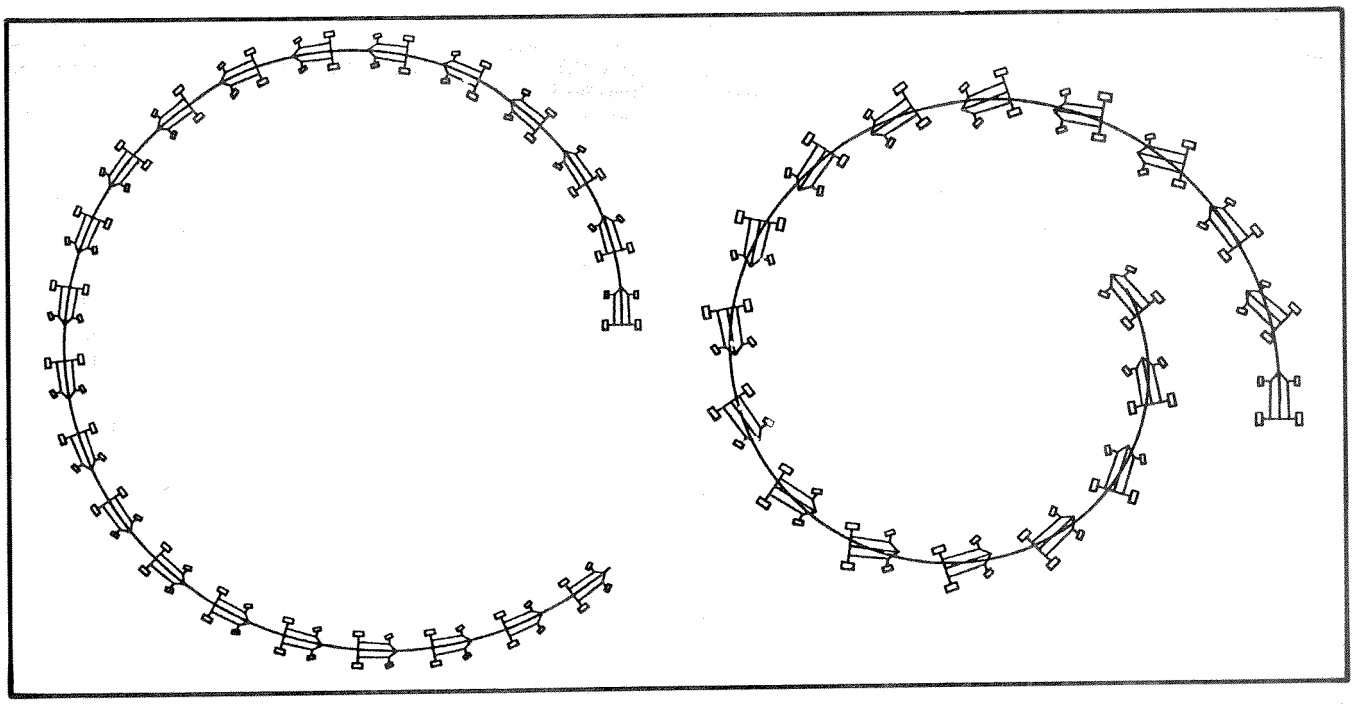

Figure 4.

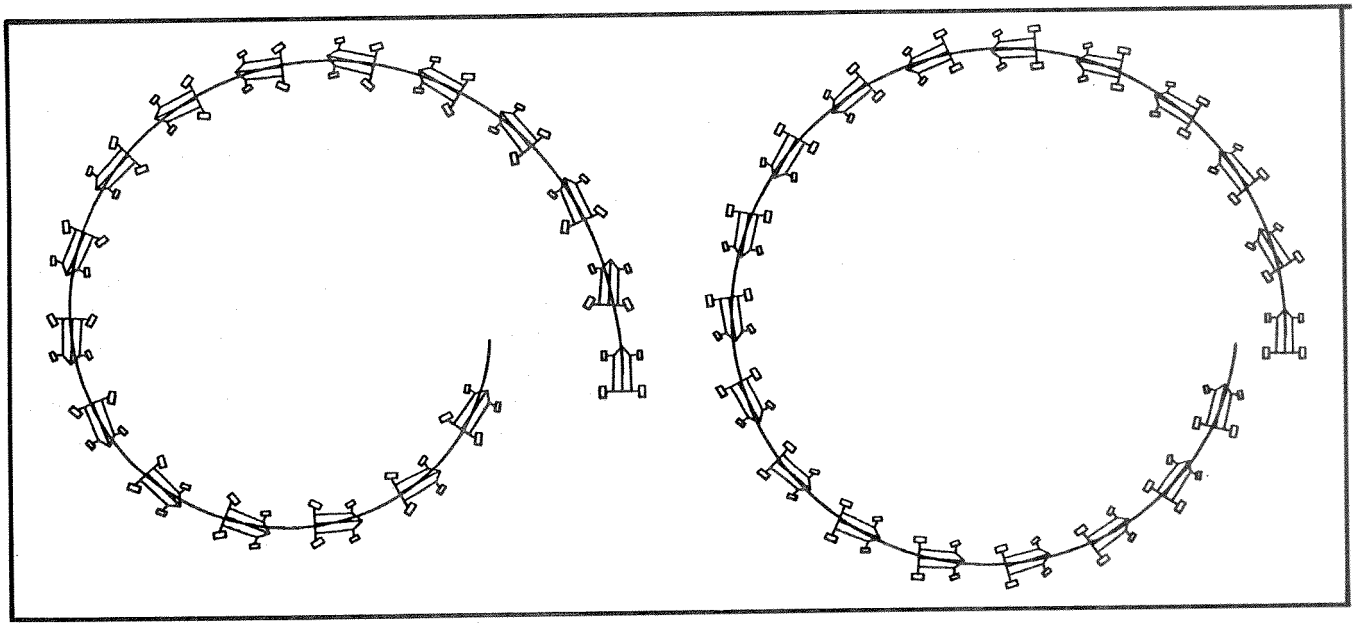

Figure 5. Internal forces for toe-in.

the vertical load it bears, the anti-roll distribution would have no effect on the behavior of the vehicle. Quite contrary to the implicit hypothesis put forward above, the tire reaches saturation point and its drift rigidity no longer increases with the load. This is understandable if we consider that the maximum transverse force with which, a tire can cope is necessarily limited by the ground adhesion coefficient.

To understand this phenomenon, one must be able to understand the operation of the tires. In the following, we give the results of tire measurement tests:

- Evolution of transverse force as a function of the drift angle
- Evolution of drift rigidity as a function of load
- Evolution of longitudinal force as a function of pseudo-slippage

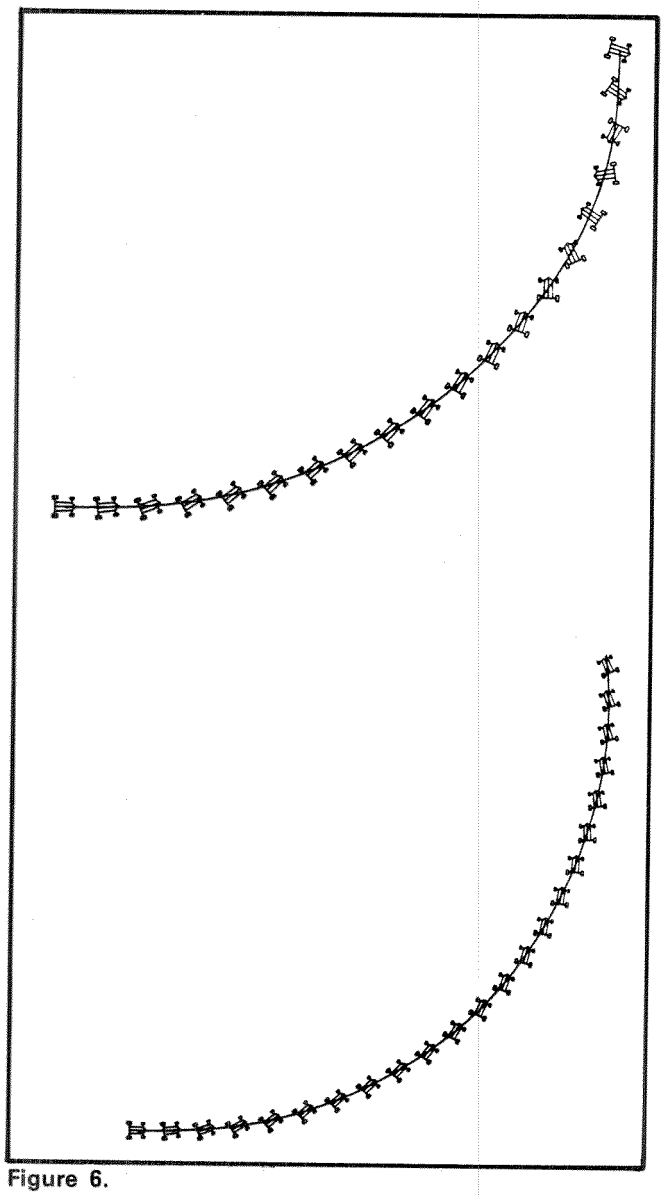

Figure 6.

- Evolution of transverse force at a given drift angle and as a function of the longitudinal force (motor power)

Taking account of the complexity of the tire's working mode, Regie Renault has developed a model of tire behavior under force (work of Mr. Ratti) which has been integrated in a simulation model of a vehicle's transitory state behavior. The results obtained with this model are presented below. The model enabled us to validate the static-dynamic approach for the improvement of behavior on lifting the foot in a car by working on—

- The analysis of the axle assembly
- The toe-in or toe-out
- The anti-roll distribution

Analysis of the Vehicle Behavior Model

Description of Model

The model takes six objects into account—the body, the four wheels, and the steering wheel.

The transverse and longitudinal Brouilhet effects are taken into account in a simplified manner: roll axis and pitch axis. The analysis of the axle assembly, including the variations of toe-in or toe-out, the steering angle variations induced as a function of the load, are incorporated in the model in the form of tables or figures. The deformation of the axle assembly under force, important phenomena we have not yet gone into, are not left out of account. We are certain they can modify the toe-in or toe-out of the axle assembly.

On the basis of the drift rigidity curves of a real tire, we adjusted the tire model. We verified that the longitudinal force variation curves as a function of pseudo-slippage were realistic, as were the transverse rigidity variation curves as a function of the longitudinal force. We were required to make this choice because we do not have a suitable measuring apparatus, which is rather to be found at a tire manufacturer. On this point, closer collaboration between car manufacturers and tire manufacturers appears essential.

Description of Simulation

The case of driving that we suggest simulating corresponds to that in which a driver is about to negotiate a motorway exit road at too high a speed, incompatible for him with the curve radius of the exit way. The speed is not excessive, but the transverse accelerations are substantial. The engine braking will generate deceleration of approximately 0.3g(3m/s2). The results of simulation confirm the improvements considered previously.

Numerical Applications

N	:	steering demultiplication ratio
αsa	:	angle on steering wheel (expressed at steering wheel)
l	:	wheel-base
γtb	:	transverse acceleration before lifting the foot
γ	:	transverse acceleration after lifting the foot

D1b : front tire drift rigidity before lifting the foot

D1a : front tire drift rigidity after lifting the foot

eps1 : steering angle induced at front wheels after (0. before)

eps2 : steering angle induced at rear wheels after (0. before)

ϑ : vehicle roll

$\alpha 01$: toe-out after at front wheels $(01 < 0)$ (rd)

$\alpha 02$: toe-in after at rear wheels $(02 > 0)$(rd)

$$\alpha sb = (1 / r + (M2 / D2b - M1 / D1b) \times \gamma tb) \times N$$
$$\alpha sa = (1 / r + (M2 / D2a - M1 / D1a) \times \gamma tb + (eps2\text{-}eps1) \times \vartheta) \times N$$

1 Vehicle Without Adjustment

D1b= 75500 N/rd
D2b= 71600 n/rd
γtb = 8.2 m/s2

D1a = 83700 N/rd
D2a = 60770 n/rd

n = 20 M1 = 549 kg M2 = 396 kg

$\alpha sb - \alpha sa$ = -16 degree

2 Vehicle With Induced Steering Angles

$\alpha sb = \alpha sa$ eps2 - eps1 = -0.12

3 Vehicle With Adjustment Of Front Toe-out, Rear Toe-in

D1b = 75500 D1a = 83700 + 1120000 × 01
D2b = 71600 D2a = 60700 + 1478000 × 02
(approximated formula)

$\alpha sb = \alpha sa$ = = > $\alpha 01 = 0.$ $\alpha 02$ = 0.023 rd
. or $\alpha 01$ = -0.018 $\alpha 02$ = 0.

Conclusion

If the simulations we have demonstrated convince you of the interest that Regie Renault has in improving the safety of the cars we put on the market, we have achieved our goal. If we believe that we can correctly control the technical factors playing a part therein, we do consider that designers are unfortunately deprived of the same latitude as computing engineers in varying the constructive parameters of the car. If we have been able to boast the advantages of a certain modification to improve the behavior when the foot is lifted, we have sometimes deliberately said nothing about the induced negative effects. Finally, everything is a question of a compromise, competition between manufacturers is severe, and the technical qualities of vehicles are improving. Let us hope safety is also improved in the process.

An Instrument To Measure Scattered Light due to Windshield Wear

Alwin Timmermann
Forschungsgemeinschaft Auto-Sicht-Sicherheit

Abstract

An instrument is described that permits the measurement of scattered light on windshields in cars in full daylight. It presents the intensities of the scattered light in the form of a diagram and calculates two indices, which can be associated with the most prominent types of wear, i.e., impact of small stones and wiper damage.

The instrument is easy to operate and permits inspection of a large number of windshields in a short time. Measurements on 300 vehicles indicate a linear increase in wear due to impact of small stones with mileage and a more-than-linear increase of wiper damage. Vehicles of identical mileage can have very different values depending on the type of use.

It is also examined how the different amounts of wear as characterized by the measured indices affect the ability of test persons to see and recognize objects on the road.

Introduction

As clear vision is of prime importance for safe driving, automobile windshields and motorcycle visors have to be of good optical quality. This is taken into account by high standards for official approval.

In actual use, both windshields and visors are exposed to the impact of small particles of sand and dust as well as the abrasive effects of cleaning efforts and scratching by fine grains that are moved over the surface by windshield wiper action.

In the case of visors, the surface will wear rather quickly. The worn surface scatters the light and may impair vision considerably (Figure 1). Motorcyclists are advised to replace their visors at reasonable intervals.

Automobile windshields, although more resistant owing to the higher hardness of glass, are nonetheless subject to wear. Figure 2 shows the typical damage in a windshield at 80,000km: The surface contains a multitude of small craters (about 180cm^2). The band of bright light is due to scattering from (locally) parallel grooves (with a statistical distribution of depths and distances) produced by the windshield wiper. These grooves extend over the entire area of the photographed glass sample. They scatter light in a direction perpendicular to them and add one or two "tails" to each light source. The tails move according to the relative position of light source, observer (or camera objective, respectively), and the direction of the grooves. Light scattered by the small craters, on the other hand,

Figure 1. Dazzling due to light scatter by a worn motorcycle visor

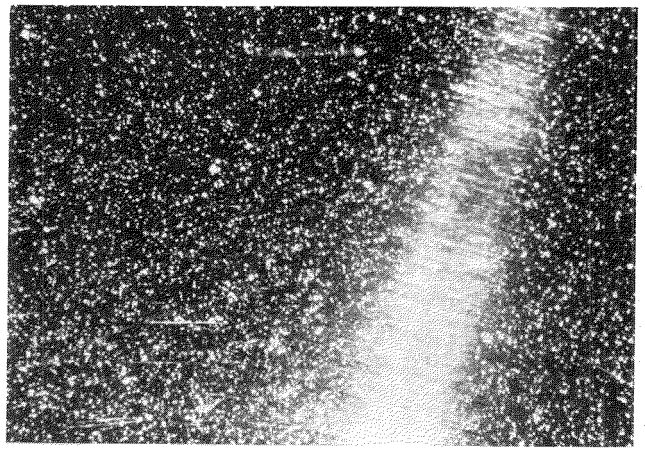

Figure 2. Surface wear on a windshield at 80,000km

appears to the observer who has his eyes accommodated to infinity, as a halo around the light source. Only few and partly contradictory data are available regarding the extent of surface damage as a function of mileage.

A recently developed instrument quantitatively measures the light scattered by surface damage while the windshield is in the car. This, for the first time, provides the capability to collect larger amounts of data. Typical values of scattering data derived from these measurements can then be correlated with the reduction in visual perception of individuals to determine the effects of worn windshields on the safety of road traffic.

Measurement of Scattered Light on Windshields in Cars

Light incident on a windshield is partially deviated from its original direction by scattering from damaged

areas of its surface (as well as films of dirt and grease). This light is called "stray light," while the portion of light transmitted without disturbance is called "useful light" (Figure 3). To characterize the scattering power, it is reasonable to take the ratio of stray light to useful light.

The human eye cannot relate the scattered light to the object from which the light originally came. The inhomogeneities of the surface appear as light sources of their own, the luminance of which is a measure for the intensity of the stray light. Divided by the intensity of the useful light, this gives us the so-called reduced luminance coefficient. Its unit is the candela per square meter and lux ($cd*m^{-2}*1x^{-1}$).

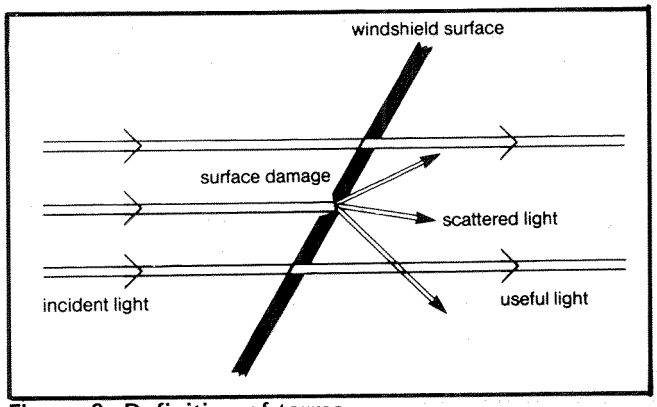

Figure 3. Definition of terms

The intensity of the stray light will depend, of course, on the scattering angle ϑ(Figure 4). Hence, values of the reduced luminance coefficient cannot be compared unless measured at the same angle. However, measurements show that the typical surface damage leads to intensities that decrease monotonously with increasing scattering angles. It seems, therefore, sufficient to restrict the measurement of stray light to a limited range of angles. The instrument is designed to utilize the angular interval from 1.5.° to 2.0° as proposed in DIN standard 4646 for the measurement of the reduced luminance coefficient.

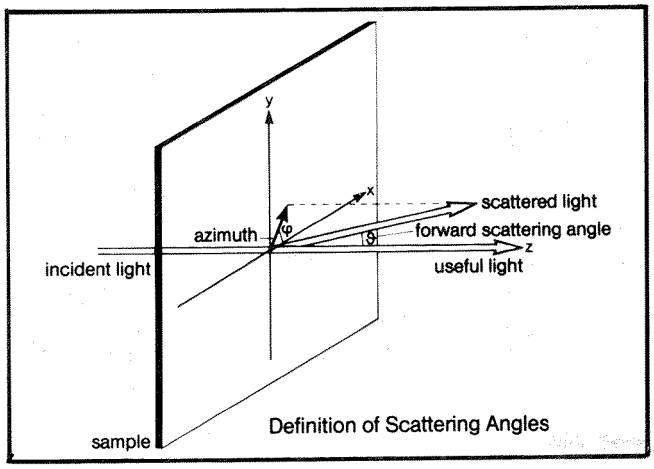

Figure 4. Definition of scattering angles

This angular interval is important for the glare while driving at night. The headlight next to the center of the road of an oncoming car 60m away and 1m lateral distance will appear at an angle of about 1.75° relative to the forward direction.

Another reason for the selection of the angular interval is that the intensity of the scattered light normally drops off rather drastically with increasing angles. The selected interval offers the advantage of higher intensities and, consequently, faster operation and higher precision. The restriction to a specified interval is necessary and sufficient to characterize the scattering power. We present our measurements taken at the interval of 1.5° to 2.0° as index values, namely as scattered light index (S.L.I.) rather than as candelas per square meter and lux.

It is desirable that the instrument discriminates between the types of windshield damage. In particular, wiper damage causes scattered light to appear as streaks that occur only in certain azimuths. Thus, a resolution of the azimuthal angle φ is required. The actual instrument based on these design considerations is shown in Figure 5 (schematic diagram) and Figure 6 (field use). A parallel light beam of 3.5cm diameter is incident on the windshield.

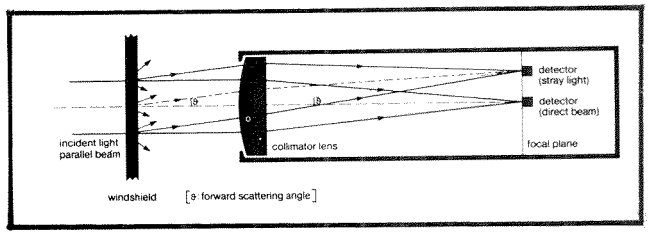

Figure 5. Schematic of the stray light measuring device

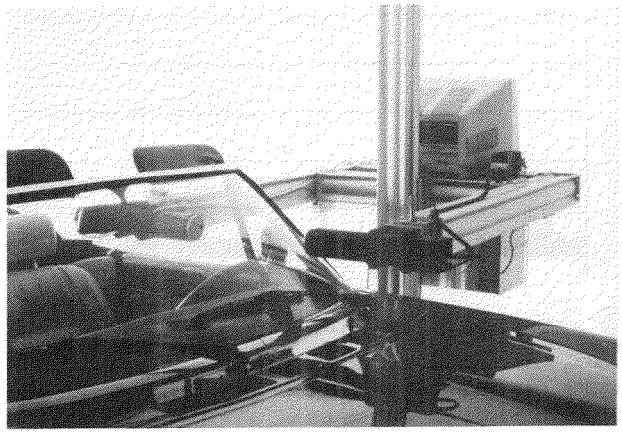

Figure 6. Instrument to measure stray-light indices on installed windshields

A collimator lens focuses the unscattered light onto a point where it is measured by a detector. The light scattered into the angle of 1.5° to 2.0° is imaged as a ring onto the focal plane. A second detector measures the scattered intensity in 250 discrete intervals, which is

equivalent to an azimuthal resolution of approximately 1.5°. The present version of the instrument takes approximately 7s for a complete measurement and automatically corrects for possible scattering within the instrument itself that may be caused by dust particles on the lenses. The S.L.I. is plotted as a function of azimuthal angle φ. Figures 7a-c show S. L. diagrams of three different samples. It can be seen that the same S.L.I., may be due to totally different azimuthal distributions.

Figure 7a shows the S.L. diagram of a glass plate damaged by dropping sand on it. The measurement was performed with the incident light perpendicular to the plate.

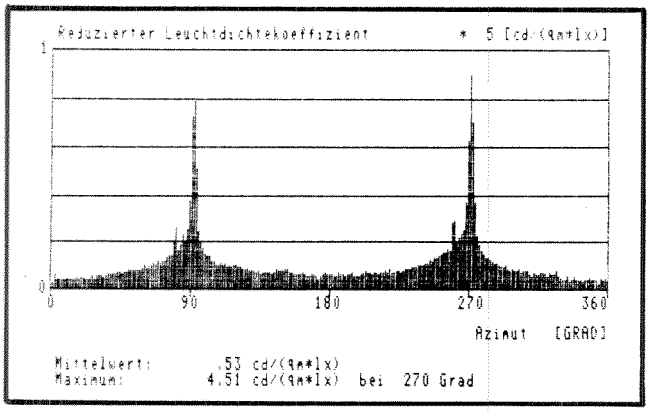

Figure 7a. Stray light diagram of a glass plate damaged by sandblast test

Figure 7b shows the S.L. diagram of a windshield after extended road use. Most of the scattered intensity is due to fine craters in the glass surface.

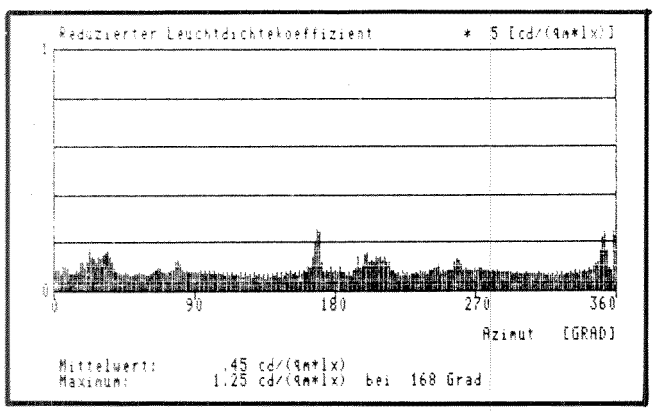

Figure 7b. Stray light diagram of a windshield after extended road use

Figure 7c shows the S.L. diagram of a windshield with damage due to wiper action. The light scattered by the resulting grooves is restricted to a narrow azimuthal range and appears as a narrow peak in the diagram.

The instrument permits the measurement of the S.L.I. while the windshield is part of the car and evaluates the scattering in the same direction in which the driver views the road.

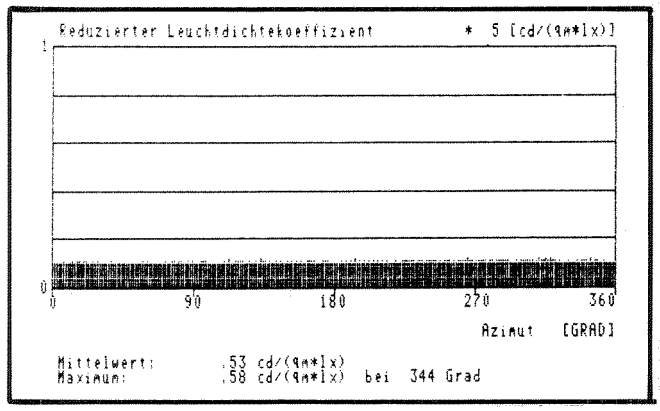

Figure 7c. Stray light diagram of a windshield with wiper damage

The geometry of the arrangement and the principle of measurement make the process of measurement insensitive to a parallel shift of the beam caused by the inclination of the windshield, which eliminates the necessity of adjusting the instrument for the measurement of windshields of varying angles of inclination. Light sources and detector systems are permanently adjusted. An electromechanical lift fits the system to the various levels of windshield position in different cars. Handling of the instrument is easy enough to be used by nontechnical personnel.

Results of Field Tests

A first set of data was obtained from 250 cars at the motor vehicle inspection station in Cologne. In the beginning, measurements were taken at various points in the main field of vision. It was found, however, that the area halfway above the steering wheel was representative of other areas, too, and measurements were subsequently restricted to this primary area. (The test was made on a voluntary basis; drivers should not be overly delayed.) The measured mean S.L.I. values as a function of mileage are presented in Figure 8, the peak values in Figure 9. For both parameters, one observes an increase with mileage as might be expected. There also is a wide variation of values, which will be discussed below.

If one tries to find a mathematical relationship between wear and mileage, one notes that the relationship is not linear in either the mean or the peak values. The peak values in particular (which are caused by scratches from the wiper blades) increase more than linearly with mileage. As peak values on averaging also enter into the mean values, this subsequently causes a nonlinear relationship of the mean values with mileage. The observed relationships can best be explained by making the following assumptions:

1. Damage to the surface of the glass by impact of stones, as an average over all vehicles, increases linearly with mileage.

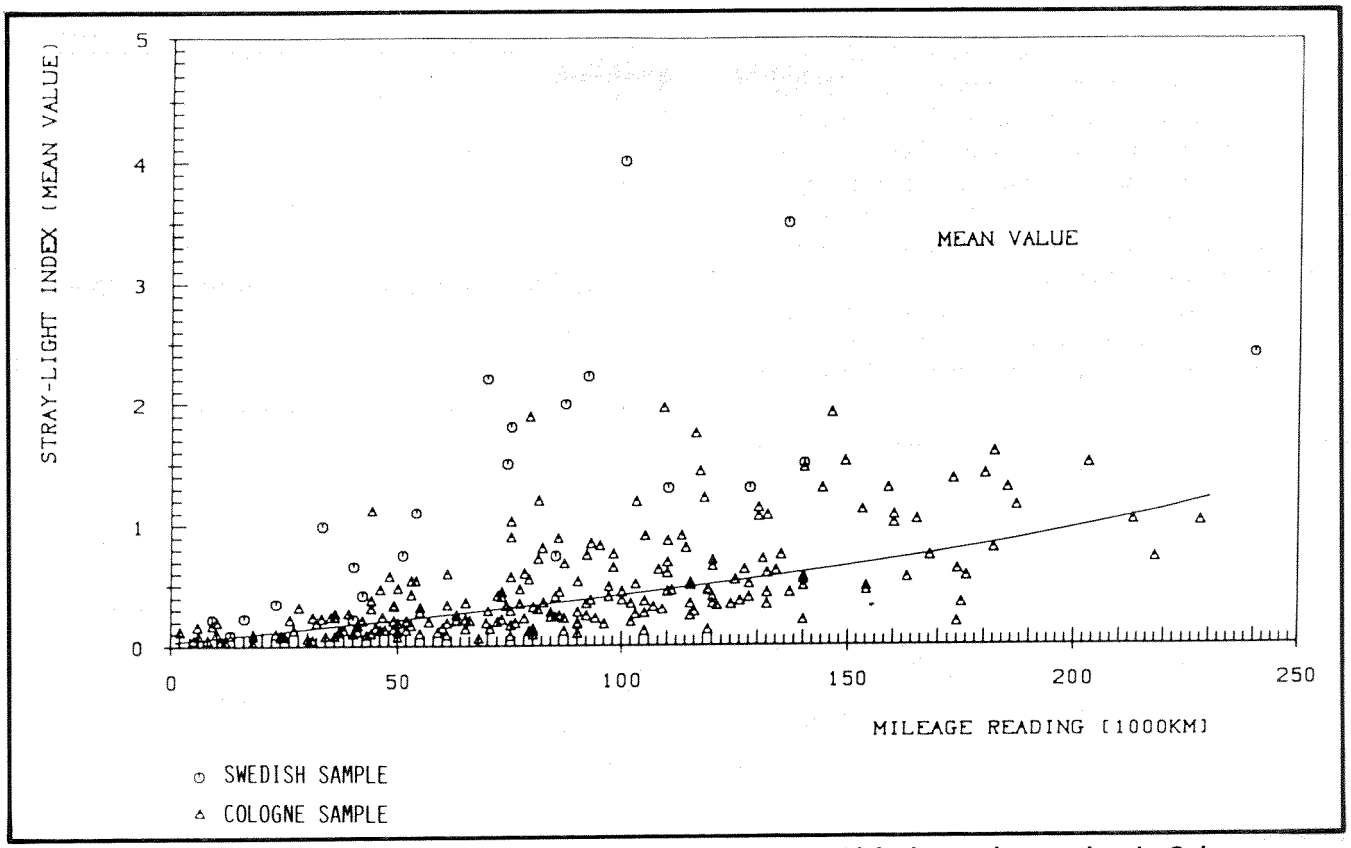

Figure 8. Distribution of mean S.L.I. values as measured at the motor vehicle inspection station in Cologne

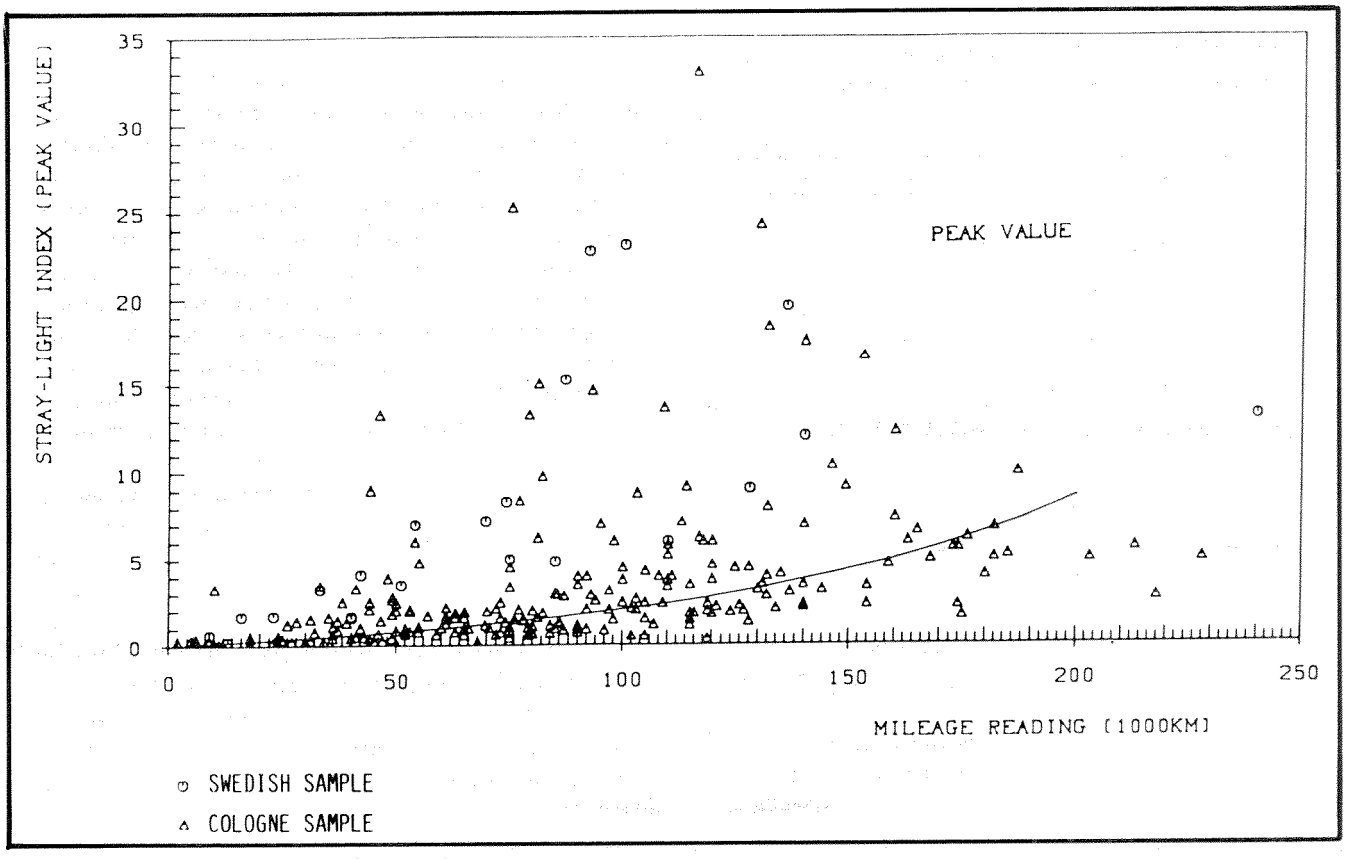

Figure 9. Distribution of peak S.L.I. values

2. An increase in wiper damage depends on the amount of previous damage already suffered at that point. The relationship between peak value and mileage would consequently be exponential.

The respective mathematical relationships in Figures 8 and 9 are represented by solid curves. Each point on the curve is chosen so that, for this particular mileage interval, half of the experimental points (Cologne sample) are above and half below.

In addition to the 250 cars from the Cologne area, a number of windshields were tested that came from other areas. Especially interesting are 25 samples from Sweden, which, at the same mileage, show three to five times higher values compared to the samples from Cologne. (The values of the Swedish samples are marked as open circles.) Such regional differences might be expected due to different road and weather conditions. To obtain a complete picture of how windshield wear affects safety, measurements will have to be made for different geographical regions.

In addition to regional influences, there is an effect on peak S.L.I. values by the amount of car care by the owner of the vehicle. It was also found that windshields of cars parked in the streets often had higher S.L.I. values than garaged cars. It is suspected that particles that collect on the windshields, and especially on the edges of the wiper blades, act as an abrasive. Dust and dirt will preferably collect in the corner between glass and wiper blade and will adhere to the glass and blade when wet. When it begins to rain and wipers are activated, abrasive material will be moved over the glass until the layers of dirt are dissolved or rinsed off. Possible remedies are covering the wiper while in the off-position and installing a ridge on the glass immediately above the off-position so that at least part of the dust and dirt particles are removed from the wiper blade.

Correlation of Measured S.L.I. Values With Loss of Perception

It is important to correlate measured values of the S.L.I. with the actual loss of perception by the individual, which will be most prominent while driving at night.

Craters caused by the impact of sand and dust particles will produce a halo around a source of light. This causes the intensity of the haze near the light source to increase, reduces contrast, and may change the state of adaptation of the eye.

Scattered light due to windshield wiper grooves appears as a "tail," which keeps changing in direction as light source, vehicle, and eye move relative to each other. This adds an additional dynamic component to the process of perception. While the psychophysiological effect of this component is not well-understood, it is nonetheless the one that causes the majority of complaints by drivers.

Light scattered by individual deep scratches and craters of 0.5 to 1.5m contribute little to the S.L.I. and reduction in contrast. However, as the relative position of the light source moves, these defects will light up suddenly and for a short time. It is this dynamic property that is most irritating to the driver and can reduce his power of concentration and his alertness.

We have made a number of tests to determine which minimum S.L.I. value will cause a noticeable reduction in the power of perception in the laboratory. Our best results were obtained by measuring the times of readaptation after dazzling and the distances at which objects are recognized using a road simulator.

Measurement of Readaptation Times Using a Mesoptometer

A standard instrument to measure the mesopic power of vision (Mesoptometer II) was used to measure the readaptation times after dazzling. It turns out these are quite sensitive to the amount of scattered light. The experimental setup is such that the test person is dazzled for 10s by a light source positioned 2° away from a given point of fixation. The object is a Landolt ring. The task is to recognize the position of the opening in the Landolt ring in the shortest possible time after the dazzling light source is switched off.

Readaptation times measured with new windshields were compared to those with used windshields of a mean average S.L.I. of 1.1. All of the 13 test persons of all age groups showed an increase in readaptation times of 6.9 to 7.9 percent. Table 1 gives the average readaptation times t_1 (new shield) and t_2 (worn shield).

It is interesting to note that among the total of 13, there are 9 cases in which the data for the worn windshield have a larger standard deviation than those with a new shield. The increase in deviation of the measured readaptation times indicates that the test person makes a stronger effort to concentrate but cannot maintain a constant level of perception. Statements of the individuals after the test confirm this impression. This means that worn windshields are a source of danger not only through an increased readaptation time, but that additional dangers may arise from an accelerated reduction in concentration.

Measurement of Detection Distances Using Simulated Road Conditions

Another series of tests to determine the influences of worn windshields in 20 subjects was made with a glare source permanently switched on. The intensity of the light was equivalent to the low beam of an approaching car. The road was simulated by a conveyer belt that

Table 1.

Testperson		Readaptation Time		Difference	Difference (%)	Signifi-cance
Sex / Age		t_1	t_2	$t_2 - t_1$	$(t_2 - t_1)/t_1$	
m	17	1.59 +/- 0.09	2.58 +/- 0.19	1.26	79%	h.s.
f	26	2.62 +/- 0.09	3.25 +/- 0.16	0.63	24%	h.s.
m	26	2.04 +/- 0.08	2.28 +/- 0.11	0.24	12%	n.s.
m	26	2.07 +/- 0.10	2.53 +/- 0.08	0.46	22%	s.
f	27	1.43 +/- 0.05	1.62 +/- 0.05	0.19	13%	s.
m	32	1.56 +/- 0.05	1.68 +/- 0.05	0.12	18%	n.s.
m	40	3.58 +/- 0.14	4.54 +/- 0.25	0.96	27%	h.s.
f	43	3.12 +/- 0.16	3.54 +/- 0.17	0.42	13%	n.s.
m	45	2.24 +/- 0.08	3.02 +/- 0.14	0.79	35%	h.s.
m	60	4.59 +/- 0.15	4.91 +/- 0.18	0.32	6.9%	n.s.
m	63	3.06 +/- 0.13	4.57 +/- 0.31	1.51	49%	h.s.
f	64	7.96 +/- 0.41	10.15 +/- 0.65	2.18	27%	s.
m	71	6.89 +/- 0.36	9.31 +/- 0.48	2.42	35%	h.s.

carried objects (cubes 20mm to the side and of low reflecting coefficient) toward the test person. At a scale 1:20, this corresponds to road conditions at night with no street lighting. The test person was told to indicate as soon as he/she believed themselves able to recognize the object. Our results show that a worn shield of S.L.I. value of 1.7 reduces the distance by 7 percent compared to a new shield.

Subjective Criteria

While measurements of S.L.I.'s of windshields were carried out, we also asked drivers as to which degree of wear they considered windshields unsafe for further use. The S.L.I.'s of such shields were between 0.5 and 1.1.

Measurement of a windshield that had been replaced by the owner because it scattered too much light (and not because of fracture) gave a mean index of 0.7 and a peak index of 6.0. These values seem to be an especially reliable indicator, as the exchange represents an expense to the owner and was certainly considered necessary. The observed correlations of measured S.L.I. values with loss of perception are summarized in Table 2.

Table 2. Threshold values for noticeable changes

Parameter	Change worn vs. new	S.L. mean	Index peak
Readaption times	6,9% - 79% prolonged	1,1	(2,8)
Detection Distances	7% shortend	1,7	(5,5)
Subjective judgement	windshield objectionable	>0,6	>4,0

Discussion

The instrument for the measurement of scattered light on windshields in cars that is presented here permits the measurement of scattered light intensities as a function of the azimuth in a fast and reliable manner. This offers the capability to inspect a large number of windshields for damage that can have a detrimental effect on road vision. Difficulties arise in the identification of large individual scratches and craters that may contribute little to the measurements but nonetheless may be irritating to the driver. On the other hand, this type of damage can be detected readily without instrument by mere visual inspection.

Loss of perception based on laboratory tests begins at an S.L.I. of 1.0. Drivers we interviewed considered windshields objectionable at a somewhat lower value of 0.5 to 1.0. It is typical for laboratory tests to result in a higher value for the threshold due to a strong interaction between concentration and physiological ability. This phenomenon is usually taken into account by so-called "field-factors" when experts give their opinions on the possible cause of accidents. Our laboratory tests measure only the correlation between loss of perception and the mean S.L.I.. The threshold peak S.L.I. value (dominated by wiper damage) at which drivers find windshields objectionable is around 5.0.

The correlation of the peak S.L.I. value and loss of perception by laboratory test is somewhat difficult. In contrast to the homogenous distribution of scattered light from craters, the light scattered from wiper damage appears only at certain azimuths, and drivers can easily see past these bright streaks of light.

The actual danger that originates in these streaks lies in the fact that they are moving as the traffic changes. This also makes it difficult to measure their effect in the laboratory. There is a lack of test parameters that can be used to estimate how such dynamic changes affect road safety. The subjective judgment by drivers indicates that the S.L.I. peak values may turn out to be the important parameter for the determination of whether or not a windshield is safe for road use.

The Development of Drowsiness Warning Devices

Keiichiro Yabuta,
Haruhiko Iizuka,
Takayuki Yanagishima,
Yukio Kataoka, and
Tetsuo Seno
Nissan Motor Co., Ltd.

Abstract

This paper describes a newly developed microcomputer-based drowsiness warning system, which detects changes in the driver's alertness through his steering behavior. In developing this system, we first quantified several levels of alertness based on such physiological factors as brain activity and blinking. Tests were then conducted in which drivers fell into different degrees of drowsiness.

Using the quantified alertness levels, we defined the "drowsy driver" and found unique steering patterns that could not be seen in normal driving. These patterns were entered into the memory unit of the microcomputer. When the sensor built into the steering wheel detects a drowsy steering pattern, the microcomputer recognizes the driver's drowsiness and activates a buzzer to warn the driver.

In this paper, the process of determining the alertness levels is explained, along with the steering characteristics of the drowsy driver.

Introduction

The continued construction of freeways in Japan in recent years and the improvement and expansion of road facilities have made it possible for drivers to enjoy pleasant, comfortable motoring. On the other hand, motorists now are more likely to drive under rather monotonous conditions, and there has been an increasing number of traffic accidents that are thought to have been caused by the driver falling asleep at the wheel.

Dozing off at the wheel is a potential danger that could befall anyone when driving under monotonous circumstances. Accidents that occur due to drowsiness, however, often tend to be of a very serious nature.

As a preventive measure against such accidents, various types of drowsiness warning devices have already been proposed by researchers at universities and other research institutions. For the most part, these devices have not been very practical because the detection system has required the attachment of an electrode to the driver's body to detect physiological reactions.

In this research, a practical drowsiness warning device has been developed by focusing on the irregularities that appear in the driver's operation of a vehicle accompanying a drop in alertness.

Prior to analyzing the driving behavior that occurs in a low alertness level, an alertness index was devised for quantifying different alertness levels. This paper will first explain the alertness index, and then the driving characteristics observed under lower alertness levels will be presented, together with a concise outline of the new drowsiness warning device.

Alertness Index

To find the characteristic driving behavior that occurs in a low alertness level, it is necessary to have some method of ascertaining when a driver's alertness level drops. However, research conducted in the field of human engineering has not yet established a method by which levels of human alertness can be grasped quantitatively.

In this study, therefore, it was first necessary to quantify levels of human alertness, and for this purpose an alertness index was formulated.

Formulation of an Alertness Index

Experimental

An experiment was conducted in which the subject's alertness level was lowered through the performance of a monotonous task. The correspondence between the results achieved by the subject during this process and different physiological reactions, including his brain waves and eyeblinking, was examined.

The experimental setup used is illustrated in Figure 1. By means of the steering wheel and the accelerator pedal, the subject controls a pursuit point with which he pursues a circular target that is moving in a circle at a uniform velocity.

Three time cycles, 50s, 20s, and 10s, were used for the circular movement of one revolution of the target circle. Measurements were taken of the subject's brain waves, blinking, facial expression, and degree of error (i.e., distance between the target circle and the pursuit point).

Formulating the Alertness Index

Special attention was focused on the subject's brain waves, blinking, and facial expression because, among the various physiological reactions of a human being, these in particular are known to vary according to the alertness level. An evaluation system was set up cor-

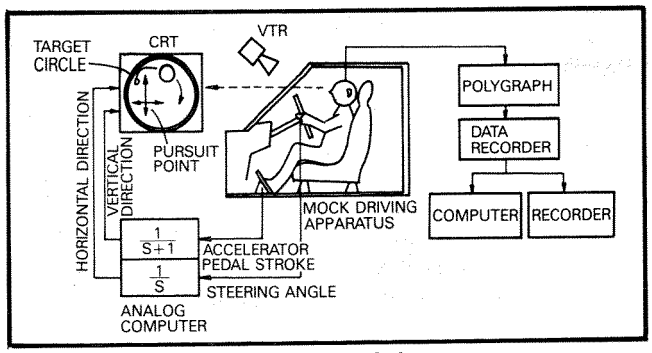

Figure 1. Schematic diagram of the test setup

responding to such variations, and a value from three points to one point was assigned accordingly, ranging from a "wide-awake state" to a "state of fuzzy consciousness just prior to falling asleep." Then, by taking the sum total of the points assigned to these three factors, seven alertness levels were ranked, ranging from "wide-awake" (nine points) to "fuzzy consciousness" (three points). Levels of human alertness were thus quantified by means of this scale (Figures 2 and 3).

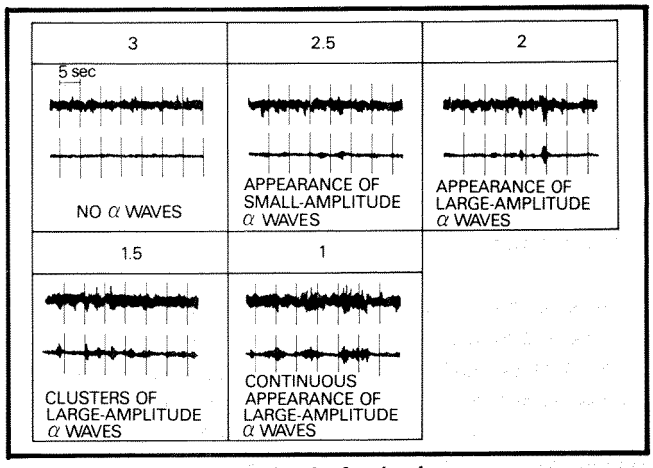

Figure 2. Evaluation criteria for brain waves

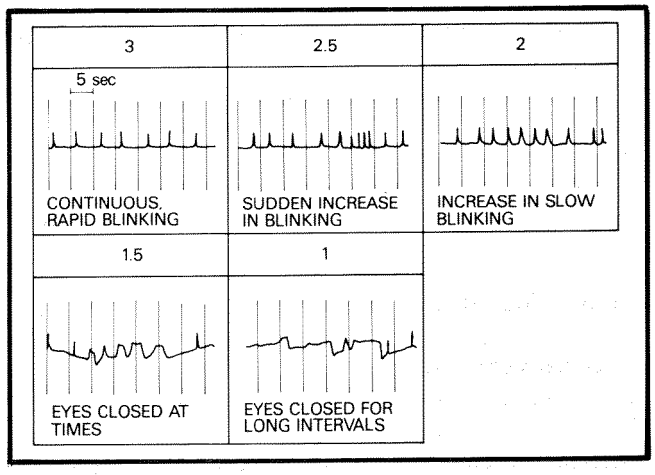

Figure 3. Evaluation criteria for blinking

Correspondence Between Alertness Levels and Control Task Results

The correspondence between the alertness level and the task results (i.e., error) is shown in Figure 4 for varying speeds of the target circle (i.e., different degrees of difficulty). The amount of error represented by the horizontal axis is an index of the off-target distance between the target circle and the pursuit point.

For an easy task (a cycle of 20s or 50s for the movement of the target circle), there is virtually no error when the alertness level is high. However, error quickly becomes conspicuous when the alertness index drops to around 6.5 ~ 6.

For a difficult task (a cycle of 10s), there is some error even if the alertness level is high. With an alertness level of 6 or lower, control becomes completely impossible.

In other words, as the alertness level drops, error increases and a person's control capability deteriorates. This confirms the appropriateness of the alertness index.

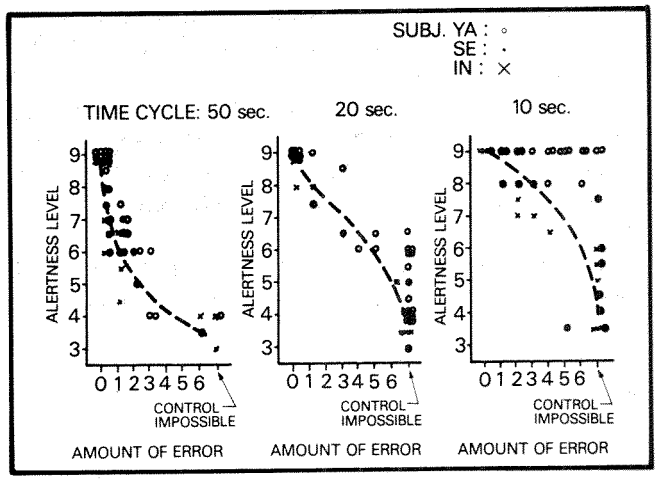

Figure 4. Correspondence between alertness level and error

Alertness Level Requiring a Warning

Using the alertness index described above, alertness levels were investigated for proving ground driving as well as for driving on ordinary roads. It was observed that the driver's alertness index fell from an initial level of 9 at the beginning of the test to between 6 ~ 7.5 after 30min of driving, regardless of whether the driver was conscious of this drop or not (Figure 5).

The relation between the alertness level and the percentage of times the driver realized he was sleepy is shown in Figure 6. The point at which a subject realized he was drowsy varied considerably depending on individual differences. However, with an alertness index of 6, the ratio was about 75 percent. With an alertness index of between 5.5 ~ 5.0, the subject was aware of being drowsy in nearly every case.

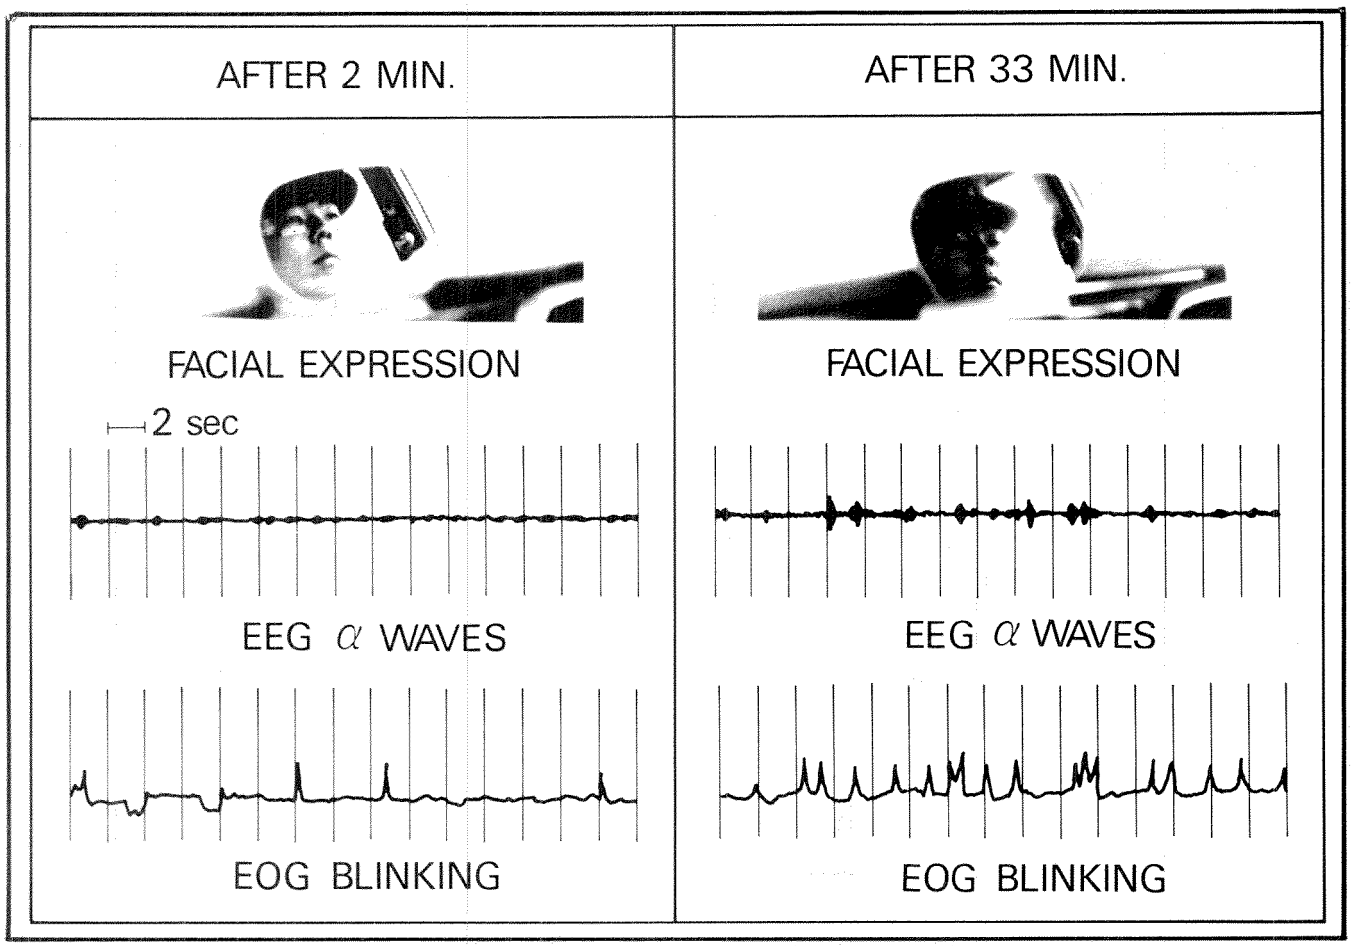

Figure 5. Example of reduced alertness level during driving

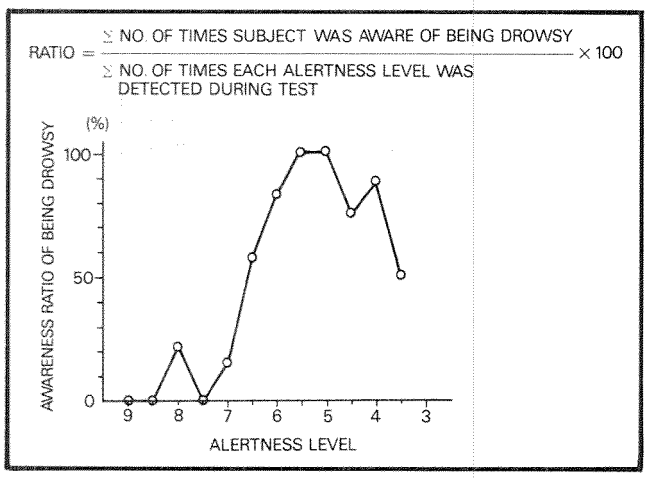

Figure 6. Relation between alertness level and awareness of drowsiness

Driving tests, which will be explained later, were also conducted under a condition of reduced alertness level using both a drive simulator and an actual vehicle. From the results of those tests and the foregoing findings, it was postulated that the alertness level that should be detected as drowsiness at the wheel, and that would not give the driver a feeling of disorientation if a warning were given, was an alertness level of 5 or lower.

The results in Figure 6 also show that for an alertness index below 4.5, the realization of drowsiness does not correlate with the alertness level and is completely unreliable.

Reduced Alertness Level Driving Test Using a Drive Simulator

This test was conducted to investigate whether or not changes would appear in the driver's operation of a vehicle accompanying a drop in alertness level (See Figures 7 and 8).

Test Procedure

The drive simulator was equipped with a color monitor that displayed the road surface, and the subject simulated a driving situation by operating the steering wheel, accelerator pedal, and brake pedal. A state of reduced alertness level was induced and recordings were made of

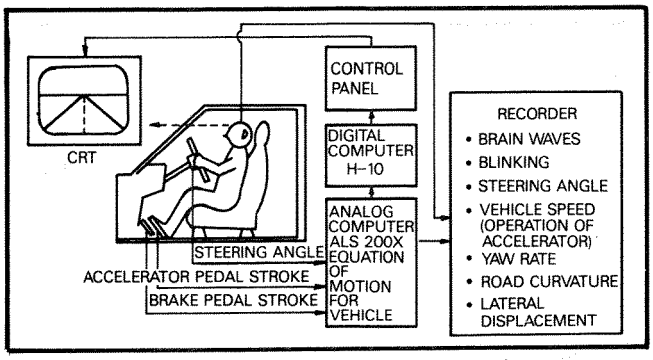

Figure 7. Schematic diagram of drive simulator

Figure 8. Photograph of drive simulator test

the subject's physiological reactions, driving actions, and vehicle behavior. The items recorded included brain waves (EEG), blinking, facial expression, steering angle, accelerator pedal stroke, vehicle speed, and side displacement.

Characteristics of Vehicle Operation Under Reduced Alertness Level

Typical examples of the test data for a wide-awake state and a reduced alertness state are shown in Figure 9.

When the subject was fully alert, he was constantly manipulating the steering wheel and the vehicle ran straight along the center line. However, when the driver's alertness level dropped, he became unable to execute minute movements of the steering wheel. The steering wheel was held stationary temporarily and then turned sharply to the right or left, producing corresponding changes in the forward direction of the vehicle. On the other hand, no substantial change was seen in the operation of the accelerator pedal.

An investigation was also made of the gripping force on the steering wheel and the driver's posture. No significant changes were observed as the driver's alertness level dropped to a state of nearly falling asleep.

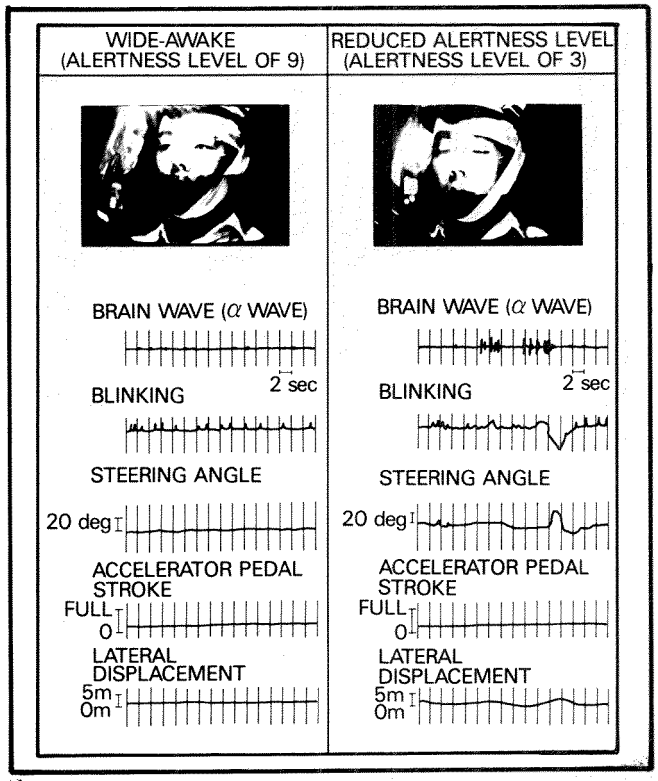

Figure 9. Examples of simulator test data

From the foregoing results, it was concluded that it would be possible to devise a method for detecting drowsiness on the basis of the driver's manipulation of the steering wheel.

Driving Test Using an Actual Vehicle

A specially outfitted test vehicle (Figure 10) was used to investigate whether the same characteristics pattern of steering wheel operation that was seen with the drive simulator would appear in a driving test using an actual vehicle. To assure safe vehicle operation during the test, a steering wheel and brake pedal were installed in the test vehicle on the passenger side. The brake pedal on the passenger side was rigged such that the fuel supply was cut off when it was depressed.

Test Procedure

The subject's alertness level was lowered through constant-speed driving on a proving ground, and a data recorder was employed to record the subject's brain waves and blinking, along with the steering angle. An examination was made of changes in the subject's manipulation of the steering wheel accompanying a drop in alertness level.

With the test vehicle as well, it was found that in a state of reduced alertness level the subject temporarily held the steering wheel stationary and then cut it sharply to the

Figure 10. Test vehicle with dual steering wheels

right or left, thus confirming the same steering pattern that was observed in the simulation test (Figure 11).

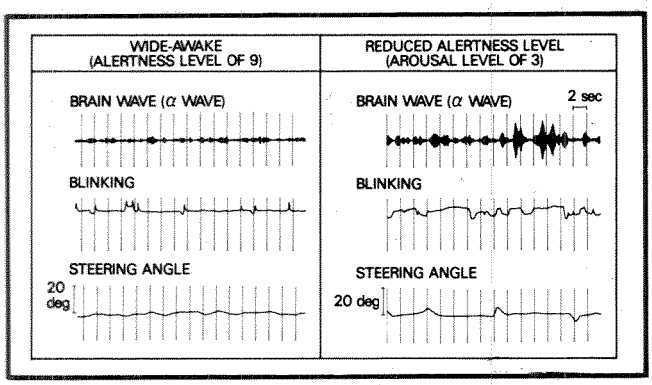

Figure 11. Examples of test driving data under reduced alertness level

Analysis of Steering Wheel Manipulation Data

Since the aforementioned tests revealed that particular characteristics occurred in the manipulating of the steering wheel in a state of reduced alertness level, an exhaustive analysis of the data was done to upgrade the performance of the drowsiness detection logic.

Analysis of Nonsteering Period

An investigation was done to determine if changes occurred in the nonsteering period when the alertness level dropped. Figure 12 shows the distribution of the nonsteering time for a wide-awake state and a reduced alertness state. As this figure indicates, no difference could be seen in the nonsteering time between these two states. It was concluded, therefore, that drowsiness at the wheel could not be detected from the nonsteering time alone.

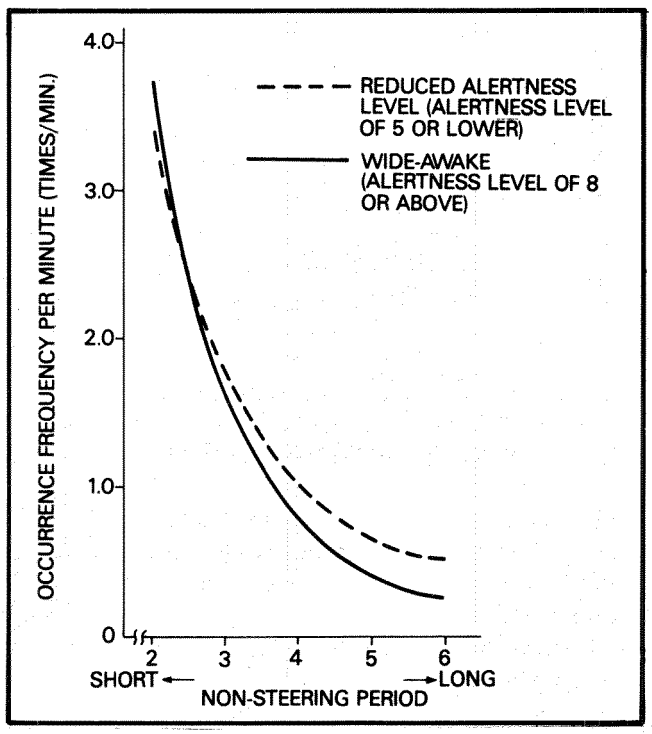

Figure 12. Difference in occurence frequencies of nonsteering period

A Steering Pattern in Which Corrective Steering Continues Following Nonsteering

The distribution of the nonsteering period in a state of reduced alertness level was found to be no different from that for a wide-awake state. However, examination of the data wave-forms revealed there tended to be a continuation of sharp, corrective steering actions following nonsteering that characterized the state of reduced alertness level, and a minute analysis of the data was done to elucidate this pattern.

A typical steering angle wave-form illustrating this characteristic is shown in Figure 13. After nonsteering, the steering wheel is turned in one direction, called the first turn hereinafter, followed by a second turn in the opposite direction.

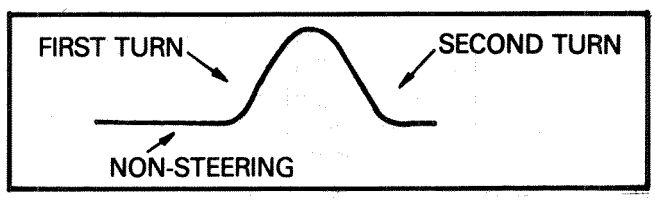

Figure 13. Steering pattern peculiar to a reduced alertness state

Figure 14 shows the occurrence frequencies of this steering pattern when the magnitude and turning speed of the first and second turns were fixed and only the nonsteering time was varied.

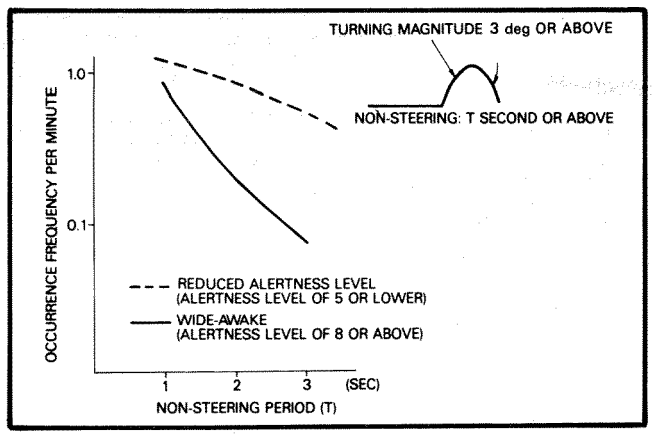

Figure 14. Occurence frequencies of steering pattern for various nonsteering periods

By making the nonsteering time longer, it became easier to distinguish between the wide-awake state and the reduced alertness state because a larger difference appeared in the occurrence frequencies. On the other hand, when the nonsteering period was set longer, the occurrence frequency dropped in the state of reduced alertness level, which indicated the possibility of a deterioration in drowsiness detection accuracy.

Figure 15 shows the occurrence frequencies of the steering pattern when the nonsteering period was fixed and the magnitude of the first and second turns was varied.

By increasing the magnitude of the turns, it became easier to distinguish between the two states, but the occurrence frequency dropped in the state of reduced alertness level. This suggested there would not be sufficient drowsiness detection accuracy.

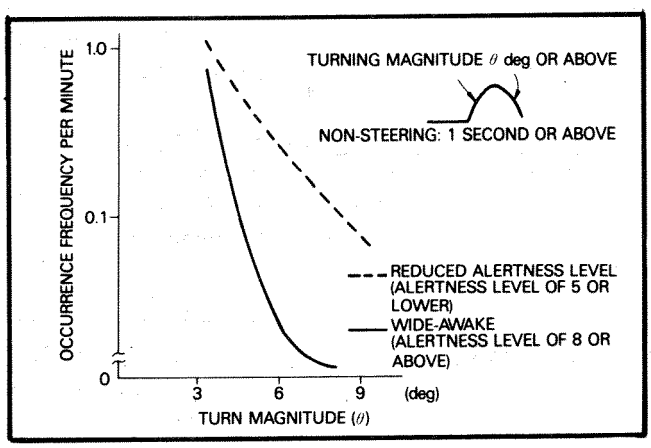

Figure 15. Occurence frequencies of steering pattern for various turn magnitudes

Figure 16 shows the occurrence frequencies when the nonsteering period and the magnitude of the first and second turns were fixed and the turning speed of the first turn was varied.

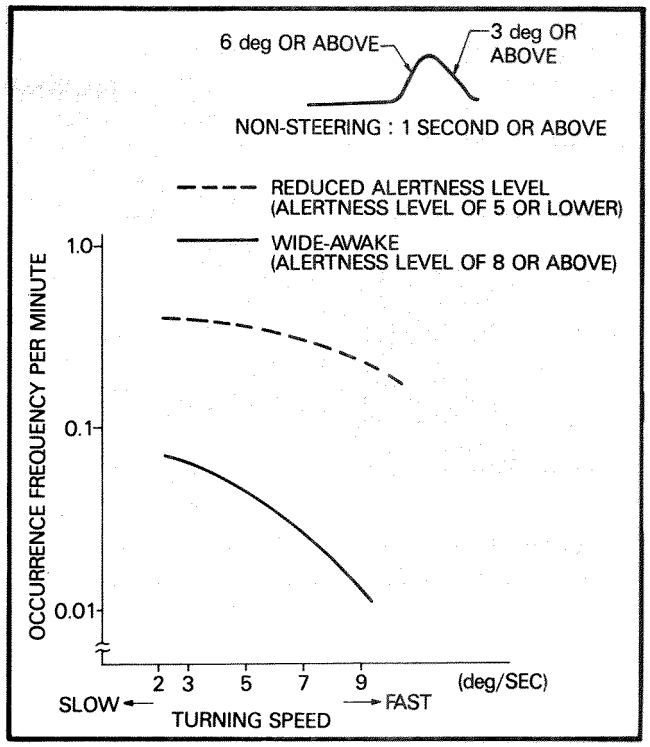

Figure 16. Occurence frequencies of steering pattern for various turning speeds

As the results explained above indicate, it was found that the steering pattern, in which corrective steering actions continue following nonsteering, would almost never appear in the wide-awake state as long as appropriate values were selected for the nonsteering time, the magnitude of the first and second turns, and the turning speed. Since the occurrence frequency in the state of reduced alertness level also became relatively small, the drowsiness detection performance was improved by incorporating multiple steering patterns into the detection logic.

Drowsiness Warning Device

A drowsiness warning device has thus been developed that detects the corrective steering pattern that appears following nonsteering and emits a warning to the driver. The practical utility of the new device has been evaluated in repeated driving tests conducted on public roads and in driving tests done under states of reduced alertness level.

In slow-speed ranges, the manipulation of the steering wheel involves many more patterns than for normal operating speeds. Therefore, to prevent mistaken operation of the warning device when the driver is wide-awake, the logic circuit has been designed so that detection is not performed at speeds below 50km/h. Furthermore, no detection is performed when the turning signals or the brakes are operated as well as during a set period of time following their operation. This precaution has been taken

to prevent the warning device from operating by mistake when a driver changes lanes or maneuvers the vehicle to avoid an obstacle on the road (Figure 17).

The drowsiness detection performance of the device was evaluated on a proving ground using a vehicle equipped with dual steering wheels.

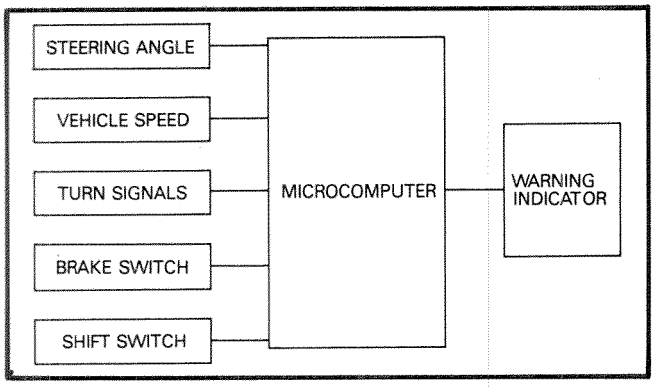

Figure 17. Block diagram of drowsiness warning device

A typical example of the test data is shown in Figure 18. At the start of the test, the driver was in a wide-awake state with an alertness index of 9. After 23min of driving, however, the alertness index had dropped to 3.5. At that point, the device detected drowsiness at the wheel and generated a warning sound that caused the driver to wake up quickly.

Conclusion

As explained in the foregoing sections, a system for quantifying human alertness levels was devised and utilized to find the vehicle operating behavior that typifies a driver in a state of reduced alertness level, particularly the characteristic steering patterns. Based on the data obtained, a practical drowsiness warning device has been developed that does not have to be attached to the driver's body.

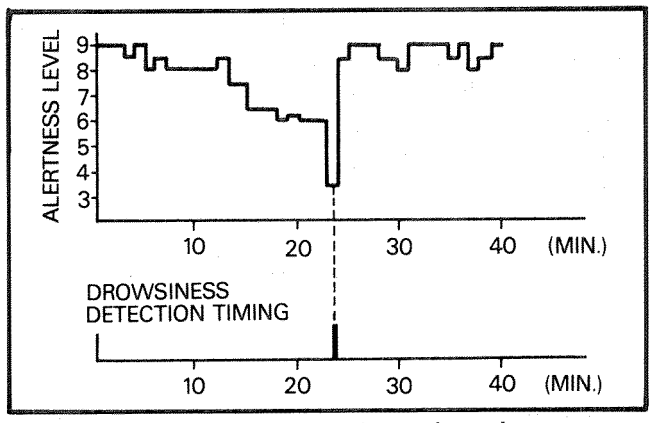

Figure 18. Examples of drowsiness detection

This indirect detection method has now made it possible to detect drowsiness at the wheel in a rather high percentage of cases, though the system is not entirely perfect. Part of the drowsiness detection logic of the new device is already being successfully incorporated into the "Safety Drive Adviser" that is available on Nissan's new Bluebird model.

To assure safety during the operation of a motor vehicle, it is essential that the driver is functioning normally and the vehicle is in proper working condition. Until recently, virtually no safety devices had been developed to check on the normal condition of the driver. It is hoped that research and development efforts in this area will see a great deal of progress in the years ahead.

Tire Pressure Warning System

Yuji Uemura,
Saiichirou Oshita,
Toshihiro Konno,
Toshiyuki Kobuna, and
Yoshihiro Yoshida
Subaru Engineering Division, Fuju Heavy Industries, Ltd.

Abstract

Low tire pressure can have adverse effects on a vehicle, such as abnormal tire wear, increased tire rolling loss, tire burst due to excessive heat generated, poor running stability due to reduced cornering power, and hydro-planing phenomenon.

The purpose of a low tire pressure warning device is to give adequate warning to a driver when tire pressure falls below the specified level, calling attention to the need for countermeasures, such as adding tire pressure or tire repairs. Thus, the equipment is to reduce the adverse effects of low tire pressure, insure safer operation, and achieve better economy.

For this, various warning devices have been developed and reported. The tire pressure warning system presented in this paper was developed to incorporate a user-friendly feature that would tell the driver which of the four wheels has low tire pressure, combined with low system price.

To achieve these targets, a combination of magnet and

Hall effect IC was selected for transmitting change in tire pressure from a rotating and vibrating tire, which also resulted in a simple control circuit.

The main components of the system are a pressure sensor using a magnet, Hall effect IC, control circuit, and alarm section, operating as follows:

- A pressure sensor is mounted on each wheel disc. When pressure falls, the magnet of the pressure sensor, as it rotates, causes a change in the magnetic field it generates.
- Each time the wheel rotates, the magnet moves across the Hall effect IC mounted on a suspension member. The IC then detects the change in the magnetic field and signals the control circuit.
- The control circuit identifies the wheel generating the signal, then operates the alarm to warn the driver.

Introduction

Maintaining proper tire pressure is essential for safe vehicle operation. Running a vehicle with low tire pressure leads to additional running cost such as abnormal tire wear, higher fuel consumption, safety hazards such as tires generating excessive heat with resultant tire burst, lower cornering power and poorer running stability, and likelihood of hydroplaning. According to a sampling survey of general road vehicles, many were found with tire pressure below that recommended of 1.8 to 2.0kgf/cm^2 (176.4 to 196kPa). As many as 12.5 percent had pressure below 1.5kgf/cm^2 (147kPa)(1).

The causes for loss of tire pressure include natural leaks over long periods, punctures, and air leaks due to rim deformation. A sudden air loss is usually sensed quickly by the driver because of a change in vehicle behavior, vibration, etc., but it may take some time to sense any difference with a gradual pressure loss. In front-wheel-drive vehicles whose rear wheel load is small, some drivers may not sense a total loss of air from a rear wheel while driving straight and are startled by the change in vehicle behavior when they attempt to steer. In such cases, warning the driver of tire pressure loss as soon as it occurs is very important for safety.

Run-flat tires that allow driving a certain distance even after pressure loss due to puncture, etc., have been developed. In Japan, their use by vehicles for the physically handicapped and police vehicles was approved in 1981(2).

Currently, such tires are still inferior to ordinary tires in terms of high-speed performance, weight, ride, cost, etc. Even the ordinary user, however, sometimes experiences difficulty or danger when attempting a wheel change to replace a punctured tire because of weather, road conditions, etc. For this reason, further improvement and commercializing run-flat tires is required. However, with this type of tire, tire pressure loss will be even more difficult for the driver to detect, and the need will be greater for an adequate tire pressure warning device.

Various tire pressure warning systems have been patented or reported(3). They can be classified roughly into the following types:

- Systems Mounted on the Wheel—Self-contained systems mounted on the wheel, with no parts installed on the vehicle body itself. There are two types, one that visually indicates tire pressure loss at the wheel center and another that warns of low tire pressure audibly with sound produced by striking the wheel rim or cap, or a spring or electrically driven bell, etc.
- Systems Indirectly Detecting Pressure Loss—Systems that detect tire pressure loss based on change in wheel rolling resistance, rate of slip, vehicle height, tire width, or tire ground contact area.
- Systems Detecting Tire Pressure Loss Mounted on the Wheel and Transmitting Signals to the Vehicle Body—Methods available to transmit signals from a rotating wheel to the vehicle body include resonance coil, electromagnetic induction, radiowave, light, and magnetism.

In developing a tire pressure warning system, we set the following targets:

- To be capable of determining, while driving, which of the four tires has abnormal tire pressure
- To have a low system price
- To make wheel changing easier
- To be maintenance-free with the alarm operating when tire pressure falls but automatically turning off once normal pressure is restored

To achieve these targets, we selected a combination of magnet and Hall effect IC from various candidate means to send signals indicating tire pressure loss from a rotating wheel to a unit mounted on the vehicle body.

General Configuration

Figure 1 shows a general configuration of the system.

A pressure sensor is mounted on the wheel disc to detect tire pressure loss. For sensing pressure, balancing between inside tire pressure acting on a silicone rubber diaphragm and reaction force of a spring in the sensor is used. When pressure falls, the spring, which is normally compressed, extends to turn and face a magnet toward the inside of the wheel. This new magnet position causes change in a magnetic field in which the Hall effect IC, mounted on the suspension member, is positioned. Once tire pressure is restored, the spring is compressed and the magnet returns to its original position. The pressure sensor has an aluminum diecast housing so its weight is

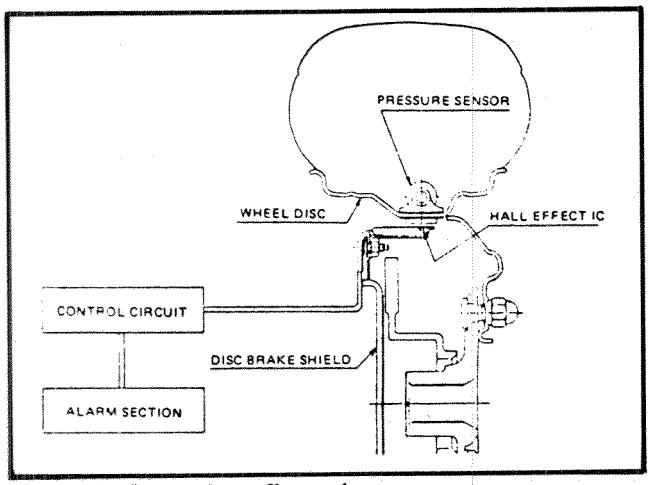

Figure 1. General configuration

within the range of ordinary adjustment for wheel balancing.

The Hall effect IC is mounted on the disc brake shield and senses a change in the magnetic field generated by the pressure sensor. This change in the magnetic field strength drives the alarm section via a control circuit and warns the driver of tire pressure loss.

The Hall effect has a temperature compensation circuit and is compact, lightweight, and resistant to vibration, making it ideal for mounting on unsprung suspension parts.

Pressure Sensor

The pressure sensor is constructed so that when a fork mounted on a slider moves according to tire pressure, it causes a magnet to turn. When the pressure is normal, the pole face of the magnet faces sideways as seen in Figure 2a.

In this position, the Hall effect IC does not sense any magnetic field, and no alarm is generated.

As tire pressure drops, the fork moves toward the right, together with the slider. As a result, the link mechanism causes a rotor carrying the magnet to turn so the magnet pole faces down (see Figure 2b).

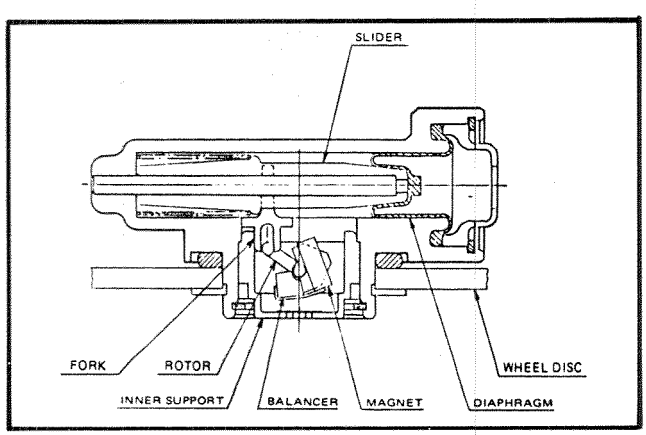

Figure 2a. During normal pressure

Then, when the IC senses the magnetic field, it sends an alarm signal. A rare earth cobalt alloy magnet is used because of less magnetic field change with temperature and because of its high magnetic force, which insures sensing even at some distance from the IC. The diaphragm used is of silicone rubber that does not harden even at temperatures as low as -40° C.

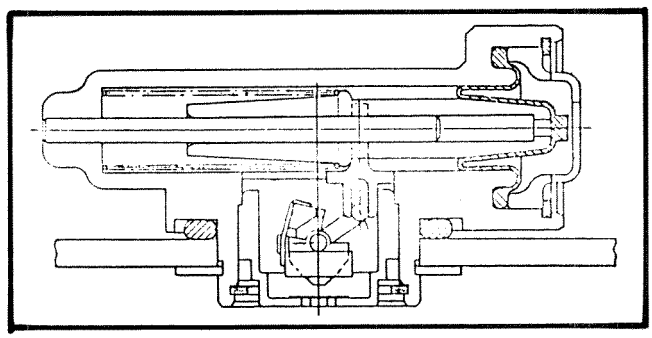

Figure 2b. During reduced pressure

With time, it is likely that a very small amount of air will pass through the diaphragm, and if the pressure sensor was made airtight, air pressure inside the sensor would equal tire inflation pressure. Then, the spring force would cause the slider to move and the magnet to turn as in Figure 2b.

Thus, it would be possible that an alarm could be generated even in the absence of tire pressure loss.

To prevent this, the pressure sensor must be open to the atmosphere but protected against entry of water and dust. These conflicting requirements have been met by a special filter mounted at the boundary between the sensor and the outside that allows air to pass but is impermeable to water.

This filter has high airflow resistance. As a result, in the event of a broken diaphragm, an alarm is generated immediately but air leakage to the outside from the sensor is obstructed by the filter, preventing any quick loss of tire pressure.

The magnet rotor is fitted with a balance weight to overcome the effects of centrifugal force during wheel rotation.

Hall Effect IC

The Hall effect device that transforms magnetic flux density to voltage making use of the Hall effect is attracting attention as a noncontract type sensor, but for improved immunity to electrical noise it is necessary to amplify the voltage signal from this device in its close proximity. It was difficult to install a Hall effect device and amplifier circuit in the form of a discrete circuit in the limited space such as a suspension part.

However, a Hall effect IC with this Hall effect device, signal amplifier circuit, etc., integrated into a single package, was recently developed to overcome this installation problem.

In this system, the Hall effect IC is used as a sensor to make noncontact detection of tire pressure change.

Figure 3 shows the transfer characteristics of the Hall effect IC used in this system. This IC, developed for automotive applications, has been designed to withstand severe operating conditions in terms of temperature range, power voltage, etc.

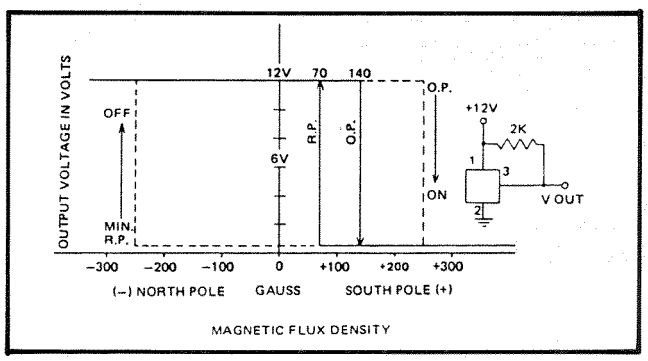

Figure 3. Transfer characteristics

Figure 4 is a functional block diagram of the Hall effect IC. This IC has a voltage regulator, temperature compensation circuit, comparator, Schmitt circuit, and output transistor. The output can be directly connected to a bipolar or CMOS logic circuit. Therefore, it was possible to simplify the control circuit that processes the output signal from this IC.

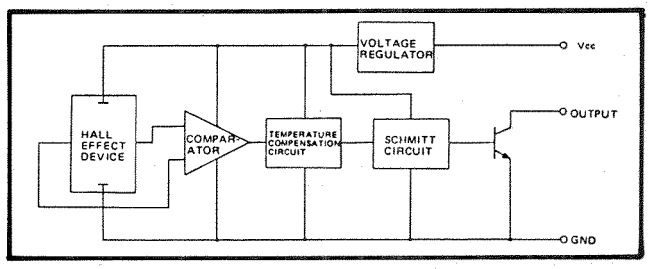

Figure 4. Functional block diagram

Figure 5 shows the Hall effect IC as mounted. The IC mounted to the disc brake shield was resin-molded for protection against vehicle body vibration, water, flying stones, etc.

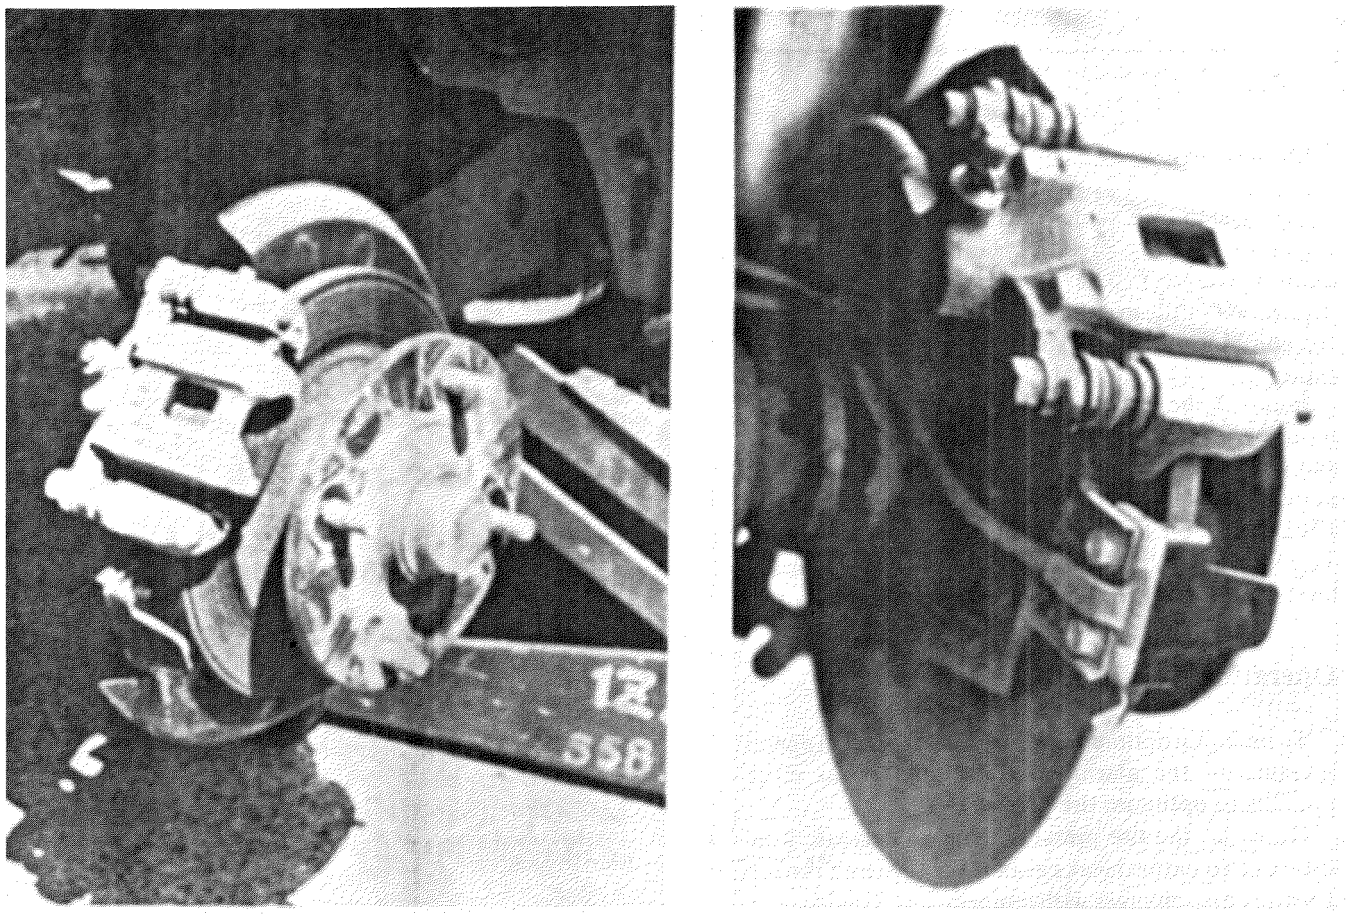

Figure 5. Hall effect IC as mounted

Control Circuit

The control circuit was formed by a hold circuit to detect change in signals coming from the Hall effect IC and a drive circuit to light an alarm lamp and sound a buzzer.

Figure 6 is a block diagram of the control circuit, which has been made as simple as possible.

The direction of the magnet in the pressure sensor fitted in the wheel disc changes as the tire pressure drops. The IC mounted to the disc brake shield detects this change of magnet direction and, as a result, the IC output voltage level also changes. The control circuit holds the IC output voltage level change and causes the alarm buzzer to flash and buzzer to sound. The alarm buzzer stops sounding after a set time, but the alarm lamp remains flashing until normal tire pressure is restored or the ignition key is turned off.

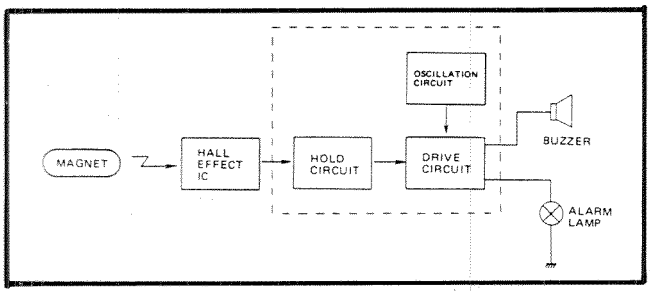

Figure 6. Control circuit block diagram

Alarm Section

This system was so designed as to positively warn the driver of low tire pressure, both visually (lamp) and audibly (buzzer). The alarm lamp, in particular, is positioned in the graphic safety monitor at the center of the combination meter so that it is readily visible at all times.

Figure 7 shows the flashing alarm lamp in the safety monitor. This alarm lamp also serves as an indicator to show 4WD mode selection. When tire pressure is at or above specified level, the lamp operates as the 4WD-FWD selection indicator (lights green when driving in 4WD mode). When tire pressure falls below specified level, the lamp of the corresponding wheel lights red.

Operating Pressure

To maintain optimum tire pressure, the actual operating pressure of the alarm system should be as close as possible to optimum tire pressure.

However, the tire pressure tends to decrease little by little due to natural leaks even if the tire itself is normal. Pressure also changes with temperature. Therefore, if the alarm operating pressure is set too closely to optimum

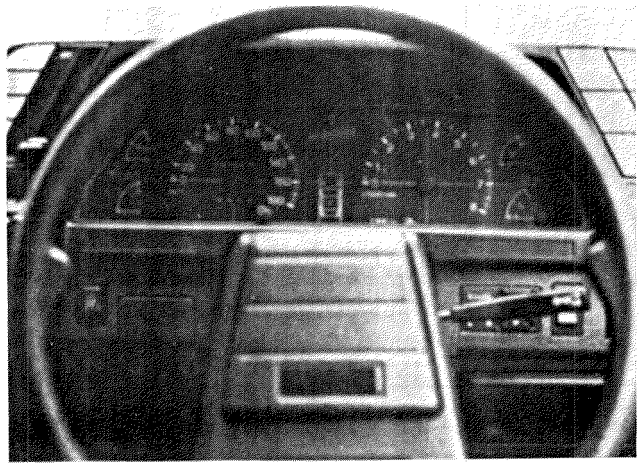

Figure 7. Safety monitor

tire pressure, alarms will be generated too frequently—to the annoyance of the driver.

The alarm operating pressure setting also depends much on vehicle and tire characteristics, and further studies and examination are required.

The operating pressure of this system can be set at any level by adjusting the reaction force of the spring in the pressure sensor.

The vehicle on which this system was installed (Figure 8) has recommended tire pressure of 2.0kgf/cm^2 (196kPa), and it can run safely under all conditions as long as the pressure is within a range from 2.3 to 1.7kgf/cm^2 (225.4 to 166.6kPa). However, when the pressure falls below 1.3kgf/cm^2 (127.4kPa), it impairs steering behavior and directional control during high-speed driving or sharp cornering.

Therefore, with these and the operating pressure setting accuracy taken into account, the operating pressure was set at 1.5kgf/cm^2 (147kPa) $\pm$ 0.1kgf/cm^2 (9.8kPa).

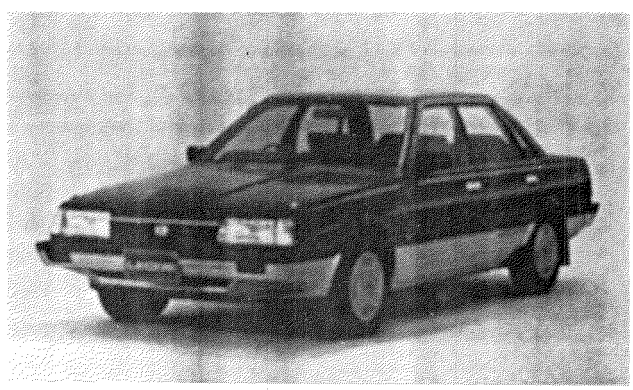

Figure 8. Test car

Results

Pressure Sensor Operating Pressure

Figure 9 shows the operating pressure of the pressure sensor. The abscissa represents the tire inflation pressure and the ordinate represents the magnetic flux density at the Hall effect IC mounted on the suspension member.

The operation point and release point of the IC used are 70 Gauss and 140 Gauss, respectively, as shown in Figure 9, and in this case the alarm turns on at 1.45kgf/cm^2 (142.1kPa) and turns off at 1.6kgf/cm^2 (156.8kPa).

This operating pressure, which is affected by the accuracy of the sensor itself, variations in Hall effect IC characteristics, and the dimensional accuracy between the pressure sensor and IC, requires full consideration in volume production of the system.

In the present system, deviation due to pressure sensor accuracy is ±0.4kgf/cm^2 (±3.9kPa), due to the Hall effect IC operating point accuracy is ±0.02kgf/cm^2 (±1.96kPa), and due to IC to pressure sensor distance accuracy (±1mm) is ±0.04kgf/cm^2 (±3.9kPa). Thus, the target value of ±0.1kgf/cm^2 (±9.8kPa) has been met.

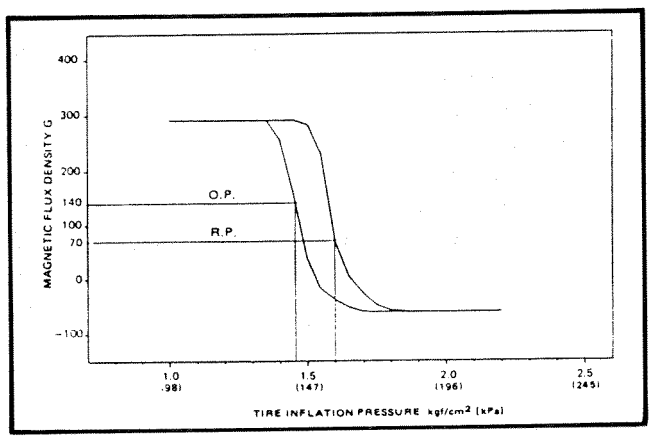

Figure 9. Pressure sensor characteristics

Change of Operating Pressure due to Speed

The pressure sensor is mounted on the wheel disc and is subjected to centrifugal force from the wheel turning. This centrifugal force not only acts directly as a force on the moving parts but also increases the frictional resistance of the sliding parts.

In this system, to minimize any operating pressure change due to centrifugal force, a balance weight is provided on the rotating parts in the pressure sensor to counter centrifugal force and resulting increase in friction force.

Figure 10 shows the change of the operating pressure due to vehicle speed.

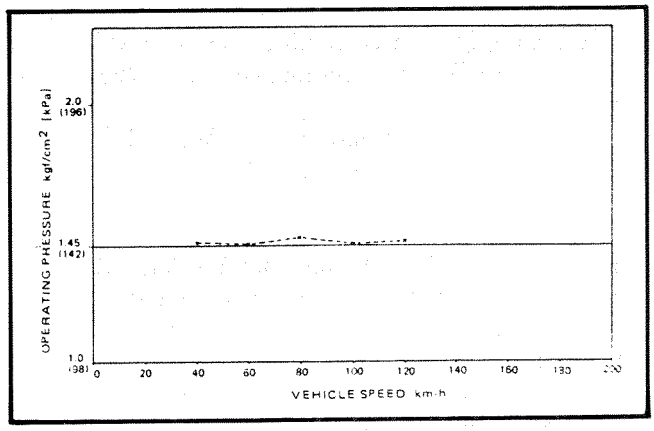

Figure 10. Operating pressure change with vehicle speed

Figure 11 shows experimental and calculated values obtained when the balance weight was changed.

By carefully selecting balance weight, it is possible to positively change alarm operating pressure with speed; that is, to raise operating pressure when speed increases so the alarm is given earlier during high-speed driving.

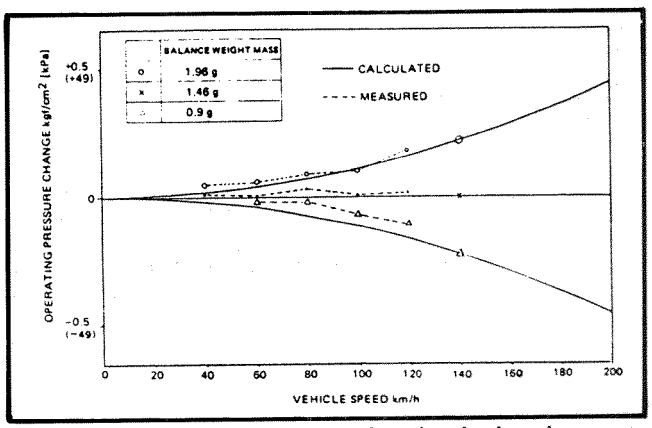

Figure 11. Change of measured and calculated operating pressure with balance weight mass change

Influence of Environment Conditions

Low Temperature

Silicone rubber of small physical change at low temperature is used for the diaphragm. No difference was observed in operating pressure between 15° C and -40° C.

High Temperature

What is most important is creep deformation of the diaphragm. A test piece of diaphragm was subjected to a

tensile load of 3kgf/cm^2 (294kPa) up to 120°C x 2,000h but permanent elongation deformation was within 20 percent.

Assuming a vehicle life of 10yr/200,000km and an ordinary and upslope running (65 percent), high-speed running (30 percent), and downslope running (5 percent), the test results and other data indicate that the temperature around the diaphragm will reach 80°C or higher for about 30h during a vehicle's lifetime. Thus, creep should not be a problem.

Water Pressure Resistance

The special filter (average pore diameter 0.6μm) separating the pressure sensor from ambient air can prevent water permeation down to a water depth of about 14m.

Test on Actual Vehicle

A vehicle (Figure 8) equipped with this system was run on in-house irregular roads for endurance testing (Belgian road, stone-paved road, and randomly waved road) over 3,000km and on snowy roads in northern Japan over 7,000km, but no change in the operating pressure was observed. No open wiring, water entry, leakage, or any other trouble were experienced.

Maintainability

The Hall effect IC's are mounted to the suspension parts as shown in Figure 5. They are protected by reinforcing members but, when removing or replacing a wheel on the vehicle, some care is necessary to avoid it striking with force at the Hall effect IC.

The pressure sensor is mounted on the rim inside, and care is necessary regarding pressure sensor location when inserting a tire lever between the wheel rim and tire bead to remove the tire.

Conclusion

The tire pressure warning system presented here adopts a simple signal processing system to make it user-friendly and at the same time achieve a low cost.

The pressure sensing accuracy of within the operating pressure ±0.1kgf/cm^2 (9.8kPa) was verified by both bench and on-vehicle tests.

Aspects of Subjective/Objective Correlation Regarding Vehicle Tyres

Dr. Lea Brindle
Cranfield Institute of Technology, Bedfordshire, England

Abstract

An introduction to vehicle steering response dynamics is followed by a discussion of the influence of pneumatic tyres on driver subjective ratings concerning vehicle steering and handling characteristics. An empirical study investigating driver sensitivity to the effects of low profile radial-ply and standard radial-ply tyres is then described.

It was found that the subjective ratings of ordinary drivers could be systematically related to objective measures of vehicle directional response. Most important in affecting favourable ratings were short lateral acceleration and yaw rate response times, and higher levels of control gain for these parameters. Low profile radial tyres were rated relatively more favourably than standard radials, mainly in respect of a combination of steering "feel," stability on dual carriageways, and roadholding

on straight roads and motorways (freeways). In contrast, standard radial-ply tyres received relatively higher ratings concerning the amount of steering return strength and the degree of comfort experienced on rural roads.

Future research directions discussed include investigating the effect of these directional response parameters on driver behaviour. Also discussed is the need for a systematic investigation of "steering aesthetics," where there would be concern for a wide range of influences on driver feedback through the vehicle's steering system. Included would be steering torque, the amount of "work done" in steering, gains and response times for lateral acceleration and yaw rate, and the linearity of response for all of these parameters.

Introduction

Overview

The introduction initially provides a presentation of aspects of the vehicle directional response dynamics necessary to facilitate an understanding of the physical consequences of change affecting vehicle steering and handling. This is followed by a discussion of the influence of pneumatic tyres on driver subjective ratings concerning vehicle steering and handling characteristics.

Vehicle Directional Response Dynamics

A description of the forces acting on the front (steered) wheels is a useful beginning for understanding the effects of pneumatic tyres on the driver/vehicle system. When the front wheels are steered, the cornering forces generated at the front of the vehicle are greater than those generated at the rear. This causes the vehicle to yaw. The cornering forces at the front (and rear) of the vehicle act via the tyres. The area where the tyre is in contact with the road is described as the "contact patch." Because of a phenomenon known as "pneumatic trail," the tyre cornering forces do not act at the centre of the contact patch. This results in the generation of "self-aligning torque," which opposes the steered force input by the driver (via the steering wheel). If the self-aligning torque is nonzero, the vehicle yaws to overcome this force and attempts to realign the steered wheels with the direction of motion of the vehicle. In general, the strength of the self-aligning torque depends on four factors. It increases as the load being applied to the tyre gets heavier. In other words, heavier cars will be more difficult to steer than lighter ones. It increases as the steered angle gets larger. It also increases for a given steer angle as the forward speed increases. Less steered angle is necessary, however, for a given cornering force as forward speed increases. Last, self-aligning torque will vary according to the geometric design of the steering system and, as we shall see, according to the type of vehicle tyre. Figure 1 shows the forces acting on the steered wheel.

The vehicle steering system can be thought of as an amplifier with similar response characteristics. Two distinct types of parameters can describe vehicle directional response. These are gains and response latencies (or response delays).

The gain of an amplifier is the ratio of output to input, or the efficiency of the system. When considering the steering system, gains operate for lateral acceleration and yaw rate response to steering wheel input. Lateral acceleration gains are defined as the lateral acceleration response per unit steering wheel angle input by the driver (ms^{-2}/Rad). Similarly, yaw rate gains are yaw rate response per unit steering wheel angle input (Rad s^{-1}/Rad). Lateral acceleration and yaw rate gains will vary according to the design of the steering geometry and type of vehicle tyre, and tend to increase as forward speed increases. The ratio of steering wheel torque to steering wheel angle input (Nm/Rad) is also influenced by the same factors (but not necessarily in the same way) as are lateral acceleration and yaw rate gains.

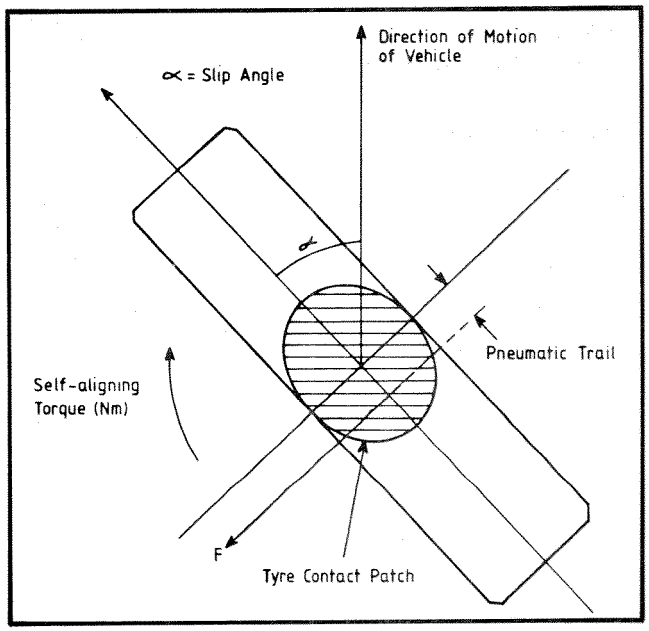

Figure 1. Forces acting on the steering wheel(10)

The other important vehicle directional response parameters are lateral acceleration and yaw rate time response to steering wheel input. These are due to the inherent time delay of mechanical systems. The measurement of these particular response parameters presents special problems since small times (which are of the order of between one-half of one second and one second for a moderately fast responding modern saloon car) are involved.

Other useful terms include transient and steady-state manoeuvres. A transient manoeuvre is one when the vehicle changes its steered direction at least once. An example of this is steering during an "S" bend. Steady-state manoeuvres are not usually encountered during normal driving but are often used by test engineers driving on vehicle proving grounds. This involves driving a vehicle during a turn with either a fixed steering wheel input or maintaining a fixed level of lateral acceleration. Open loop testing generally involves a steady-state manoeuvre, although it can involve transient manoeuvres. The term comes from control theory and refers to the fact that there is no feedback from vehicle to driver. A vehicle receiving a step input from a robot-driving machine would be a good example of an open loop system. A closed loop system is the way human factors psychologists would view the relationship between driver and vehicle—as elements in the system, each responding to feedback from the other.

Finally, some discussion of vehicle tyres is necessary. Cross-ply (or bias-ply) tyres are fitted to a minority of passenger cars nowadays. This is because the steering systems of modern cars are designed to be driven with radial-ply tyres. Radial-ply tyres last longer and generally have superior response qualities than cross-plies. However, cross-ply tyres have certain qualities that radials could do well to imitate. For example, although the roadholding limits of cross-ply tyres are lower than those of radials, cross-plies exhibit a more linear response toward the limit of their performance. Radials generally exhibit sudden break-away at their limit, a nonlinear and undesirable response. Low profile (or low aspect ratio) radial-ply tyres are a new development. These tyres are designed to put a larger area of tyre (contact patch) on the road and are generally acknowledged to have superior response qualities and higher limits of roadholding than conventional radials.

Driver Sensitivity to Vehicle Directional Response Parameters

The steering parameters most frequently reported as affecting driver opinion and driver/vehicle system are response latencies (time delays) and gain functions. A review of the literature regarding driver sensitivity to these parameters can be found in Brindle and Wilson (1983) and Brindle (1984). Brindle and Wilson showed that it was the effect on these vehicle directional response parameters that was mainly responsible for the variation in driver opinion as influenced by tyre type.

Using a methodology similar to that described in the present study, Brindle and Wilson investigated driver sensitivity to radial-ply and cross-ply (bias-ply) tyres. Following Principal Components Analysis of responses to 22 interview questions, driver opinion regarding vehicle steering and handling was reduced to nine components. Discriminant Function Analysis then performed on relatively orthogonal approximations to these nine components found three to be successful discriminators between tyre type ($p < 0.01$, canonical correlation = 0.74). It was found that drivers rated radial-ply tyres relatively more favourably than cross-ply tyres regarding a combination of perceived safety and security, control in emergencies, stability and course following on straight roads, and the amount of effort required in steering the vehicle. This was contrasted by relatively higher ratings regarding steering "feel" for drivers on cross-ply tyres.

Further analysis showed that driver opinion thus described could be systematically related to objective measures of the driver/vehicle system directional response. When lateral acceleration and yaw rate were examined, significant negative correlations were obtained between driver subjective ratings regarding both safety and effort and response time ($-0.66 < r < -0.40$, binomial probability $p < 0.001$), while significant positive correlations were obtained for gain functions on these parameters ($+0.33 < r < +0.62$, $p < 0.02$). In other words, favourable driver opinion concerning safety and effort was associated with shorter response times and higher levels of control gain. Steering "feel" was also strongly associated with both response time (positively) and control gain (negatively) and, to a lesser extent, positively with an objective measure of work expended (the product of steering wheel angle and steering wheel torque) by drivers in steering the vehicle ($+0.33 < r < +0.46$, $p < 0.07$).

Brindle (1984) explained this relationship between driver opinion and vehicle directional response parameters by examining the known engineering properties of the tyres. It was suggested that the manufacturing quality mainly responsible for the superior response characteristics (notably shorter response times) of radial-ply tyres was the higher cornering stiffness of these tyres, typically about 20 percent higher than cross-ply tyres. Thus, favourable driver opinion associated with radial tyres, which were related to short response time and higher levels of control gain, can be considered primarily attributable to this technical quality. The concept of pneumatic trail largely explains the higher levels of steering wheel torque associated with cross-plies, due to the relative movement rearward of the contact patch for these tyres. The amount of work done in steering the vehicle, also important in affecting driver opinion, was possibly affected by a combination of higher levels of steering wheel torque (as a result of increased pneumatic trail) and the high levels of steering wheel angle associated with the lower levels of control gain found for cross-ply tyres.

The Study

Research Objectives

The findings from Brindle and Wilson (op. cit.) were investigated in an expanded study examining a wider range of driver opinion. The effect of a more modern tyre contrast (low profile radials versus standard radials) on vehicle steering and handling characteristics, and the influence of these characteristics on driver opinion, was investigated under realistic driving conditions.

Research Design

A total of 46 subjects (Ss) drove a medium-size estate car (1978 Ford Cortina 1.6 L) on public roads in an independent-groups, repeated measures research design. Three treatment groups were used: 18 Ss drove using Pirelli P6 low profile "sixty series" radial-ply tyres (185/60x14) on dry roads, 18 Ss drove using Pirelli P4 "standard" radial-ply tyres (165x14) on dry roads, and 10 Ss drove using P4 radial tyres on wet roads. The route was 40.6km and included a range of rural country roads, suburban dual carriageways, and a section of motorway (freeway). Additionally, Ss drove an 8.2km practice route before commencing testing.

A total of 33 males and 13 females took part in the experiment, and Ss were aged between 18 and 60 (median 27.7 years). Driving experience ranged between 1 and 38 years (median 16.0), and driving exposure ranged between 1,000 and 25,000 miles per annum (median 11,400).

Medium-powered tests (one-way analyses of variance), carried out to check for random group assignment, failed to detect any systematic effects due to possible confounding variables (e.g., age, driving experience, miles driven per annum). The power of these tests was such that a strength of association (w^2, see Hays, ibid., p. 417) of 10 percent would have been detected at the $p < 0.05$ level ($N = 46$, $J = 3$) with a probability of 0.20 (Beta = 0.80). Groups were considered, therefore, to be adequately randomised.

Ss drove an instrumented vehicle equipped to measure steering wheel angle, lateral acceleration, yaw rate, and forward speed for a range of transient manoeuvres. These included low-, medium-, and high-speed bends and curves, and roundabouts (circles) in rural Bedfordshire and Buckinghamshire. Data were recorded on a Racal analogue tape recorder and were subsequently interpreted using a microcomputer analogue to digital routine. Ss were interviewed on a range of items both during and after each test drive.

Results

Interview data were initially analysed using Principal Components Analysis. Thus, 40 Likert scale items relating to driver subjective ratings of vehicle steering and handling, ride quality, and safety were reduced to 10 components. Before rotation, these 10 components accounted for 79.3 percent of the total variation among driver opinion. An orthogonal rotation according to the "Varimax" criterion was carried out, and relatively orthogonal simplified versions of the 10 components were subjected to Multiple Discriminant Function Analysis (DFA) for three groups. This method results in "...the reduction of multiple measurements to one or more weighted combinations having maximum potential for distinguishing among members of the different groups." (Overall and Klett, 1972, p. 280). The "Wilks" criterion for inclusion of meta-variables in a stepwise DFA was used. For further details of these multivariate statistical techniques, also see Brindle and Wilson (op. cit.).

Table 1 describes how much variance each of these 10 factors accounted for after rotation.

Table 2 shows the structure of the simplified meta-variables used in the Discriminant Function Analysis after "Varimax" rotation. A "+" in any column indicates that the respective row variable was given a weighting of +.1.0 in the composite meta-variable. Variables were thus only included in the factor structure where a "+" appears in the appropriate column. All other variables were

excluded. The criterion for assigning a weight of +1.0, or otherwise zero, was for factor loadings >0.65 in the SPSS Rotated Factor Structure matrix.

Two canonical discriminant functions were computed. The first function (which explained 67 percent of the total variance, $p < 0.05$, canonical correlation = 0.47) discriminated between P6 tyres and P4 tyres. The second function (which explained the remaining variance, $p < 0.14$, canonical correlation = 0.35) discriminated between dry and wet road conditions. Results indicated that P6 tyres were rated relatively more favourably than P4 tyres regarding a combination of steering "feel," stability on dual carriageways, and roadholding and handling on straight roads and motorways. Drivers on P4 tyres, however, expressed relatively higher ratings concerning the amount of steering return strength and the degree of comfort experienced on rural roads than drivers on P6 tyres. Drivers on dry roads expressed relatively higher ratings concerning a combination of steering return strength, responsivity and sensitivity, and roadholding and handling on straight roads and motorways than drivers on wet roads.

An analysis of the vehicle directional response parameters confirmed that response time and control gain were important parameters affecting driver subjective ratings. Since multiple correlations were made, results were examined using probabilities associated with the binomial distribution (see Hays, 1974, p. 184) for the expectation of these results due to chance. Yaw rate response time was negatively correlated with favourable

driver opinion regarding perceived safety ($-0.37 < r < -0.14$, binomial probability $p < 0.001$), and straight road and motorway performance ($-0.35 < r < 0.18$, $p < 0.02$). High levels of speed-adjusted lateral acceleration and yaw rate gain were associated with favourable ratings concerning steering "feel" ($+0.16 < r < +0.30$, $p < 0.04$), and safety ($+0.13 < r < +0.37$, $p < 0.01$). An inverse relationship was found between speed-adjusted lateral acceleration and yaw rate gain and high ratings concerning rural steering and handling ($-0.30 < r < -0.16$, $p < 0.01$), and steering responsivity and sensitivity ($-0.37 < r < -0.14$, $p < 0.04$). A marginally significant result was found suggesting a direct relationship between high ratings regarding steering responsivity and short lateral acceleration response time ($-0.22 < r < -0.11$, $p < 0.08$).

It was found additionally that, for lateral acceleration and yaw rate steering gains, standard radials had a more linear response as affected by forward speed ($r^2 = 0.91$, and 0.82, respectively) than low profile radial tyres ($r^2 = 0.84$, and 0.75). In other words, for the range tested, steering gains increased approximately linearly with increased forward speed. Results also showed that driver-adopted yaw rate had a more linear (inverse) response to forward speed ($r^2 = 0.89$) than driver-adopted lateral acceleration ($r^2 = 0.79$). These results are discussed more fully in Brindle (1984).

Conclusion

Results showed that the subjective ratings of ordinary drivers could be systematically related to objective measures of vehicle directional response. The main influences on favourable driver opinion were short response times and high levels of control gain, qualities that were, in general, associated with the superior response characteristics of low profile radial tyres. However, drivers were also sensitive to other effects of vehicle tyres, notably to rural comfort and rural steering and handling performance—qualities that were relatively more likely to be associated with standard radials than with low profile tyres. It is also possible that favourable ratings for standard radials could have been affected by the more linear lateral acceleration and yaw rate response for these tyres.

These subjective ratings by ordinary drivers match expert evaluations of the known engineering qualities of the tyres tested. Early discussions with the Technical Services Department of Pirelli U.K. Ltd. indicated that higher levels of roadholding and handling would be expected from the low profile (P6) tyres. Sandberg, Formgren, and Ohlsson (1976) reviewed several engineering reports investigating the relative merits of standard and low profile radial tyres. They concluded that standard radial tyres, apart from other benefits, would be expected to produce a higher standard of ride quality, and that low profile radials would be expected to have improved cornering stability together with some other benefits, though at the expense of ride quality. These characteristics can be seen to match the subjective ratings of ordinary drivers.

Discussion and Recommendations

The studies reported have shown that ordinary drivers are sensitive to the effect of different tyres on vehicle steering and handling. Further, it has been shown that driver subjective ratings can be systematically related to vehicle directional response parameters. This is important since, as Ray and Gibson (1983) have concluded, " . . . subjective assessments of vehicle handling performance are useful if used in conjunction with other objective test procedures," (ibid., p. 169). In conclusion, these results have a high degree of generalisability since data were collected from representative drivers under realistic closed-loop conditions. However, in addition, several research directions were indicated.

Although it has been shown that driver opinion is affected by different tyre types, the effect of this sensitivity on driver behaviour also requires investigation. For example, do drivers adjust their driving by, say, cornering faster to compensate for the superior response qualities of low profile tyres? (This question is examined in Brindle, 1985, and at length in Brindle, 1984.) Further, the effects on driver opinion and behaviour require investigation for other subsets of drivers. It is important to investigate the response for different groups, such as young versus older drivers, accident involved versus no-accident drivers, etc.

Another intriguing area involves investigating the relative effects of driver sensitivity to yaw rate and lateral acceleration response. Early indications (from both of our studies) suggest that as forward speed increases, driver-adopted yaw rate is more linear than driver-adopted lateral acceleration. Other authors have also been concerned with this distinction recently. For instance, Nakaya, Sano, Furukawa, and Oguchi (1982), using an experimental drum-type simulator with front- and rear-wheel steering, concluded from the data from three subjects "...that during evasive manoeuvres the driver attaches greater importance to the vehicle's lateral displacement as the necessary input information, while in normal driving, he puts more weight on yaw angle" (ibid., p. 109.6). It is interesting to note that lateral acceleration and yaw rate are, respectively, second- and first-order derivatives of lateral displacement and yaw heading. However, more research is required before any serious conclusions can be reached on how these parameters contribute to driver directional feedback.

Finally, it has been shown that a wide range of vehicle directional response parameters can influence driver

opinion. Previously, steering "feel" has been defined (e.g., Anderson, 1983) only in terms of "the force-feedback characteristics" (ibid., p. 16) of the steering. It is suggested that the concept of "steering feel" be broadened into that of "steering aesthetics," where there is concern for a wider range of driver feedback from the steering. Apart from steering torque, drivers have been shown to be affected by the amount of work done, lateral acceleration and yaw rate gain and response time, and the linearity of response for these parameters. This hierarchy of importance for these influences for different drivers under different driving conditions also requires clarification. It may well be that, for instance, the same characteristic may not necessarily be as important when driving on rural roads as, say, when driving on motorways.

Acknowledgments

The author would like to express his gratitude to Pirelli U.K. Ltd., which provided technical and material support for the experiments reported.

Tire Performance Measurements—Wet and Dry

Lloyd H. Emery
U.S. Department of Transportation, National Highway Traffic Safety Administration

Abstract

Vehicle accident avoidance potential is very much dependent on the vehicle braking and cornering performance potential. In the past, much effort has been concentrated on the suspension and braking systems to raise their performance level. However, vehicle braking and cornering performance is also strongly influenced by the braking and cornering force characteristics of the vehicle tires. The study of vehicle tire dynamics has been generally limited by the absence of accurate braking and cornering tire data representative of the vehicle performance range of interest. This absence of tire performance data is particularly true in the nonlinear tire performance range of large cornering slip angles and braking slip. Accident avoidance vehicle performance research requires tire performance data representative of the tire braking and cornering forces generated by the vehicle tires when operating in the regime of large slip angles, large normal load transfers, and high braking slip, even up to locked wheel performance. The study of vehicle stability and accident avoidance through cornering and braking maneuvers requires tire performance data from 0 to 90° slip angle and from 0 to 100 percent slip for braking.

This paper reports the results of an effort by NHTSA to measure the braking and cornering forces of a P185-80R13 tire produced by Goodyear Corporation. Tire force measurements were made at the Tire Research Facility (TIRF) located at Calspan Corporation. Tire force measurements were made on both dry and wet

surfaces. Braking force was measured for each slip angle from 0 to 100 percent slip. The tire slip angle was varied over a slip angle range from 0 to 90°.

Introduction

The motivation to perform this study was the need to analyze vehicle stability and spin out performance during accident avoidance maneuvers involving steering and braking and the realization that the open literature provided insufficient tire performance data to do so effectively. Accordingly, it was decided to measure the braking and lateral forces produced by a tire when subjected to both braking and slip angle simultaneously as a function of normal load on both a wet and dry surface. The tire of interest was the Goodyear-produced P185-80R13 radial tire, which is representative both in size and construction of many tires presently being produced.

The 1984 Tire and Rim Association Manual gives this tire a rating of 1301-lb normal load at 35PSI. The measurements were performed at 30mph, at 34PSI inflation pressure, on a wet and dry surface, on the TIRF located at Calspan Corporation, Buffalo, New York. Tire force measurements reported on in this paper are the longitudinal and lateral tire forces produced by braking and cornering. These force measurements were performed at 0, 4, 12, 20, 30, 50, 60, and 90° slip angles. Tire force measurements reported on in this paper were made at the three normal loads of 250 lb, 600 lb, and 1,027 lb, at each of the above slip angles. In addition, the tire braking and lateral forces were measured as a function of braking slip from 0 to 100 percent slip. The wet friction coefficient of 0.30 was established by the usual wet ASTM tire and recommended procedure. The dry friction coefficient of 0.85 was measured by a locked ASTM tire on the dry surface.

Test Results

The braking force test results are contained in Appendix A. The lateral force test results are contained in Appendix B.

Discussion

General

The normalized braking and cornering forces of the test tire are significantly different as a function of normal load, slip angles, and slip ratio. Figures 1 through 4 have the normalized lateral force plotted as a function of normalized braking force for different slip angles and slip

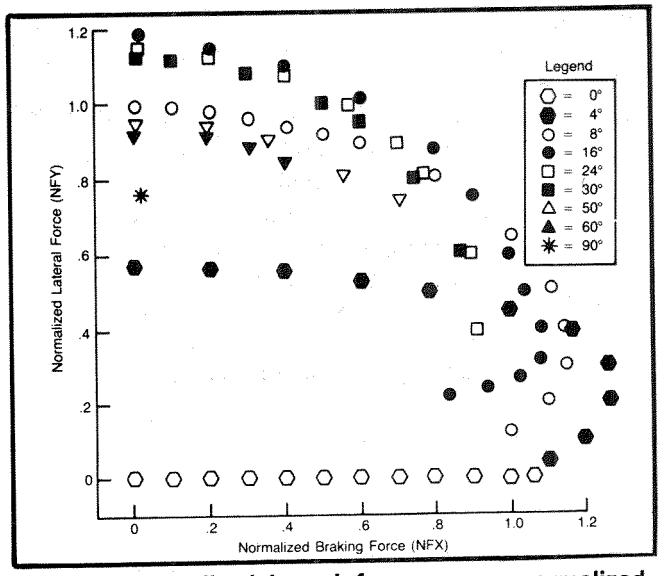

Figure 1. Normalized lateral force versus normalized braking force as a function of slip angle and percent braking slip on a dry surface with a 250 lb normal load

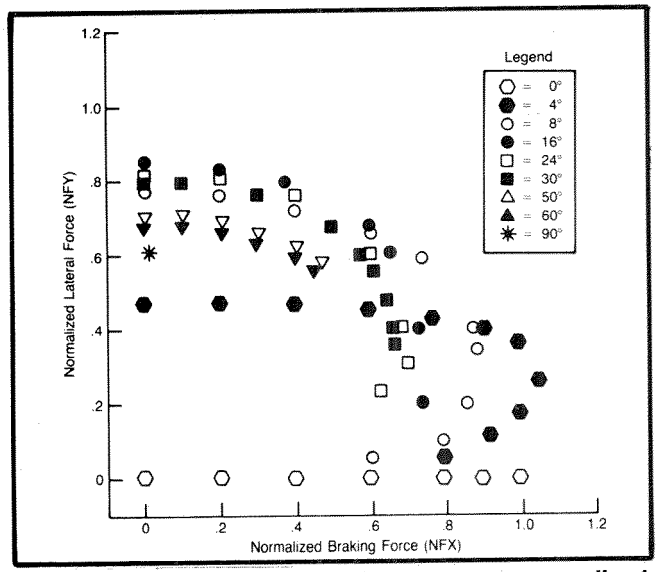

Figure 2. Normalized lateral force versus normalized braking force as a function of slip angle and percent braking slip on a dry surface with a 1,027 lb normal load

ratios for a normal load of 250 lb and 1,027 lb on both a dry and wet surface. The following observations become apparent when Figures 1 through 4 are examined.

- The normalized lateral and longitudinal forces for each slip angle are higher for the 250-lb normal load than for the 1,027-lb normal load. Thus, one can conclude this tire is more efficient at generating forces as the normal load is decreased. This observation is true for both and dry surfaces.
- The maximum normalized lateral force for both normal loads on the dry surface occurs at around the 16° slip angle at the zero slip ratio braking

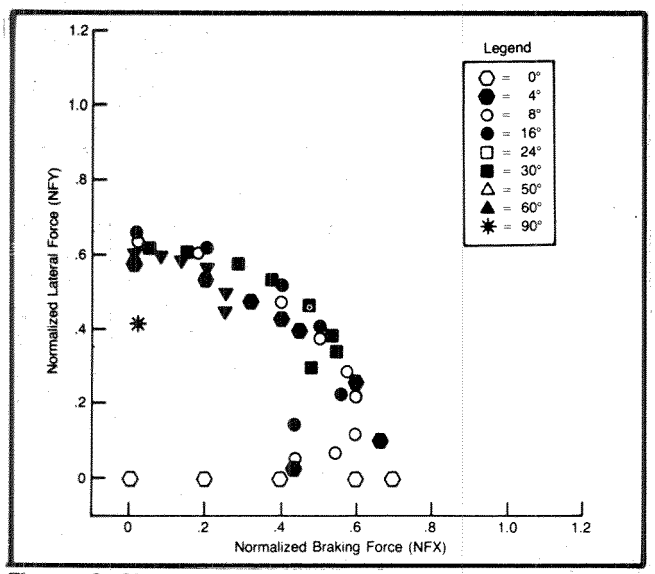

Figure 3. Normalized lateral force versus normalized braking force as a function of slip angle and percent braking slip on a wet surface with a 250 lb normal load

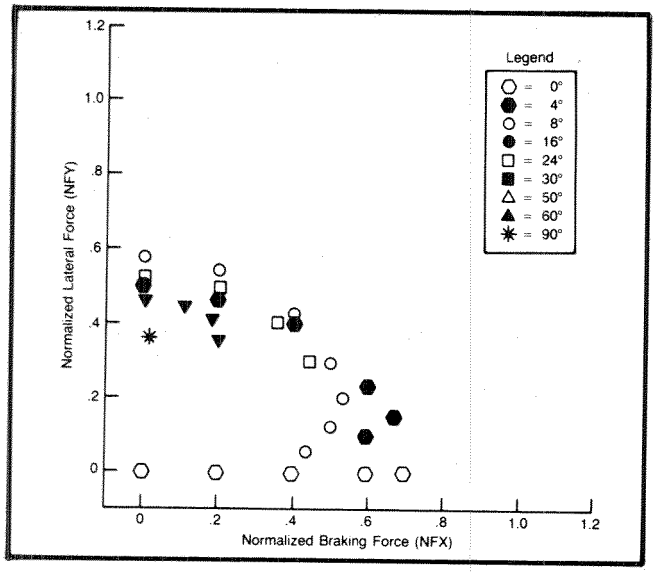

Figure 4. Normalized lateral force versus normalized braking force as a function of slip angle and percent braking slip on a wet surface with a 1,027 lb normal load

condition. Slip angles less than and greater than approximately 16° produced less normalized lateral force.

- The maximum normalized braking force on the dry surface occurred at the 4° slip angle rather than the 0° slip angle. There is presently no adequate explanation as to why the maximum normalized braking force should occur at some slip angle greater than zero. Future research will be necessary to explain this unexpected result.
- The normalized braking force on the dry surface for the 4°, 8°, and 16° slip angles shows a peak value and then a curl back to the left. The peak normalized lateral force for these three slip angle curves represents the peak normalized lateral force that occurs at some slip ratio, which is usually around 20 percent slip for straight line braking. However, the percentage slip at which the peak normalized braking force occurs increases as the slip angle increases. Examination of Appendix A clearly shows this effect.
- The peak normalized braking force on the dry surface begins to coincide with the 100 percent braking slip condition at around the 24° slip angle level.
- The normalized lateral force of about 0.76 for the 90° slip angle in Figure 1 is considerably less than the normalized braking force of about 1.05 for the 0° slip angle for the 250-lb normal load on a dry surface. A similar comparison can be made for the 1,027-lb normal load data in Figure 2. The data show that the tire is much more efficient at producing force in the longitudinal or braking mode than it is in the lateral or cornering mode. It would be interesting to rerun this experiment using wider wheels with the same tire to see if the wider wheels would increase the tire lateral force production efficiency.
- In contrast to the dry surface, the maximum normalized braking force on the wet surface for both the 250-lb and 1,027-lb normal loads occurred for the straight line braking condition rather than at some small slip angle.
- The normalized lateral forces and braking forces for all slip angles on the wet surface are much less than their counterparts on the dry surface.
- The normalized braking force on the wet surface for the 4°, 8°, and 16° slip angle with a 250-lb normal load also shows a peak value and then a curl down and to the left. The peak normalized braking force occurs at about a 20 percent braking slip for a straight line stop. The peak normalized braking force occurs at higher levels of percent braking slip as the slip angle increases. The peak normalized braking force coincides with the locked wheel condition after the 50° slip angle condition is reached.
- The normalized lateral force of about 0.4 for the 250-lb normal load and a 90° slip angle on the wet surface is again considerably less than the maximum normalized braking force of about 0.7 for the 0° slip angle condition in Figure 3. Again the tire is much more efficient at generating maximum force in the longitudinal direction compared to the lateral direction at a 90° slip angle. This tire performance characteristic is detrimental with respect to vehicle stability when the rear wheels are experiencing large slip angles.

The normalized braking force and the normalized lateral force are plotted as a function of slip angle for a locked-wheel condition in Figures 5 and 6, respectively. The maximum normalized braking force occurs not at the 0° slip angle but at about the 4° slip angle. The maximum normalized lateral force also does not occur at the 90° slip angle but at about the 60° slip angle. Again, there is no adequate explanation at the present time to explain these somewhat unexpected results.

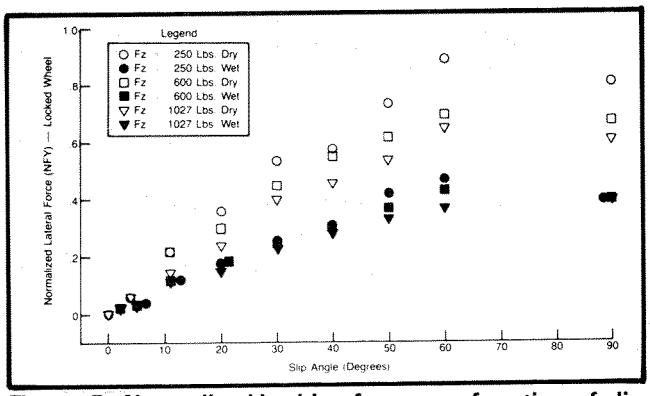

Figure 5. Normalized braking force as a function of slip angle-locked wheel

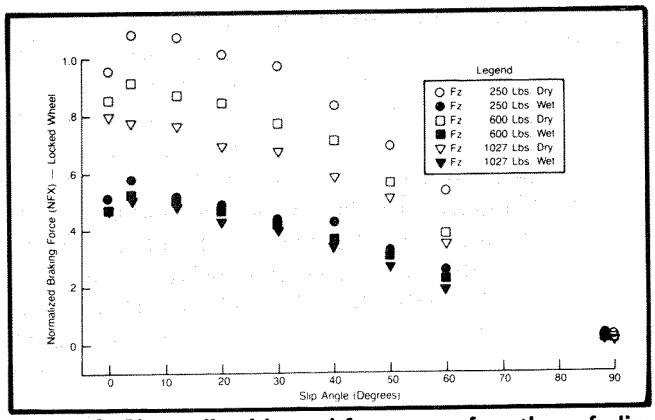

Figure 6. Normalized lateral force as a function of slip angle-locked wheel

The normalized lateral force for a normal load of 1,027 lb is plotted as a function of slip angle and braking slip in Figures 7 and 8 for a dry and wet surface, respectively. The overall normalized lateral forces are much less on the wet surface than on the dry surface; however, the normalized lateral force for very small slip angles is about the same on both the dry and wet surfaces, especially for small percentages of braking slip. The normalized lateral force has a pronounced peak at around the 8° slip angle point on the wet surface and at about the 12° slip angle point on the dry surface at the zero braking slip condition. As the percentage of braking slip increases, the peak normalized lateral force diminishes in pronouncement and occurs at larger slip angle conditions.

The locked-wheel normalized braking force is plotted as a function of the locked-wheel normalized lateral force

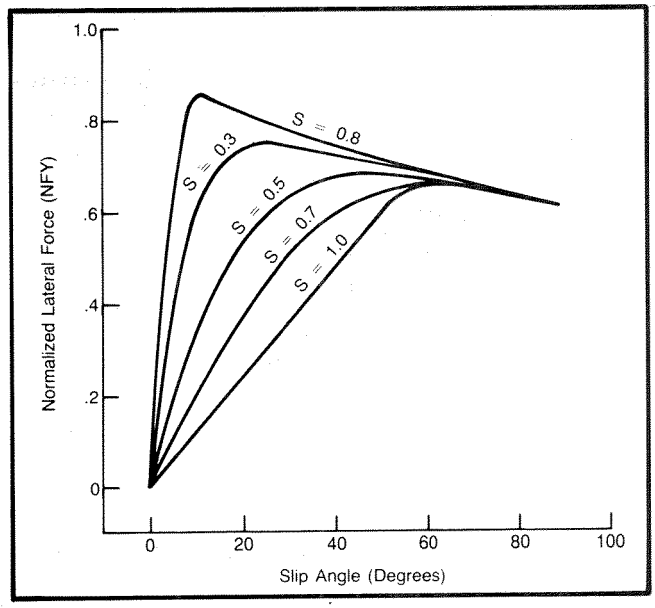

Figure 7. Normalized lateral force as a function of slip angle and percent braking slip on a dry surface with a 1,027 lb normal load

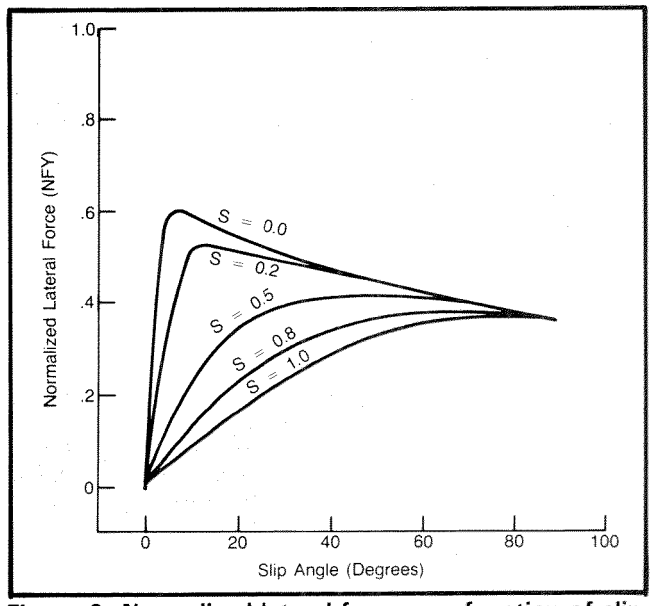

Figure 8. Normalized lateral force as a function of slip angle and percent braking slip on a wet surface with a 1,027 lb normal load

for different slip angle conditions in Figure 9. The data are plotted for three normal loads on both a wet and dry surface. Again, the normalized braking force shows a peak near the 4° slip angle and the normalized lateral force shows a peak at the 60° slip angle condition. Thus, the data show that a friction circle does not perfectly describe the braking and lateral force behavior of this tire. Both the normalized braking force and the normalized lateral force show a curl, which has never been explained.

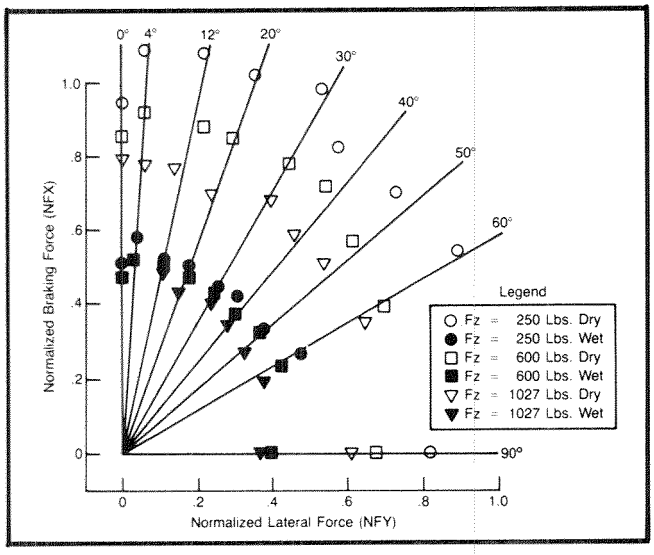

Figure 9. Normalized braking force versus normalized lateral force locked wheel

Appendix A

Examination of Appendix A reveals the following observations:

- The test data in Figure A-1 show that the test tire has a similar braking stiffness on both the wet and dry surfaces. A driver applying his brakes in a straight line braking situation would feel little difference in brake gain (vehicle deceleration versus pedal effort) between a wet and a dry surface up to about 0.2 normalized braking force. However, there is a big difference in the peak braking force between the wet and dry surfaces. The peak normalized braking force for the dry surface is about 60 percent greater (depending on normal load) than the peak normalized braking force for the wet surface. The sliding normalized brake force for the dry surface is also about 50 percent greater (depending on normal load) than the sliding normalized brake force for the wet surface. One can clearly see the increased braking potential of this tire on a dry surface versus a wet surface. It can easily be speculated that drivers can be lulled into a false sense of security when driving in the linear range on a wet surface; thus, when emergency stopping performance is needed, the expected dry deceleration potential cannot be attained. Based on these data, a locked-wheel deceleration on a wet surface may be over 40 percent less than on a dry surface. The straight line normalized braking force is largely independent of normal load on a wet surface; however, the normalized braking force is inversely proportional to normal load on the dry surface. For those vehicle designers who want to increase the straight line braking performance envelope on a dry surface, the data suggest this can be accomplished by using tires with a higher designed load range. It is also clear that the effective brake proportioning can be altered on a vehicle by the mixing of different load range, tires front to rear.
- The data in Figure A-2 represent the normalized braking force for combined cornering and braking at a 4° slip angle. The normalized braking force for the dry surface is significantly higher than the normalized braking force on the wet surface and is very much a function of normal load. The observations about A-1 are also valid here. In addition, the peak normalized braking force on the dry surface of 1.25 is very high for the lightly loaded condition of 250 lb. The peak normalized braking force for the wet surface is becoming less pronounced and is moving toward higher slip values as the slip angle increases.
- The data in Figure A-3 represent the normalized braking force for combined cornering and braking data at a 12° slip angle. The peak normalized braking force is again occurring at higher slip values as the slip angle increases. The normalized braking force for the dry surface is significantly higher than the normalized braking force on the wet surface. The normalized braking force on the dry surface is again very much a function of normal load.
- The observations made about the data in A-3 are also valid for the data in Figure A-4. The normalized braking force for the 20° slip angle data in A-4 still show a peak although the peak is occurring at about 80 percent longitudinal slip (braking). The normalized braking force on the dry surface does not show a peak for slip angles greater than 30°. The normalized braking force on the wet surface does not show a peak for slip angles greater than 50°. Also, the wet and dry normalized braking forces are starting to converge toward the same value at the 60° slip angle. Of course, the data in Figure A-8 show that the normalized braking force has converged to zero at the 90° slip angle for both wet and dry surfaces.

Figure A-5. Normalized braking force versus slip ratio (braking)—slip angle = 30°

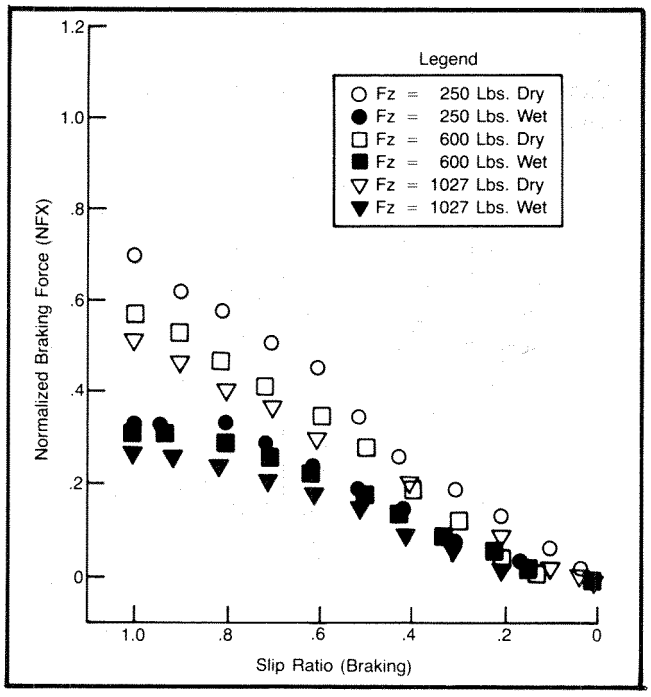

Figure A-6. Normalized braking force versus slip ratio (braking)—slip angle = 50°

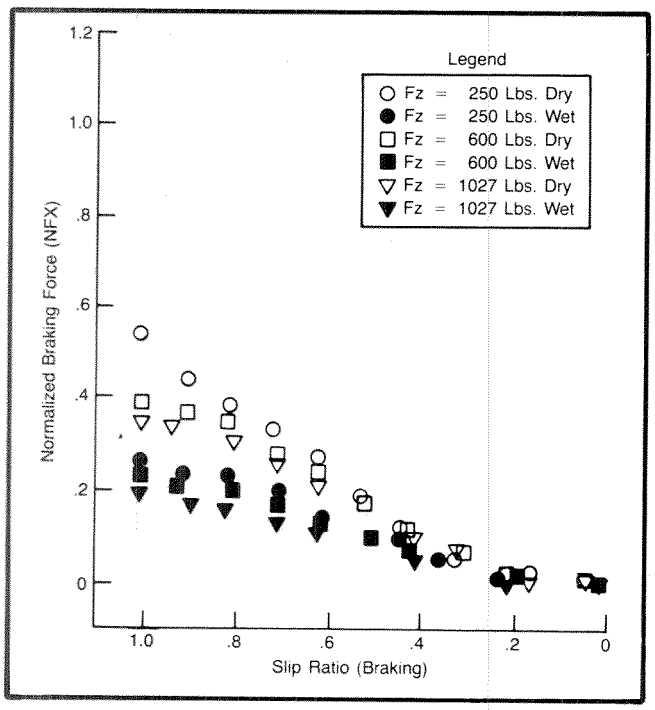

Figure A-7. Normalized braking force versus slip ratio (braking)—slip angle = 60°

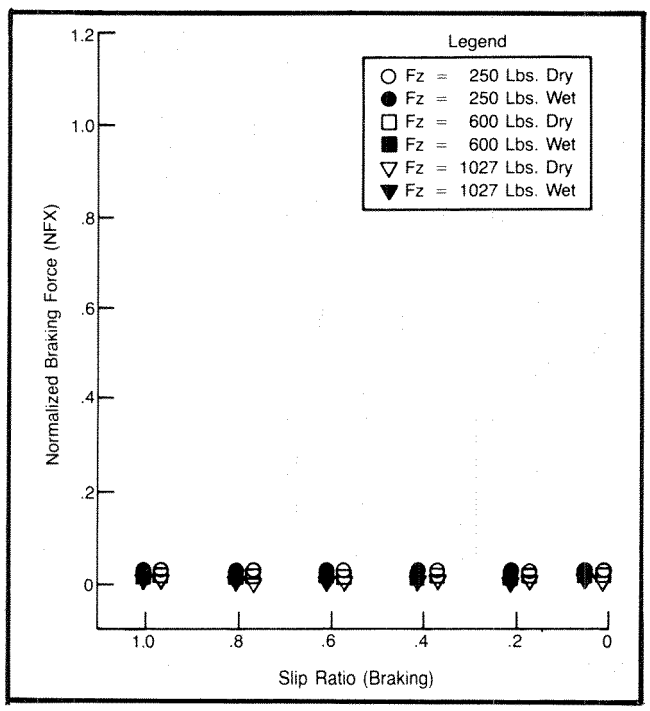

Figure A-8. Normalized braking force versus slip ratio (braking)—slip angle = 90°

Appendix B

Examination of Appendix B reveals the following observations:

- The normalized lateral force data in Figure B-1 are for combined cornering and braking at a 0° slip angle. The normalized slip force is zero on both the wet and dry surfaces regardless of the degree of braking slip. However, once the tire develops a slip angle, the normalized lateral force becomes very much a function of braking slip. The data in Figure B-2 show the normalized lateral force decreasing from around 0.5 to 0.05 as the tire goes from a free rolling condition to a locked-wheel braking condition. The data in Figure B-2 show only a limited difference between a wet and dry surface.
- The normalized lateral force in Figure B-3 is for combined cornering and braking at a 12° slip angle. The normalized lateral force is much higher on the dry surface than on the wet surface. However, the normalized lateral force on both the wet and dry surfaces again decreases rapidly as the tire approaches lockup. The data in Figures B-3 through B-8 show that as the slip angle increases, the locked-wheel normalized lateral force becomes higher and higher until it is the same value as the free rolling tire at the 90° slip angle value.
- The normalized lateral force in Figure B-8 shows higher normal load dependency on the dry surface when compared to the wet surface. It is clear from the data that the higher normalized lateral forces are achieved with lower normal loads. This effect is very prominent for the dry surface.

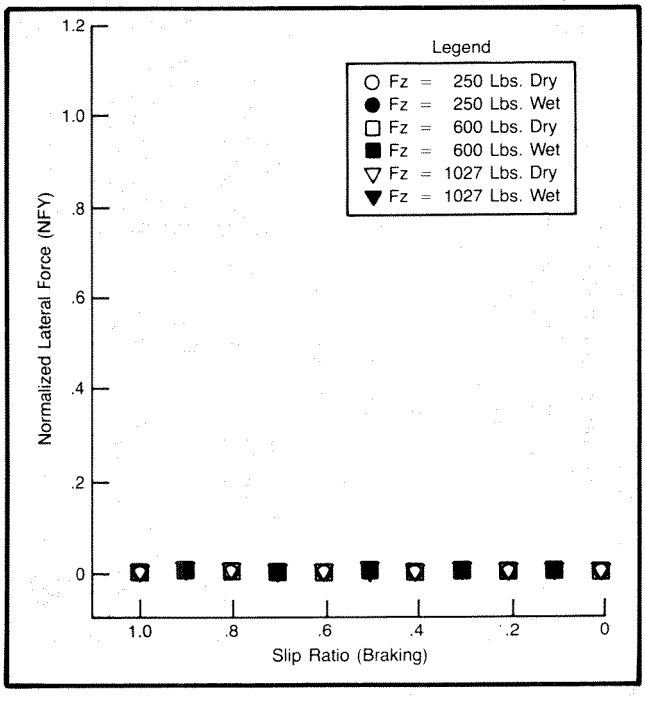

Figure B-1. Normalized lateral force versus slip ratio (braking)—slip angle = 0°

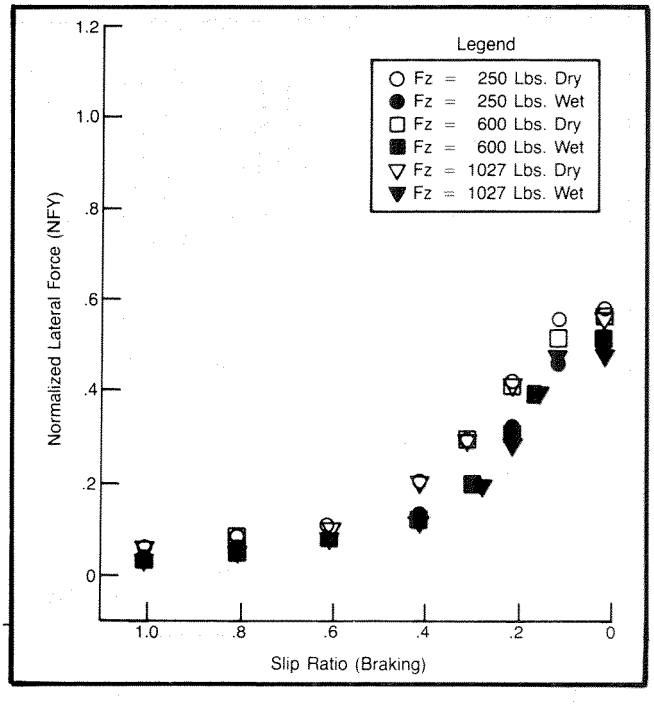

Figure B-2. Normalized lateral force versus slip ratio (braking)—slip angle = 4°

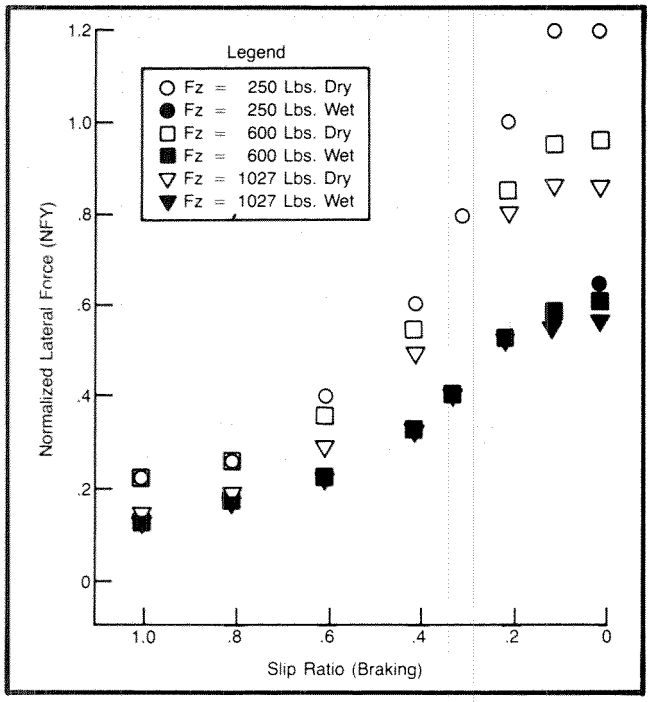

Figure B-3. Normalized lateral force versus slip ratio (braking)—slip angle = 12°

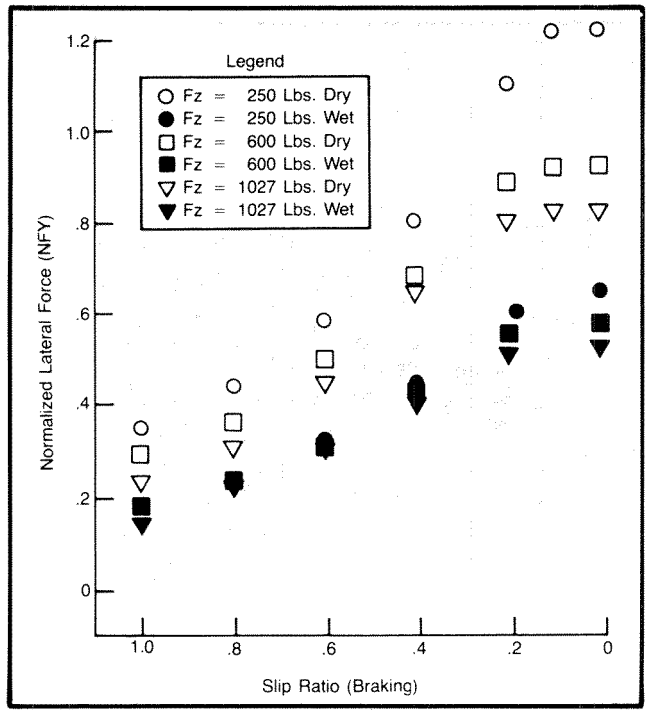

Figure B-4. Normalized lateral force versus slip ratio (braking)—slip angle = 12°

Figure B-6. Normalized lateral force versus slip ratio (braking)—slip angle = 50°

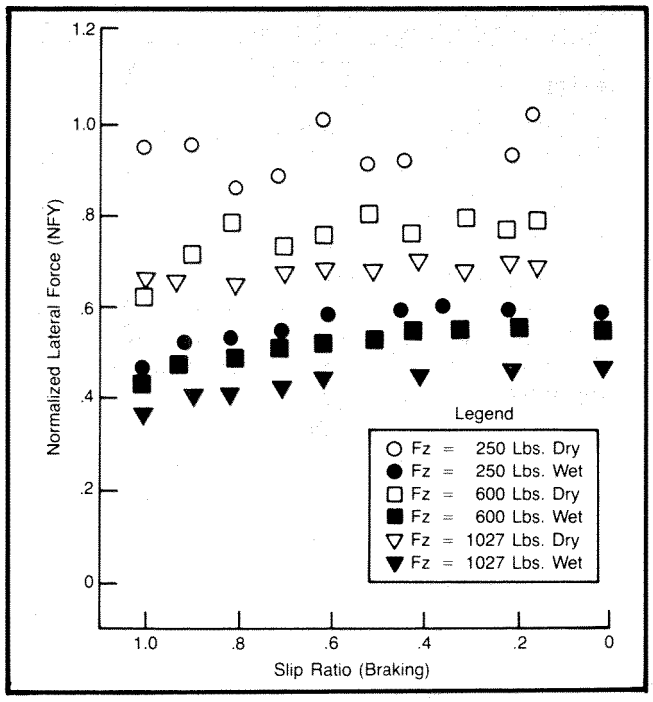

Figure B-7. Normalized lateral force versus slip ratio (braking)—slip angle = 0°

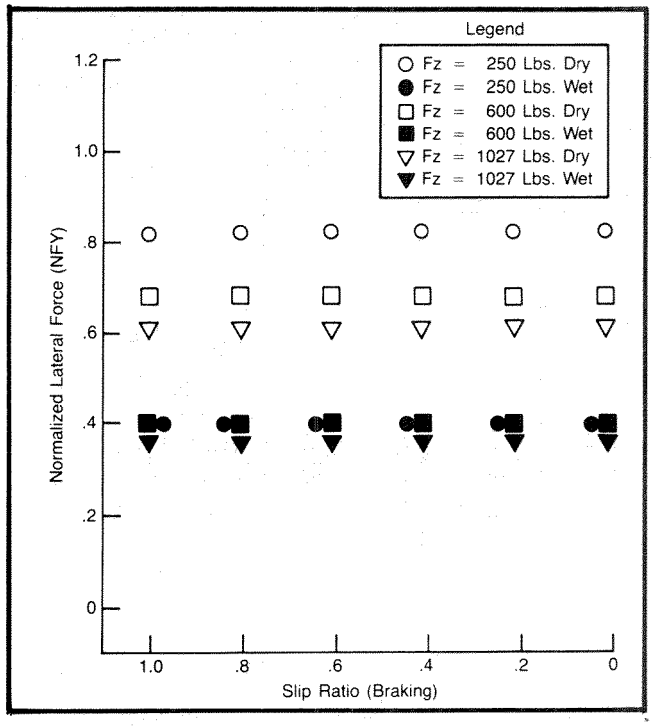

Figure B-8. Normalized lateral force versus slip ratio (braking)—slip angle + 90°

Conclusion

- Tire braking and cornering performance for the test tire, and thus the resulting vehicle performance, has been shown to be very similar on both wet and dry surfaces in the small slip angle and braking slip range. The braking and cornering performance on wet and dry surfaces has been shown to be very different in the large slip angle and braking slip range.
- The data have shown that the overall vehicle braking and cornering performance level can be increased by equipping vehicles with higher load range tires.
- The tire performance data in this study have also shown the possibility that vehicle stability during cornering and braking might be increased by equipping the rear wheels of vehicles with higher load range tires.
- Tire normalized cornering forces are largely surface-independent in the region of small slip angles (less than 4° slip angle).
- Tire normalized cornering forces are largely surface-independent in the region of small braking slip (less than 20 percent slip).
- The peak and slide normalized braking force is very much surface-dependent. The higher the friction coefficient, the higher the peak and slide values.
- The normalized lateral force is surface-dependent above 4° slip angle.
- The normalized braking force is normal load-dependent, especially on a dry surface. The lower the normal load, the higher the normalized peak and slide braking forces.
- The normalized lateral force is normal load-dependent for slip angles above 4°. The lower the normal load, the higher the normalized lateral force, especially on dry surfaces.

The above conclusions are based on the tire performance data measured in this one study.

Recommendations

- Tire design should be explored to increase wet tire braking and cornering performance.
- Tire wheel rim diameter and width, as well as tire aspect ratio, should be examined for their potential to increase tire braking and cornering performance, especially in the nonlinear, more severe, performance range.
- Tire load range should be explored as a potential tool for increasing vehicle braking and cornering performance as well as vehicle yaw stability.
- Tire normalized cornering forces are largely surface-independent in the region of small slip angles (less than 4° slip angle).

Accident Avoidance—Crosswind Sensitivity of Some Streamlined Cars

M.A. Jacobson
Consultant, The Automobile Association, United Kingdom

Abstract

This paper is based on a detailed analysis of real-life situations and is intended to highlight some of the problems that can occur with modern lightweight cars when their aerodynamic shape approaches that of an aerofoil. The problem of disappointing straight line stability when travelling at speed may be more pronounced in the United Kingdom than in Central Europe where one of the cars so flawed was conceived and developed. The topography, significantly higher crosswind speeds, the alignment of the main trunk roads relative to the prevailing winds of high speed, and the proneness for such winds to have extraordinary gust levels are cited as an explanation for the difficulties experienced by motorists when the low drag, front-engine, rear-wheel-drive car was launched in 1982/83. Progress has been made to minimise the handling problems under high speed and crosswind situations, but there is little chance of achieving better driver skill. Therefore, it must fall on the carmakers to do better and make their product fit for even morons to drive safely and be as predictable in their road manners in wet, windy weather as under less demanding conditions.

Introduction

Despite many significant advances in techniques, the information on the contributing factors to accidents or near-misses is still very scant and imprecise.

It would be wonderful if automobile engineers and those concerned with preventing road accidents could have the same feedback the aircraft industry has on the operational performance of its products and even on the causes and sequence of events leading to a near-miss or actual accident. The precision of the results obtained in forensic analysis of aircraft mishaps is beyond what can reasonably be expected in a reconstruction of road accidents. In car accidents, there are generally no precise and reliable data up to the moment of collision or impact. Motor cars do not have black boxes or flight recorders to assist an investigator in reconstructing the sequence of events, including operator errors of judgement and their consequences.

By comparison, the reconstruction of road accidents is fairly crude and remains more of an art than a science since it is often based on intuitive reasoning.

Major Contributing Factors to Road Accidents

In accident reconstructions, it is rarely possible, nor indeed necessary, to give precise answers as to what did take place, e.g., speed and driver avoidance action. The best one can hope for is to note the limiting values of the principal parameters that determine if a situation arose where an accident became inevitable or could have been avoided by a driver exercising reasonable care and competence.

The principal and interacting factors are—

- The driver, his care and attention, skill and experience, concentration and alertness, and state of well being, which includes not only drink and drug side effects, but also emotional stress
- The speed of the vehicles involved
- The road layout and special topographic features
- The dynamic characteristics of the vehicles involved
- The weather conditions, including ambient temperature, intensity, and direction of strong winds
- The condition of the tyres

Generally it is difficult to give precise values to the first two factors listed above. However, it may be possible to state a range of probable values and, by a process of iteration, give a close approximation of the most likely sequence of events that led up to the incident. In particular, the driver's reactions to a given traffic situation can span a wide range of possible options, from timid and slow to brash and erratic.

It is, regrettably, still left to professional test drivers and motoring journalists to pass judgement on the general handling characteristics of vehicles. Their approach to a car is not typical of more normal motoring. It takes most drivers quite a while to become attuned to an unfamiliar model. The insurance companies can verify that a disproportionate number of minor scrapes occur during the first few weeks following a change of car. This may be a sad reflection on how well we prepare motorists for modern fast-flowing traffic and dealing with confined parking spaces.

The only deduction one can safely come to is that wherever possible, the cars and subsystems should compensate for the inadequacy of those who drive them to get them safely out of tricky situations. In other words, make the car inherently safe even when the driver is not as competent as he or she should be.

I have chosen a particular accident, not because it was a fatal one, but because it illustrates a number of interesting features and was particularly well investigated in greater detail than most such accidents. It was a single-car accident on a well-maintained trunk road.

Accident Analysis Involving an Airborne Family Car

The case involved a young driver with only limited driving experience and on his first outing with a new 1.6-l car capable of a top speed of 101mph in wind-free conditions on a level road. He survived, but his fiancee did not. His general alertness and ability to respond to changing circumstances was poor, at least when he was subjected several months later to fairly simple tests.

There are some features of this car that make this model distinctly different from others of the same general shape and weight (2,400lb). It is front-engine, rear-wheel-drive, has all independent suspension, but does not have a very stiff floorpan, particularly on that section against which the rear suspension struts react. It has a pronounced aerodynamic shape. When travelling at speed, it has been noted and adversely reported on by several independent car testers that the early models (1982/83 build year) could be affected easily by strong winds.

Driven steadily but vigorously into a fast bend, even the 1982/83 models behave well, starting off with a mild understeer and then progressing into a mild oversteer as speed is increased, provided the throttle is kept constant. But if the driver loses confidence halfway through the bend and takes his foot off the accelerator pedal, the rear can slide out so rapidly that many motorists could find it quite difficult to regain control.

When one encounters strong crosswinds or fairly low tyre-to-road grip conditions, this model is more prone to rear-end breakaway than a comparable front-wheel-drive car.

One should not forget that the instinctive reaction of most drivers is to take their foot off the accelerator pedal when they note they have entered into a bend too fast or feel that the rear end of the car is about to drift sideways. Attempts to correct this by counter-steering are usually too late, partly because of the steering system characteristics and primarily because most drivers lack experience of "driving at the limit."

The ability to drive effortlessly and surefootedly at the limit of tyre-to-road adhesion characterises a good rally driver, for he can control a drifting car by rapid steering and throttle application. An ordinary motorist cannot.

It was considered worthwhile to compare the 1982/83 model with a 1984/85 model (in which several modifications were introduced to improve the car's behaviour) and with its direct competition (which is front-wheel-drive), and to do so not only under proving ground test conditions but also on motorways under strong crosswind conditions. Under wind-still conditions, all three behaved predictably and were at all times under perfect driver control. However, at the time of the accident, conditions were far from ideal. Under strong crosswinds, the latest version of the front-engine, rear-wheel-drive car was much improved, but even then it was still not as well balanced as its front-wheel-drive competitor. The manufacturer achieved this improvement in his later model by subtle changes in some body panels, notably stiffening the floorpan torsionally, stiffening the suspension, and lowering the ride height. Also, attempts were made to introduce a controlled amount of eddying of the airflow over the rear quarters and thereby reducing aerodynamic lift at the rear end.

The Accident Site Conditions

Although the inspection of the site and the relevant measurements were undertaken some time after the accident, clear marks were left on the road, the kerb stone, grass verges, hawthorn hedges, telegraph posts, farm gate, and the grassy bank beyond the sunken farm track. They allowed one to plot the progress of the car throughout the incident, including its trajectory while airborne. It also helped to pinpoint where the car made contact with fixed objects and to note concentrations of scattered glass from light units, dirt from under-wing areas, window glass, wheel trim, etc.

The car had come up fast along a stretch of dual carriageway, and had overtaken a slower moving vehicle while still climbing the long 1 in 12 rise. The road then levels out before dipping into the West Broughton Hollow, again at 1 in 12; it follows a wide curve.

I have safely negotiated this stretch of road in almost wind-free conditions with a wide-open throttle, reaching 86mph as I breasted the rise and 91mph as I thundered down into the hollow; the road was dry. But the test car was a 1.6-l front-wheel-drive car of a competitor's make.

Wind and Weather Conditions at the Time of the Accident

There had been some sporadic, moderate rain showers and considerable gusting of winds, with wind speeds over nearby Met Office Stations exceeding 20mph.

When the car breasted the rise, the gusty crosswinds were coming at it at an oblique angle of about 40° to 60° relative to its line of progress, but the presence of hedges on both sides of the dual carriageway and a dense windbreak of trees on the opposite side would cause the full force of the crosswind to be deflected upwards and most of it would pass over the roofline of the car.

Shortly before coming into the hollow proper, the line of fir trees stops abruptly and a car travelling westward toward Uttoxeter would suddenly be experiencing the full force of the crosswind striking the car at about 50° relative to its line of progress.

The wind speeds recorded at the time of the accident are by no means exceptionally high for the United

Kingdom. Much more severe conditions must be catered for in the overall design of a modern car.

The Condition of the Tyres

Since the car in question had only covered some 280mi prior to the accident, the tyres had hardly been bedded in and had not yet developed their full grip potential, particularly on a rapidly drying, yet still damp road surface. Table 1 gives an indication of how the surface condition of well-maintained roads influences the optimum braking one can expect. The braking distance is a measure of tyre-to-road grip.

While some tyres are "grippier" than others under thin film conditions, thanks to their special tread rubber compositions, all tyres behave very indifferently when a well-trafficked road surface is covered by only a thin film of moisture, though more and more modern tyres develop a good grip on rain-drenched roads.

Determination of Car's Speed at Moment of Leaving the Road

Skid marks were left on the road and some were clearly striation marks, indicating that the car was travelling sideways for a time. It was relatively easy to obtain values of tyre-to-road grip for the three conditions—dry, wet, and damp road surfaces—by braking to a standstill with locked wheels.

At speeds above about 60mph, there is the risk of aquaplaning when the depth of water is about 2mm; this is typical for summer rainstorms. Generally, though a thoroughly wet road tends to give a better tyre-to-road grip than when it is just damp, as, for instance, in fog or morning mist conditions or where the road is drying in patches. It requires frost, salt, and grit application and ample rainfall to open up the road surface texture and remove the thin layer of oil, diesel fuel, and abraded rubber that makes heavily trafficked roads so slippery. *Damp spells Danger.*

Table 1. Emergency braking distances for different road conditions.

The distances are the best that can be expected on well-maintained roads having either a tarmac or concrete surface. The figures are the distance, in feet, from a given initial vehicle speed to standstill and include reaction distance.

Initial speed mph	Total Braking Distance (ft.) For Different Road Surface Conditions & Sound Tyres				
	Black Ice	Damp	Wet Road		Dry Road
			1mm Tread Depth	5mm Tread Depth	
5	11	7	7	6	6
10	34	17	16	15	14
15	70	30	28	26	24
20	120	47	42	39	36
25	155	60	55	50	47
30	260	90	85	73	67
35	345	117	105	93	85
40	440	148	130	116	106
45	555	185	161	141	129
50	675	222	195	170	156
55	815	265	230	205	185
60	960	315	270	240	215
65		365	350	275	250
70		420	500	315	285
75		480	600	360	320
80		545	800	400	365
85		620	930	450	405
90		700		500	450

Depth of Water 2mm

For the road in question, typical values were found to be:

μ (dry road surface) = 0.75 to 0.8
μ (wet road, rain) = 0.6 to 0.68
μ (damp, particularly after a long dry spell) = 0.55

The striation marks indicated that the car was driven in excess of the critical speed for the curve. As long as the car is maintained at this critical speed, there exists a balance of forces: $a.r_c = v^2$

In this:

v = constant forward velocity of the car
r = radius of curvature
r_c = critical radius of curvature, i.e., the minimum radius of curvature at which a neutral steering car can be driven at constant speed v without drifting out
a = limiting lateral acceleration = μg
μ = maximum tyre-to-road grip coefficient
g = acceleration due to gravity

The radius of curvature at the critical location is around 700 to 780ft, depending on the line taken by the driver:

For the dry road condition:
v_c= critical speed = 88½mph to 96½mph
For wet and rainy conditions:
v_c= 79mph to 89mph
For damp road surface:
v_c= 76mph to 80mph

This leads to the conclusion that the car must have been travelling in excess of about 75mph when the driver lost control.

The Airborne Phase

There was ample evidence, on the spot where the car had left the road, that it had struck the kerb with the front wheels still rotating, for good tread pattern imprints were left on the kerbstone and the verge.

Striking the kerb would tilt the car very slightly upward. The aerodynamics of the car would encourage rather than suppress this attitude at takeoff. Thereafter, the car continued as a free-flying object across a sunken road, hedges, a pond, and a pasture before striking a rising grass bank some 88ft from where it took off, riccocheted off, and rolled over twice forward and once backward before coming to rest as a broken and buckled piece of machinery.

In the analysis used, the slowing-down effects due to brushing against hawthorn hedges, a telegraph pole, and the pole of a traffic sign as well as air resistance have been ignored. There was no evidence that the car had been badly dented by contact with these fixed objects.

Since the top of the hedge can yield elastically when the car first strikes it and since there were two nicks on the wooden telegraph pole, caused by the edge of the front and rear bumpers of the car, two of the points of the trajectory could be fixed only approximately. Also there was a degree of uncertainty about the actual height of the point of first strike on the soft bank some 88ft away from the takeoff point, i.e., relative to the starting point of the free-flight parabola, for the car had spun in mid-air and there was evidence that the first part of the car to make ground contact was the side of the car. It could, however, only be within a fairly narrow range.

When due correction is made for the centre of gravity position of the car, it had to be at least 7ft and no more than 8½ft below the take off point.

Altogether, seven points of the trajectory could be ascertained, of which three were only approximate. Accurately plotting them and giving the uncertain ones a realistic tolerance range confirmed that the car had followed a true parabolic trajectory and partly turned while still in free flight.

It was, therefore, considered legitimate to use a simple formula, which is familiar to those interested in ballistics.

The general formula for an object propelled like a flying projectile is:

$$\mu = R \sqrt{\frac{-g}{2\,(H - R\tan\Theta)\cos^2\Theta}}$$

in which:

μ = initial velocity at start of free flight through the air
g = acceleration due to gravity
R = range
H = height of point of impact above or below starting point
θ = angle of elevation of flying object relative to the ground at the start of its trajectory

Measurements taken on site were:

R = 88ft
H = -7½ft to -8½ft

There could be a range of values of θ; however, the scrape marks left on the hedges clearly rule out a large proportion, e.g., negative values of θ, as well as those greater than about +3°.

For R = 88 ft and H = -7 ft or -8½ft respectively

$\Theta = 0°$	μ = 91mph	μ = 82½mph
$\Theta = 1°$	μ = 82½mph	μ = 76mph
$\Theta = 2°$	μ = 76mph	μ = 71mph
$\Theta = 3°$	μ = 71mph	μ = 66½mph

Given the situation of a relatively inexperienced driver, unfamiliar with the road manners of the make of car, which is so markedly different from its predecessors and many other current motor cars, and the damp road surface on this fast downhill bend in the dual carriageway road, as well as the gusty side winds, it would be almost a

foregone conclusion that the driver would lose control of his vehicle if travelling at speeds in excess of about 80mph. It would all be over in about 1.5s, during which the car would be airborne for about 2/3s.

Why Should This Model of Car Be So Sensitive to Crosswinds?

It is not unknown for aerodynamic-shape cars to be crosswind sensitive, and a number of well-known manufacturers did have to stop selling, withdraw, or drastically modify the offending models, usually only after public pressure, severe criticism by the media, dramatic "roof bending" incidents, or fall-off in sales. In the case of the early Beetle, lack of top speed meant that the most likely and fairly disturbing feature when encountering strong and gusting crosswinds was that the car might be blown across one traffic lane when crossing an exposed road viaduct. In other words, it lacked straight line stability under crosswind conditions.

I have experienced a flip-over in three quite dissimilar models, all without suffering serious injuries, for it was a relatively long period during which lift-off or being turned on the side took place, several seconds in fact, and the slowing down to a stop was on a permanent top road surface or in cultivated fields, where the retardation was due to paint and metal being abraded by physical contact over a large surface area.

To the credit of the manufacturers of these early cars, they did eventually undertake major design changes to minimise these undesirable trends. Also the knowledge of aerodynamic forces and couples generated by strong crosswinds did not exist at the time. It is, therefore, not surprising that mistakes occurred. But since then, a great deal of factual, numerical data have been accumulated in many design studios. Racing cars have developed aerofoils to keep the rear end firmly on the ground, and air dams are now commonplace. The arguments about whether ground effect skirts gave unfair advantages to a particular racing stable could not have gone unnoticed.

The new shape car had been developed in the wind tunnel and undergone extensive proving ground and road testing in Central Europe. Apparently the test drivers and development engineers did not encounter any transient instability or other handling problems.

Limitations of Wind Tunnel Test Results

Adverse comments on the straight line stability were confined to the United Kingdom. The manufacturer concerned had placed total confidence in the results obtained during his wind tunnel testing. Also, since the car was intended for all markets in Europe and had to be very competitively priced, management did not see any need for fitting a rear end spoiler, though this is a standard and very prominent feature on all the more powerful models in this range. They use the same basic body shell.

In the early days of wind tunnel testing, the emphasis in most research departments was on reducing aerodynamic drag, and any side effects this might produce, such as unwanted aerodynamic lift and sensitivity to strong crosswinds, were barely considered to be of any relevance.

In several wind tunnels, it is difficult to yaw the test car sufficiently to simulate a strong crosswind without the wind tunnel bloc effect coming into play; moreover, this bloc effect can give very misleading numerical values. A wind tunnel will, of necessity, have limitations in tunnel cross section, shape of side walls, and power output of the wind generators. It will, therefore, be almost inevitable that when a vehicle is significantly yawed relative to the wind generator fans, some of the air blown over it in a parallel stream of uniform velocity will be deflected against the sidewalls of the wind tunnel and then be bounced back to pass over the rear end of the vehicle so being tested and thereby significantly modify the air velocity gradients in the wind tunnel. In most real-life situations, this crowding effect is absent. The greater the yaw angle, the more unreliable the wind tunnel results tend to be.

One way around this would be to use wind generators on proving grounds more extensively. Judging by the rusty state of several of them (for example, those at MIRA), they are not being used all that often, and the reasons are all too plain. The airflow mass and pressure characteristics of even very powerful compressors are puny when compared with nature. The nozzle size and the airflow velocity are such major limitations that only moderate crosswinds can be simulated. To create a yaw angle situation representative of what can take place in high winds, say a 15° to 18° angle of attack of the resultant airflow as it passes over the car's body, the speed of the vehicle as it passes the compressor exit duct nozzles at a right angle will have to be quite modest, i.e., about half the maximum speed of the car. In most modern cars, crosswind sensitivity will not occur at legal speeds in the United Kingdom, i.e., 70mph or less. However, people do motor well above that speed.

Since this 1982/83 model has neither a small air dam at the front nor anything resembling an aerofoil spoiler at the rear end, the car will experience a considerable aerodynamic lift when travelling at speed.

The effect of aerodynamic lift increases as the square of the velocity of the air flowing over the body shell. The airflow velocity over the body is the resultant of two velocities, which must be compounded by vector analysis. The first force is due to the forward speed and the second is due to crosswinds.

As long as the car travelled in the wind shadow provided by the line of trees, there was hardly any

crosswind contribution. But as the car emerged from the wind shadow of the trees and dipped into West Broughton Hollow, there was not only the additional air speed component of the gusting crosswind to be considered, but also the two effects it produced:

1. It suddenly and materially increased overall lift to around 1/10 the weight of the car, which made the steering go light, for there was then less weight acting on the front wheels, and it also lowered the effective load on the rear wheels, which provided the forward momentum.
2. Whereas in a more or less straight-ahead driving mode the centre of gravity and centre of pressure coincide, the presence of a crosswind would tend to make the car yaw in much the same way that a sailing boat reacts to wind forces.

The centre of pressure is the point at which one can consider all the wind forces to act on the car, but it does not coincide with the centre of gravity. The greater the distance between the centre of gravity (the point at which one can consider all the weight acting on the suspension to be concentrated) and the centre of pressure, the greater the leverage of crosswind forces. This creates a moment of trying to turn the car off its original straight line course. Such a moment must be resisted by sidegrip forces exerted by the tyres on the road. The sideways grip will be limited by the tyre and road surface conditions.

There is a third centre—the centre of lift at which one can assume the combined vertical lift forces to act. Ideally this centre of lift should not move as the car travels faster, nor should it be influenced by crosswinds. Should the centre of lift move rearward, then an aerodynamically induced oversteer will occur, which is exactly the opposite of what is desirable.

The car in question suffered badly from this aerodynamically induced oversteer phenomenon, particularly at higher speeds. When the winds were gusty and exceeded about 30mph mean velocity, then the sensation of crosswind wander and the need for instant and rapid countersteer would occur even at 70mph. One moment the car would be going as straight as an arrow; the next it would appear to dart off at an angle or move over bodily when passing close to a high-sided truck or coach. I have repeatedly experienced this in the United Kingdom.

This tendency is less noticeable on the continent of Europe for several reasons.

It is a little known fact that the geography and topography of Great Britain has resulted in many of the major trunk roads being so aligned that when strong crosswinds do occur, they strike traffic at an oblique angle of 15° to 90° on their North-South progress and on the East-West connecting roads on the sections where the hills provide little windbreak at around 30° to 90°, all relative to the line of progress of the vehicle.

In Central Europe, and that includes the manufacturer's proving ground area, the prevailing winds tend to be of lower intensity and less gusty inland. Also the terrain tends to be more broken up by hills, forests, and copses acting as wind force moderators.

There are, of course, exposed sections of trunk roads and motorways, but these and bridges and viaducts are liberally equipped with wind socks, which give unambiguous signals of wind intensity and direction. This gives the driver the sort of early warning that allows him to moderate his speed and thereby minimise his being blown about as he emerges from the protection of the wind shadow.

Where no such advance warning is received, it is all too easy for an average motorist to brake hard when he suddenly feels the crosswind buffeting him. This can result in a fairly sudden transfer of weight from the rear to the front. This reduces the weight on the rear tyres to the point of momentary loss of grip on the road, particularly in the damp, and the back may then slide out at an alarming rate.

Comparison of the 1982/83 Model with Previous Models

Whatever one may have thought about the previous models and their lack of all-around independent suspension and other modern refinements, hundreds of thousands of motorists all over the world proved that these three aerodynamically unrefined box cars were utterly predictable and far less affected by crosswinds; also there was no aerodynamic lift at high speed making the steering go very light.

By current standards, these earlier models are aerodynamically clumsy. Their general shape—a three-box arrangement—and the detail treatment of the body panels, windows, etc., lead to considerable eddying and absence of an uninterrupted flow of air over the body shell. In a well-streamlined body shape with smooth contours, the flow of air over the body is laminar, not turbulent, and this laminar flow follows Bernoulli's law. For airflow over the body to be continuous, that part of the airstream that passes over the bulbous (more convex) upper part of the body must meet up, a short distance behind the body, with that part that passes over the almost flat underside. The part of the airstream that has further to go over the bulbous part must, therefore, be travelling faster than the average air speed.

It is a fundamental law of nature that, as air is speeded up as it flows over the more convex part of an aerofoil (the upper part), it creates a lift. The faster the airflow, the greater this negative pressure (the lifting force). The basic principle underlying powered flight of heavier-than-air machines relies on this law of nature.

Fastback cars are particularly prone to generating lift at the rear end because the airstream on this relatively smooth contoured, very aerodynamic car remains well

attached to the upper body without much eddying or turbulence. Broken flow causes a loss of lift. In an aeroplane, this is called wing stall.

As the aerofoil approaches the stall situation, the lift diminishes to the point of collapse.

It is surprising that the manufacturer, who had ample experience of building fast motor cars for sports and rally enthusiasts, did not make a discrete rear and spoiler a standard feature across the model range. More and more competitors add simple and discretely short rear-end bustles and/or rear-end spoilers to their family cars and not only to their high-performance derivatives.

The purpose of these rear-end spoilers, which take extreme proportions on racing cars, is to insure that at speed and in crosswind conditions there is a downward force acting on the rear wheels rather than an aerodynamic lift.

This is most needed in powerful rear-wheel-drive cars, for any lowering of such downward forces reduces the tyre-to-road grip. For the same tyres, the greater the downward thrust, the greater the ability of the tyres to provide the necessary control forces. These are fore and aft for acceleration, steady speed, and braking, and sideways to hold the car on a predetermined course to prevent sliding or skidding. Absence of adequate sideways grip causes the car to be jolted by crosswinds, particularly when these are gusty and coming out of the wind shadow of tree-lined banks onto open, exposed road sections or after overtaking high-speed trucks or passing bridge parapets. The lighter the car and the more aerodynamic its shape, the more pronounced its tendency to be upset by gusty crosswinds unless spoilers are fitted.

A new industry now caters to motoring enthusiasts. Since the launch of the car, some specialist accessory manufacturers have cashed in on the reluctance of the manufacturer concerned to do it in-house. Offered are well-advertised add-on fitments to improve both the front and rear end deflection of airflow and thereby reduce crosswind sensitivity at speed. The car manufacturer concerned is now making the optional extra of stylish add-ons available through some of its major dealers, at least in some of its European markets. Does that imply this large carmaker is accepting that wind forces can be troublesome, at least in the United Kingdom, and that it is up to the carmaker to so design even his base models that they can cope with the worst that nature and press-on motorists can do to upset straight line progress?

United Kingdom Wind Conditions

Table 2 gives an indication of what the motorist in the United Kingdom has to face from time to time. The resultant wind-speed yaw angle increases rapidly as crosswind velocity rises. Moreover, what should concern the stylists and body designers and those perfecting the running gear is the rate of this increase from zero to more than 7°, which occurs as the car proceeds from the wind shadow of a tree-lined bank, or that provided by long high-sided trucks, into the full force of a crosswind of around 30mph. It takes only a fraction of a second for this transient, yet powerful, disturbance to get a hold on the car. It is the dynamic response of vehicle and driver to reestablish a new state of equilibrium, rather than the actual displacement of the car from its straight line progress, which can occasionally unnerve the ordinary motorist.

The wooliness of the response to transients is often due to there being too much compliance in the various rubber-bonded attachment points of the suspension and steering elements to the body structure.

It is of little concern to the ordinary motorist that all this may be due to either an inadequate, over-simplified mathematical model used in the early stages of product evaluation and assessment of design options or that the car will have to be tethered in an unrealistic way during wind tunnel testing. Nor is it any comfort to him that such problems will be cured by a step-by-step refinement as time goes by. Nor can one hope that the explanation will be accepted as adequate, that in mass-produced cars it may be necessary to have a considerable amount of built-in compliance to smooth assembly and that at the same time it minimises noise transmission from running gear to the passenger compartment. It will not cure the problem nor restore public confidence in some models.

Crosswind effects should not be seen in isolation, of course. It is all too easy to exaggerate the frequency of the occurrence of strong crosswinds. It is possible to draw up tables that indicate the intensity and duration of strong winds likely to occur in the United Kingdom and, e.g., Germany. The one given here is based on United Kingdom and German Met. Office records covering a 10-year period. Strong winds are not an everyday risk factor, nor do the winds always blow from the same quarter.

How Strong Are the Transient Wind Gusts Experienced in the United Kingdom?

While it would be unrealistic to demand that a carmaker design his lightweight cars to be able to proceed at almost maximum speed under every wind condition, a realisation of what the peak wind speeds can be would not come amiss. In the flying car analysed here, the peak gust speed was only 42mph and the yaw angle this induced rose in a fraction of a second from zero to 12°.

Very high winds are occasionally encountered in Scotland. Mean hourly wind speeds in excess of 70mph have been recorded at Glasgow and Edinburgh Airports,

Table 2. Annual percentage frequencies of wind near main trunk roads

For the purpose of direct comparison, wind conditions are also given for two North German locations.

All these values refer to steady wind speeds averaged on an hourly basis. A gust factor of 1.6 to 2.0 has been established on many sites, where duration of such gusts may only be a few seconds at a time.

* less than 0.1 percent but more than 0.05 percent

with short gusts, lasting at least 5s, exceeding 100mph. On the Firth of Forth Road Bridge, the corresponding values were over 75mph and over 105mph.

But the southeast of the country is not spared either. Winds in excess of 55mph, gusting to over 85mph, were recorded in 1978 close to the main trunk route linking London and Dover. A little more inland, but close to the M20, these winds were 53mph, gusting to 76mph on a number of occasions.

Even the Midlands do not escape high wind speeds: 50mph winds with a minimum duration of 1 hour have been noted near Birmingham and also near Bristol, Gloucester, and further north near Shrewsbury. On a number of occasions, short-duration wind gusts of around 80mph were recorded at these locations.

Well inland, average wind speeds of between 45mph and 55mph and a duration of at least 1 or 2 hours have been recorded, particularly near Nottingham, sweeping across the main North-South motorway and its connecting spurs. Wind gusts well in excess of 80mph were also recorded in the same areas.

The more exposed areas of the West Country, Wales, and Scotland experience such high winds not for a few seconds or even minutes at a time; here it can take much longer before the ferocity of such winds abates. The same applies to the East Coast and, due to its topography, this spells trouble for motorists driving on the northern ends of the M1 and A1. The M5 and M6 motorways have been buffeted by wind gusts of over 90mph.

The topography plays a major role because it is the funnel shape of such prominent features as the English Channel, the St George's Channel, between the land masses of Ireland and Wales, and, of course, the Bristol Channel that causes an acceleration of air masses sweeping in from the Atlantic. Such hills as the Mendips and others fringing broad valleys act as deflecting vanes in turbo machinery; they redirect the wind. In short, there are far more major trunk routes in the United Kingdom that are affected by wind than in most European countries.

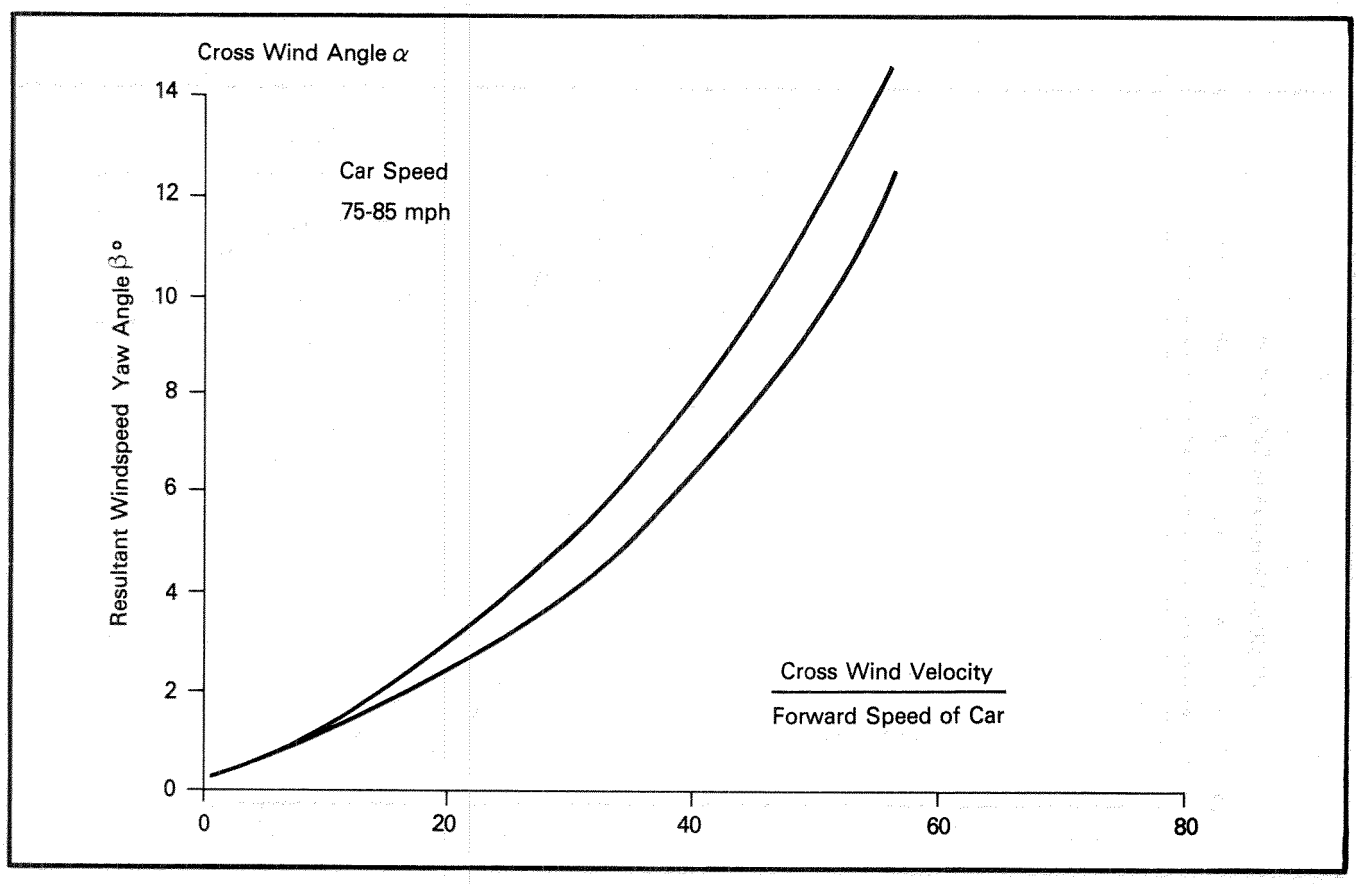

Figure 1. Angle of elevation at takeoff Θ°

Typical High Wind Speeds in Central Europe

Extreme values of wind gusts of at least 5s duration may cause concern to architects and civil engineers who have to erect tall buildings and similar structures capable of withstanding the most severe wind loading, even though they may occur only about once every 50 years. To the automotive engineer, the peak wind speeds that persist for at least 1 hour at a time, on average at least once every decade, are of more relevance. These should be included in the vehicle handling simulation, which can now be so colourfully shown in computer graphics, and therefore allow modifications to be advocated before the cars go on sale.

On the Dutch Coast, they are likely to be 50 to 55mph, yet for many places in Northern Germany, including, among others, Hamburg, Braunschweig, Hannover, Berlin, Essen, Düsseldorf, and Hildesheim, it is more likely to be around 40 to 45mph.

Geography is the prime reason why in places such as Frankfurt/Main, München, Nürnberg, Stuttgart, and Ingolstadt, it is not likely to reach 40mph. In the Danube region of Germany and Austria, wind speeds in excess of 30mph are fairly rare.

Efficient Energy Absorption of Automobile Side Rails

S. Yamaguchi,
H. Kato, and
T. Okazaki
Toyota Motor Corporation

Abstract

The method for stabilizing the axial collapse of side rails in a progressive folding mode, in which more efficient crush energy absorption was insured than in a bending mode, was examined by crush tests of closed-hat section members.

The tests have shown that the properly designed beading functions effectively and the critical collapse length of slant-mounted side rails could be estimated.

Introduction

Side rails absorb a large part of energy in head-on barrier crush tests of automobiles. The side rails deform in two different ways. One is bending deformation and the other is axial collapse in a progressive folding mode, or the axial collapse. The axial collapse absorbs crush energy more efficiently than bending and, therefore, in some cases side rails are designed to be expected to deform in the axial collapse mode for a certain length the head-on barrier crush tests. However, in many cases the side rails fail in a bending mode before the axial collapse mode reaches the expected value.

In this paper, two items are examined concerning the axial collapse stability and critical length of closed-hat section members generally used for automobile side rails.

1. Effective beading (designed dents or bulges) shapes and their arrangement to stabilize the axial collapse
2. Critical length of the axial collapse of slant-mounted side rails

Test Procedure

Figure 1 shows a schematic drawing of the test equipment. Test pieces were attached to the movable barrier and impacted to the fixed barrier. The deformation behavior of the test pieces was observed by high-speed cameras. Crush loads were measured by load cell installed on the fixed barrier face.

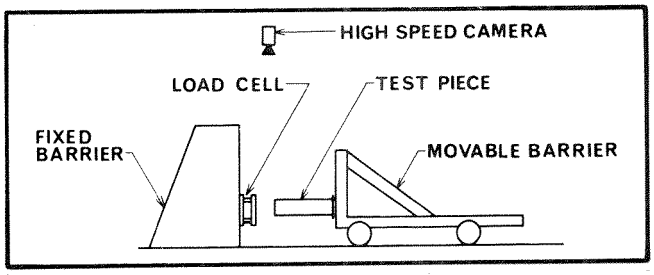

Figure 1. Test equipment

Effective Beading To Stabilize the Axial Collapse

Figure 2 schematically shows the axial collapse mode in regular folding of a closed-hat section member. In stable axial collapse, initial folding occurs near the impact end with peak and bottom lines of waves perpendicular to the axis, and subsequent foldings progress toward the other end with the same wave length (λ).

The purpose of beading is to trigger the stable axial collapse. Therefore, the foremost beading must trigger an initial folding and the other beading must trigger subsequent foldings progressively with the same wave length.

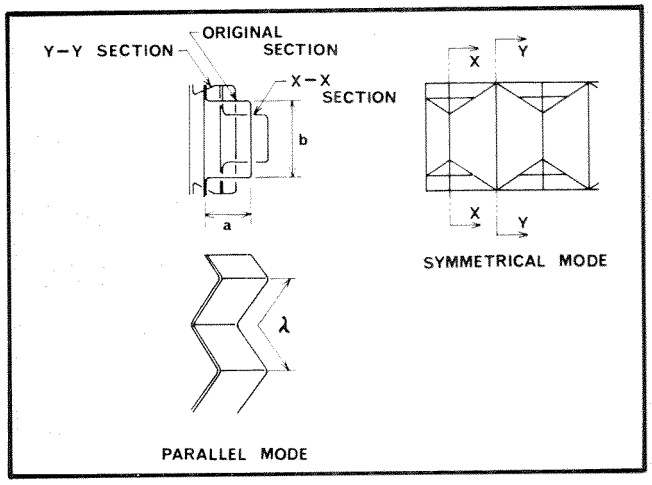

Figure 2. Axial collapse mode

Two series of tests were conducted to examine the effective beading shapes and their arrangement. One was to examine the effect of various beading shapes on a collapse mode and their proper pitches; the other was to examine the effect of combination and arrangement of the beading chosen from the previous tests. It was conducted for the members with and without the combination of beading.

Effects of Various Beading Shapes and Their Proper Pitches

Six types of test beading shapes and their expected effects are shown in Figure 3. Beading was applied to the hat-plate of the member.

Four or five beading pitches (λB) were investigated. The pitches were:

$$\lambda B = \frac{a + b}{2} \times k_i$$

where:

a : *section width*
b : *section height*
k : *coefficient*
i : *1,2,3,4,5*

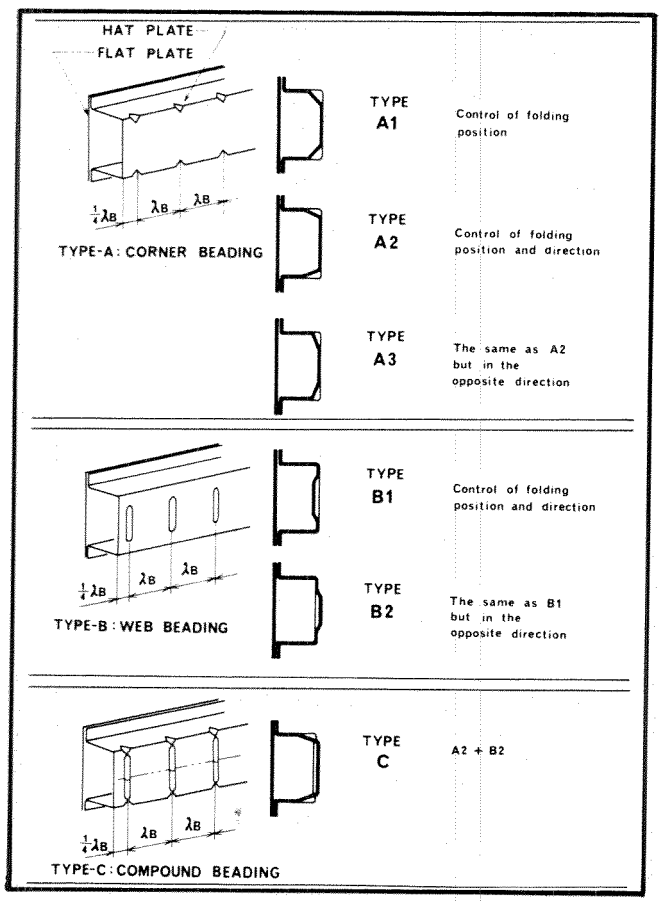

Figure 3. Beading shapes

Test results of maximum crush load (Pmax) are shown in Figure 4. The following were discovered:

1. The corner beading (A1, A2, A3) reduces the maximum crush load approximately by 20 percent.
2. The web beading (B1, B2) reduces less load than the corner beading does.
3. The compound beading (C) reduces the same load as the corner beading does, but it does not progress in subsequent foldings (see test results of folding mode).

Test results of folding mode are shown in Table 1. The table shows the following:

1. Each type of beading, except type C, had its proper pitch (λBO) to collapse the member in a regular folding mode. The proper pitch was:

$$\lambda BO(A1) = \lambda BO(A3) = \frac{a + b}{2} \times k3$$

$$\lambda BO(A2) = \lambda BO(B1) = \lambda BO(B2) = \frac{a + b}{2} \times k2$$

2. Type B1 and B2 beading folded the webs of the section in the opposite directions. Types A2 and A3 beading folded them in the same direction.
3. Type C beading did not allow the member to collapse in a progressive folding mode. All sections with the beading locally collapsed at the initial stage of the deformation, and subsequently the remaining sections between the beading were crushed. This is an extremely unstable collapse mode.
4. All the flat plates did not fold regularly.

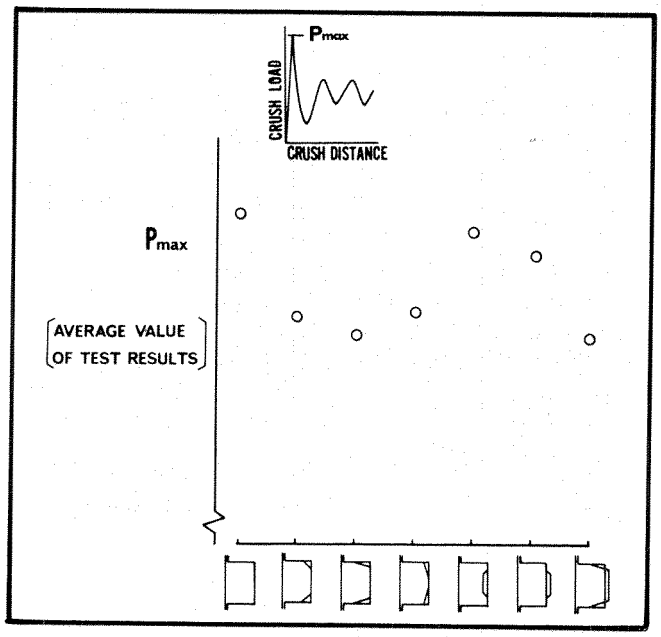

Figure 4. Maximum crush load

Table 1. Folding modes

BEADING TYPES / BEADING PITCHES	A1	A2	A3	B1	B2	C
$\frac{a+b}{2} \times k1$						
$\times k2$	HAT-PLATE / FLAT-PLATE					
$\times k3$						
$\times k4$						
$\times k5$						
NOTES						Regular folding did not occur. All the section with beading locally collapsed at first.

From the results described above, the corner beading (A1, A2, or A3) is suitable for the foremost folding point because of its low crush load. For the other folding points, the web beading (B1 or B2) is suitable because it has a relatively high crush load and regulates the folding direction.

Effect of a Beading Combination

The effect of a beading combination was examined by crush tests of the members with and without the beading. Two types of members were tested. One was straight and the other was tapered, shown in side view in Table 2. Figure 5 shows the combination and arrangement of beading. Figure 6 shows a test member schematically.

Test results are shown in Table 2 and Figures 7, 8, and 9. Both types of the members without beading failed in a bending mode, but those with the combination of beading collapsed axially in a regular progressive folding mode.

Critical Collapse Length and the Mounting Angle of Bumper-Equipped Side Rails

In many cases, side rails require positioning with some mounting angle. Therefore, designers need to estimate

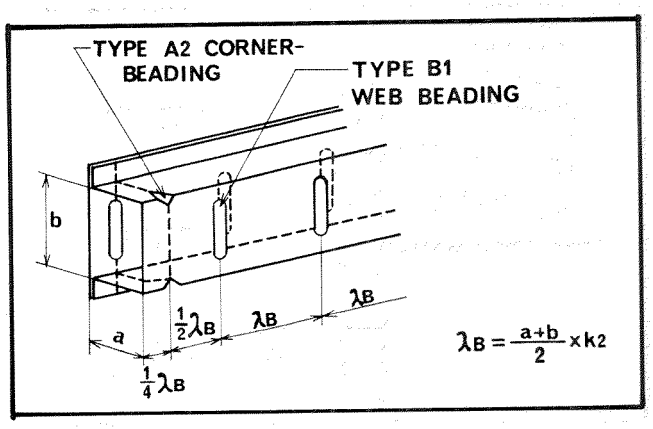

Figure 5. Combination and arrangement of beading

critical length of axial collapse to decide the angle. Slant-mounted side rails fail in two different modes shown in Figure 10. Bending mode A can be prevented by installing an appropriate reinforcement to the rear portion of side rails. Here, the collapse length, before resulting in a bending mode B, is called the critical collapse length of the side rail assembly including the bumper. The critical length was examined by crush tests for various mounting angles of the side rails.

The test side rail is shown in Figure 11. The side rail had a sufficient reinforcement to prevent the mode A bending. The tests were conducted for five levels of the mounting angles (θA and θB shown in Figure 12).

Table 2. Folding modes

SIDE VIEW OF MEMBERS \ BEADING	NO – BEADING	COMBINATION – BEADING
STRAIGHT 	PLANE VIEW HAT – PLATE  FLAT – PLATE	PLANE VIEW HAT – PLATE  FLAT – PLATE
TAPERED 	HAT – PLATE  FLAT – PLATE	HAT – PLATE  FLAT – PLATE

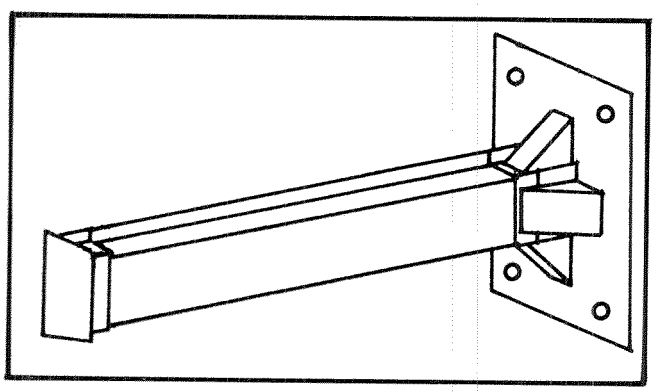

Figure 6. Test member

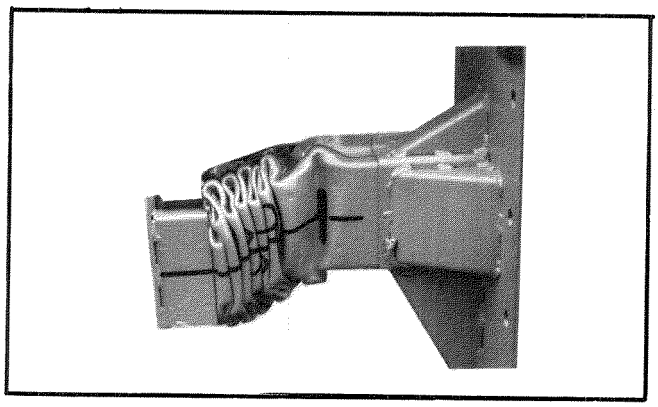

Figure 8. Hat plate of straight member with beading

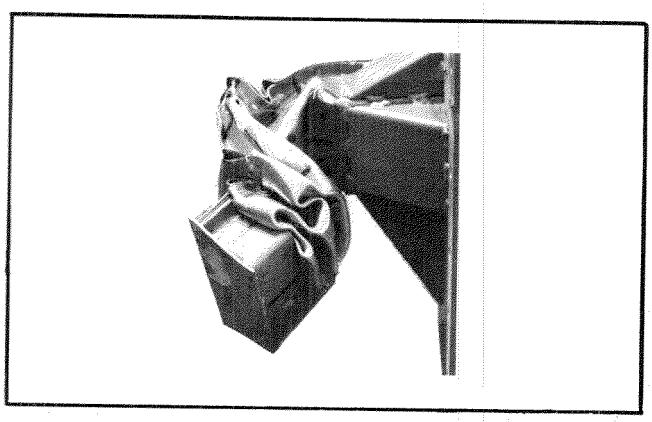

Figure 7. Straight member without beading

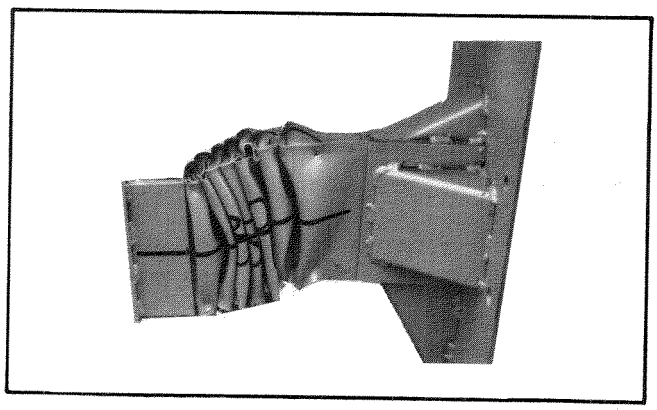

Figure 9. Flat plate of straight member with beading

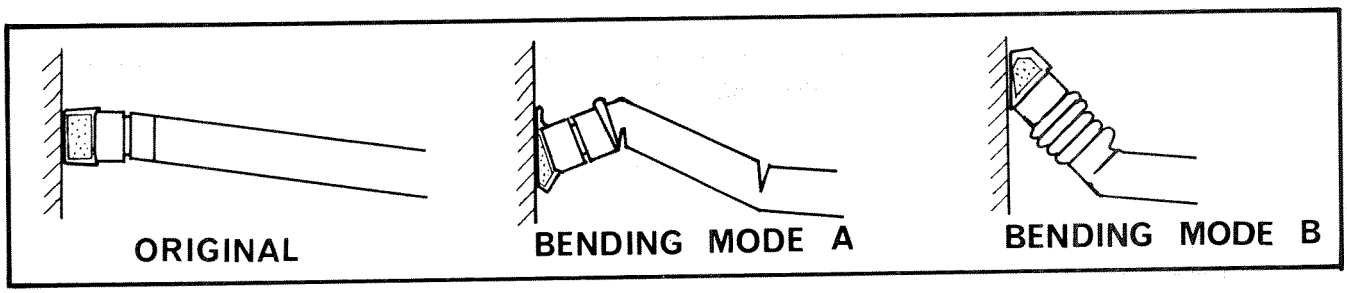

Figure 10. Bending mode of slant-mounted side rail

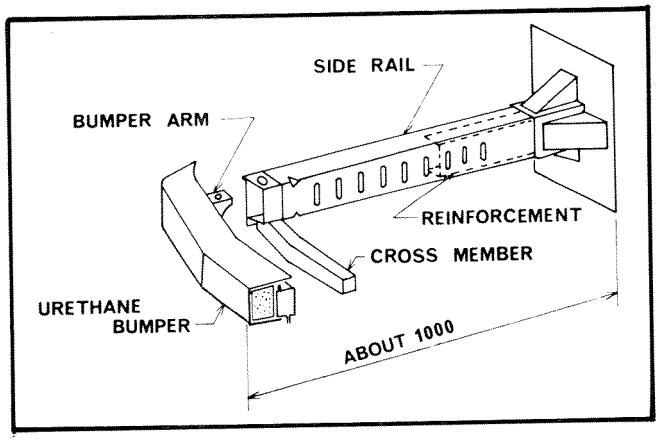

Figure 11. Test side rail assembly

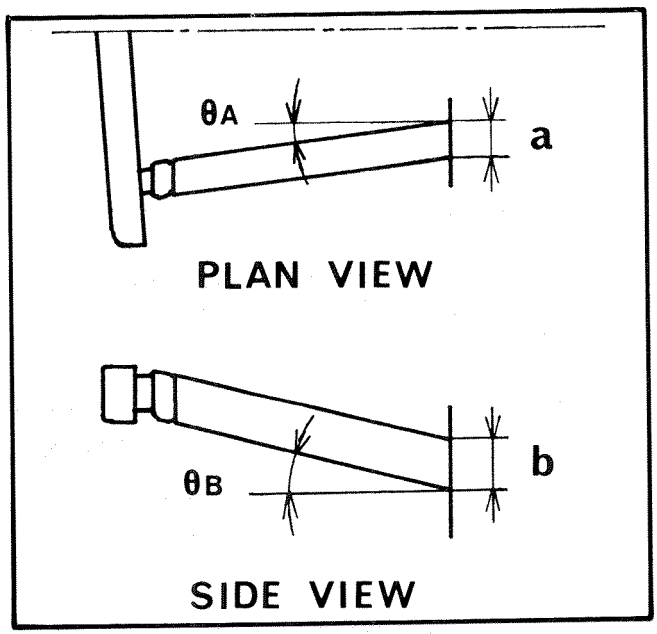

Figure 12. Mounting angle

Test results are shown in Figure 13. Dots in the figure show the mounting angles of the test side rails. The number under each dot shows the critical collapse length of the test side rail. However, the length of 600mm is the maximum value limited by dimension of test side rail. That means the critical length is 600mm or more.

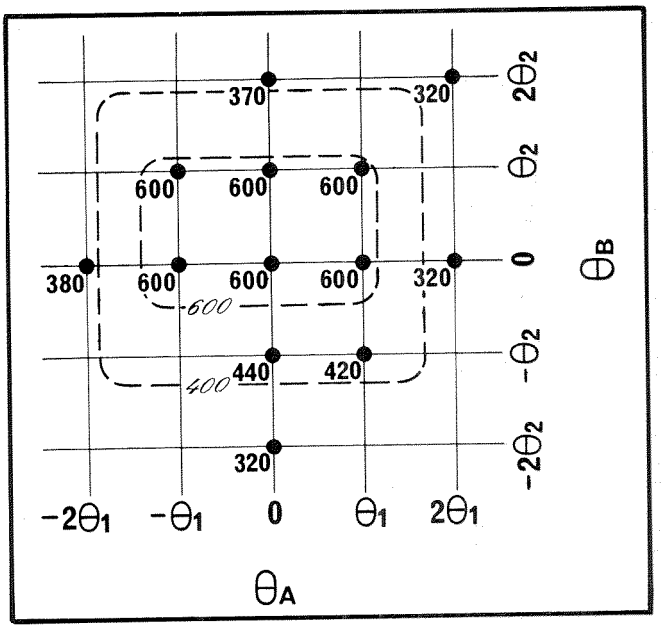

Figure 13. Critical collapse length

The figure shows that the critical length of slant-mounted side rails depends on the mounting angle and that the increase in the absolute value of the angle reduces the critical collapse length. The combination of θA and θB does not significantly affect the critical collapse length. Thus, the regions where the critical length is estimated to be 600mm and 400mm are indicated by broken lines.

Additional tests were conducted to examine the relationship of the critical collapse length and section height (b). In the case of slant-mounted side rails, the axial collapse progressing reduces the overlap (c shown in Figure 14) between the front end section and the section just collapsed.

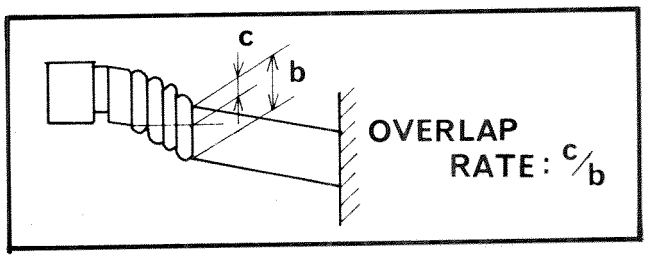

Figure 14. Overlap rate

Figure 15 shows the overlap rate, which is c divided by b, at the instant of failing in the mode B bending. This shows that the critical overlap rates are roughly the same.

Thus, the critical collapse length could be estimated for mounting angle and section height.

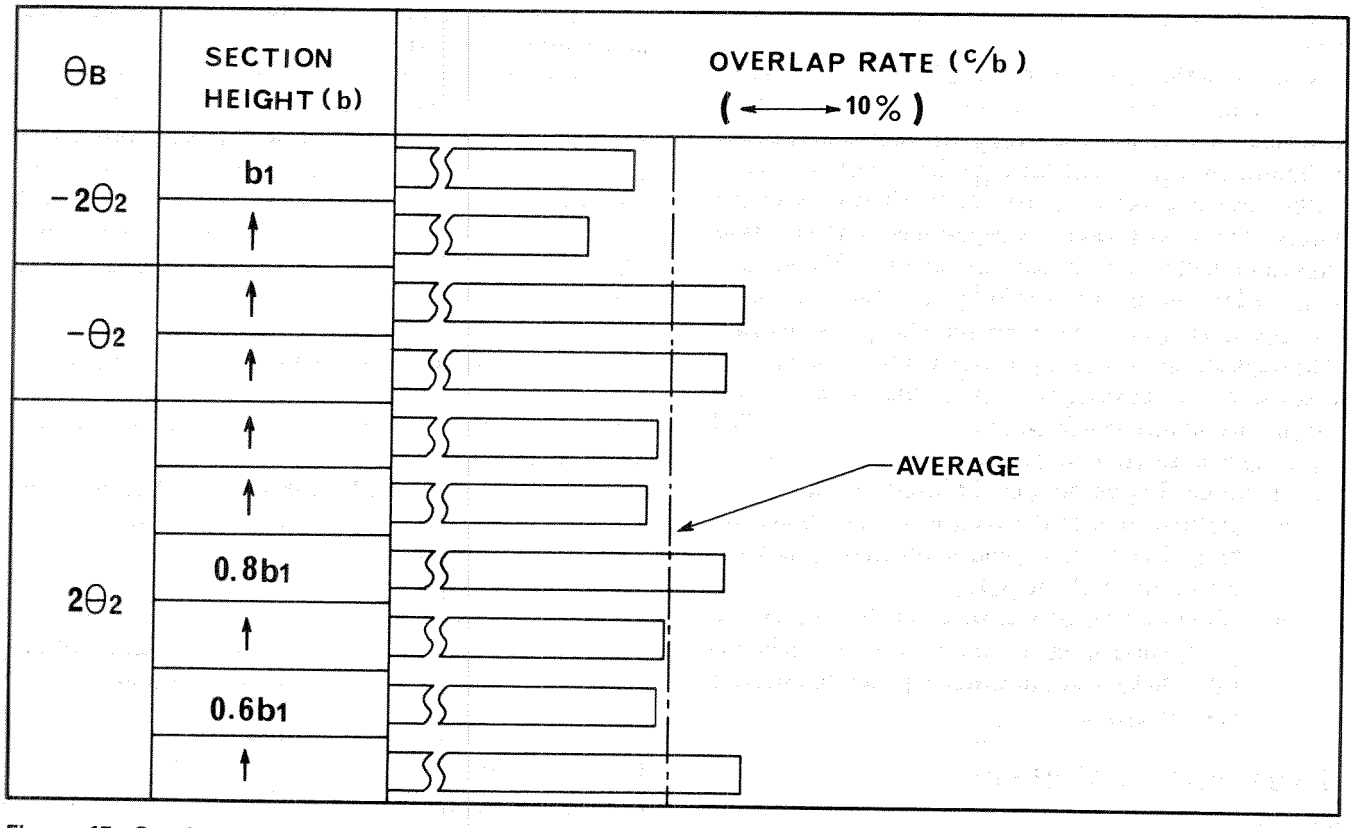

Figure 15. Overlap rates at the instant of failing in bending mode-B

Conclusion

1. Effective combination and arrangement of beading have been obtained to collapse axially closed-hat section members in a regular folding mode.
2. The critical collapse length of slant-mounted side rails could be estimated within limited conditions.

Collapse Behavior Development of Body Components

Reiner Brasche,
Georgios Giazitzis, and
Helmut Schmitt
Ford-Werke AG

Abstract

The development of car bodies is much affected by safety requirements, such as the FMVSS 208. Package is of major importance. In other words, space must be made available, affecting the dimensions of car front and rear end as well as the passenger compartment.

It is our objective to provide basic information about the optimal structure conditions, to study and implement better development tools, and to make use of any new methods for the benefit of the product and the safety of its users.

As a result of our development, we came across the application of analytical methods predicting rather than retesting the component form, gauge, material, and their influence on car crash behavior.

Introduction

The protection of vehicle passengers under impact conditions is mainly a function of controlled energy absorption, at least from a body engineering point of view.

Control in this sense means a minimization of passenger loading under the given change of velocity and a given deformation of space, where the permissible deformation is limited by the request for a sufficient survival space within the passenger compartment. On the other side, the injury criteria are related to the passenger's deceleration pulse and shall not exceed defined values(1). Within these boundaries, the inertia effects govern the loading of passengers as a function of chosen change of velocity. Although static tests have proven their worth in various cases of structural strength, they are unsuitable to treat the important inertia effects. These effects can be studied by using a calculation or dynamic test to do parametric investigations. Important areas of investigation are—

- Optimization of the vehicle collapse mode and body energy management for appropriate deceleration level and pulse
- Minimization of passenger loading by appropriate design of restraint systems, including safety belts, seats, instrument panel, and steering column system

Experimental Methods

The test device, Dynamic Crusher, is used to provide information about the behavior of vehicle structures, structure components, and dummy trajectories under different kinematic conditions. Measured signals are analyzed by using the data processing equipment. The following results are obtained (Table 1):

A typical example is the dummy resultant head acceleration as shown in Figure 1.

This test was conducted with a dummy fastened by a production seatbelt on production vehicle seats mounted on the sled of the Dynamic Crusher; the deceleration was about 17g mean value at an initial velocity of 41km/h. The test analysis shows the deceleration time of the sled and the resultant head deceleration curve of the dummy. The calculated Head Injury Criterion (HIC) is 283 for a time interval of 108ms.

Series of tests in this manner are evaluated and given the HIC dependence on the initial velocity and the mean deceleration. The variation can be derived with 25 percent, due to small changes of the head deceleration pulse (Figure 2).

To meet the HIC limited to 1,000, the mean deceleration shall not exceed about 24g for a 56km/h initial velocity

Table 1. Test results

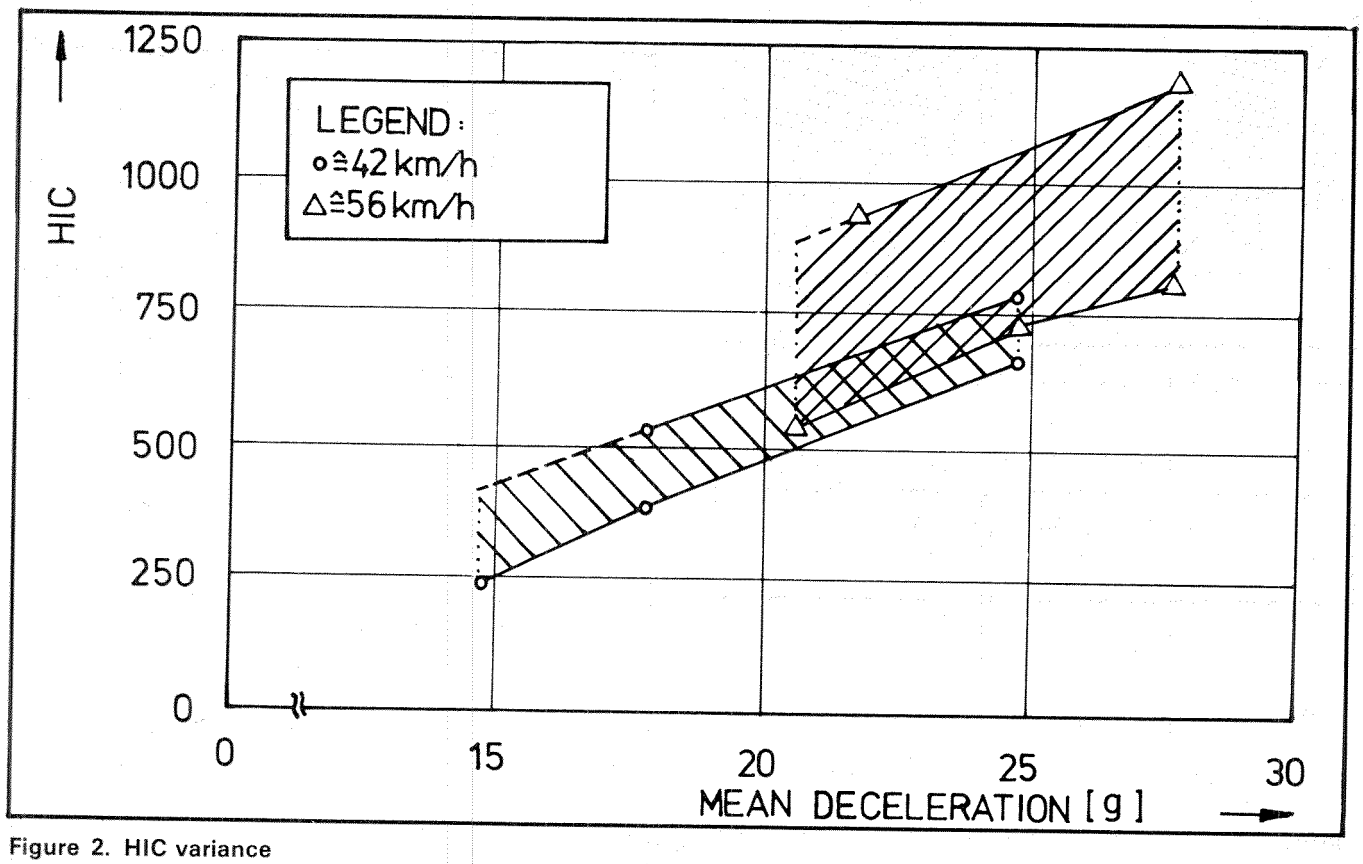

Figure 2. HIC variance

test, although single peaks can be higher. With the known mass of the vehicle, including driver, co-driver, and luggage, the mean deceleration value leads to the design requirement of sufficient structural crush space.

The structural crush of the first phase is governed mainly by the behavior of the front side rails. This behavior can be studied statically and dynamically. Figure 3 shows the sled with a mounted body side rail prepared for a dynamic test.

The figure shows a body side rail of our Scorpio vehicle prepared in a way that preformed darts reduce the peak load and insure the regular folding pattern. It should be understood that the pattern shows the final step of parametric studies as released. The energy curve and the force displacement characteristic are shown on Figure 4.

Analytical Methods

Analytical tools have the advantage of supplying information early in the development stage when physical parts are not available. There are simulation methods as shown in Table 2.

These are based on models with an appropriate mathematical description. Depending on the objectives and the availability of the above tools, the suitable one is selected.

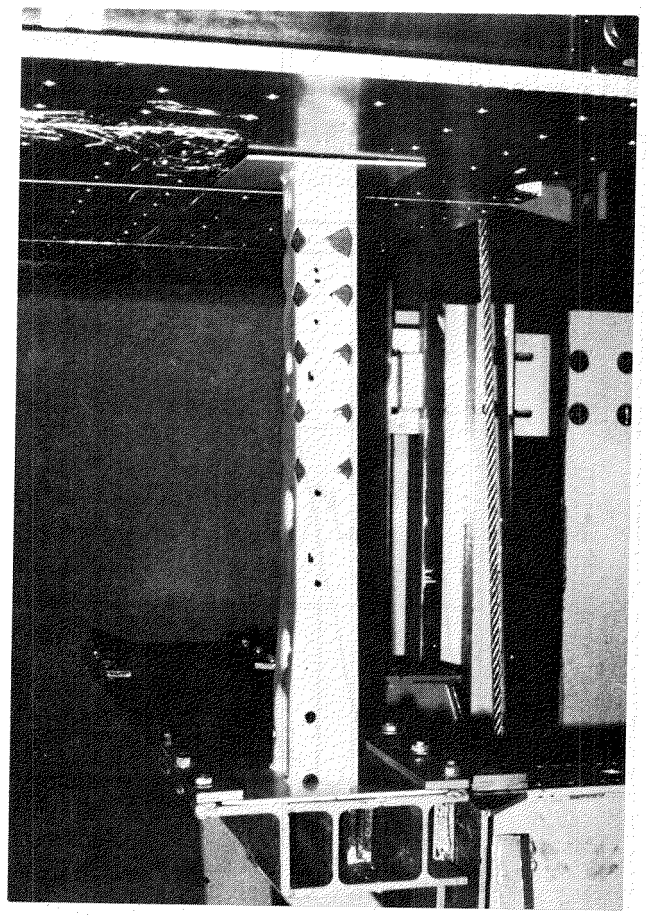

Figure 3. Scorpio body side rail—component

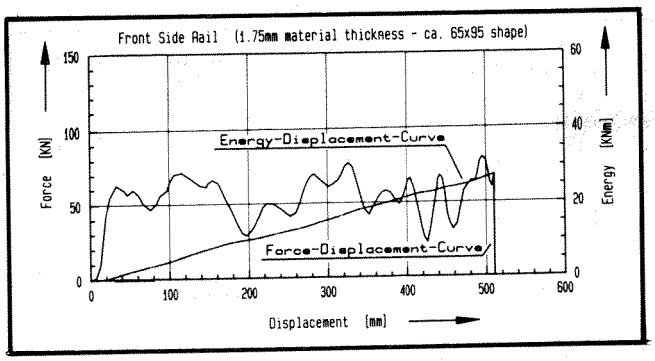

Figure 4. Scorpio front side rail-characteristic

Table 2. Analytical methods

• Spring Mass-Systems
• Finite Element Analysis
• Finite Difference Analysis

Spring Mass Models

For energy management investigations and dummy kinematic studies, the simulation tool, Ficem (in-house program), is applied. The advantages are fast preprocessing and quick turnaround of results at low cost. This tool gives the engineer information, for example, on simulation results (Table 3).

Table 3. Simulation results

• dummy displacements
• dummy velocity
• dummy deceleration
• rotation of head and chest

These results are obtained in relation to the simulation time. A typical dummy head swingline is shown on Figure 5.

Finite Element Analysis

Finite element models are used for static and dynamic analyses. As an advantage, this type of model is usually available from investigations in the field of Elastic Theory. The geometric information can be carried over. Elements, however, need to be redefined for two reasons:

- Element definition and connectivity (QUAD4-NASTRAN—TRIANGLE-WRECKER-F)
- Coarseness of model to comply with computer capacity

It is evident this tool allows the investigation of different shapes of members, material gauges, and swag patterns. Of specific interest also is the influence of small deviations of nominal surface as a result of the stamping process.

Figure 6 shows the peak load difference depending on these deviations.

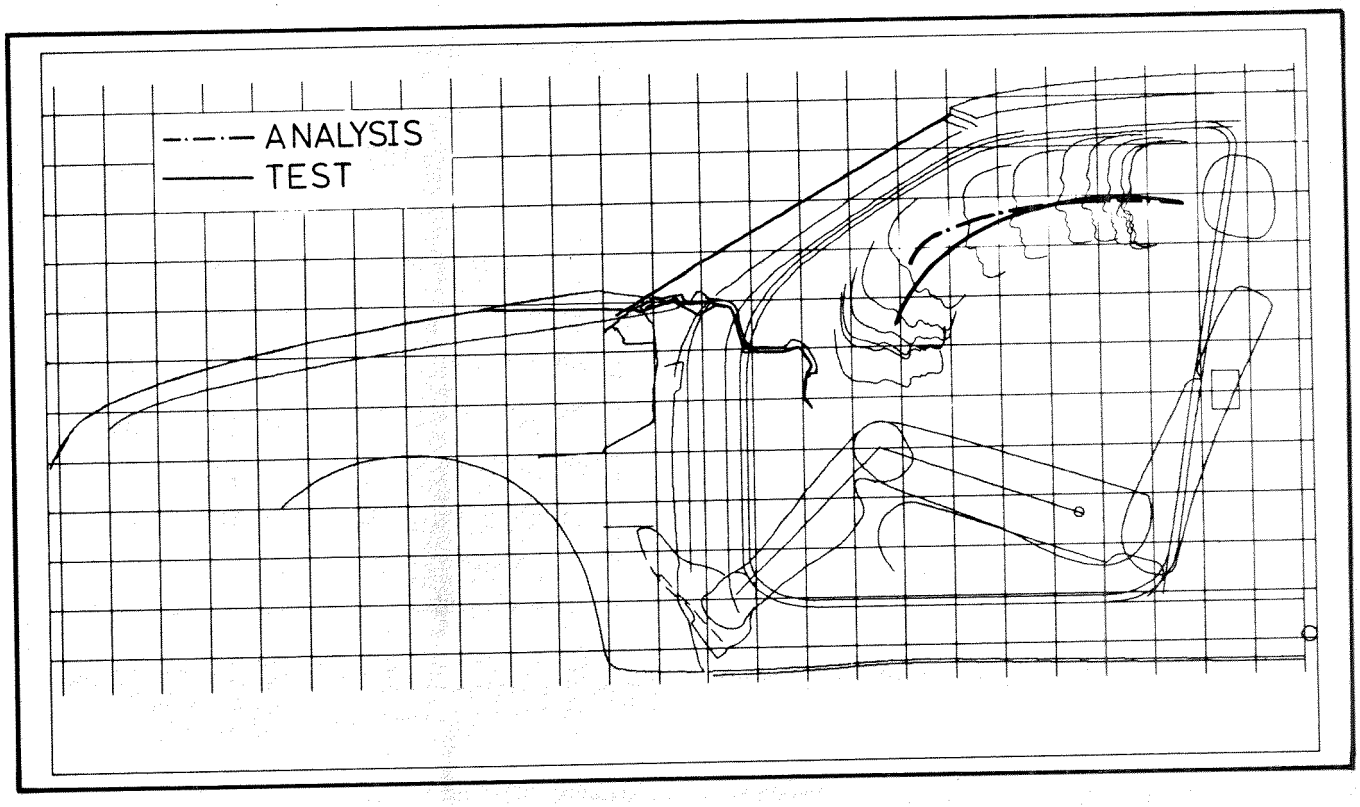

Figure 5. Dummy trajectory

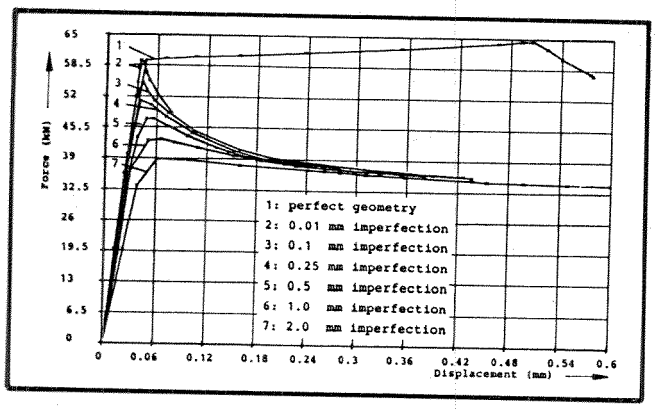

Figure 6. Influence of geometrical imperfections

It can be seen that small imperfections in the order of material gauge cause a great reduction of the peak load. The following folding process, once initiated by always-existing imperfections, is nearly independent from the above mentioned peak load reduction.

Figure 7 shows the post-peak-load behavior of a longitudinal member, as computed(2,3).

The further folding will progress until internal contact of surfaces occurs. The contact of any two points needs to be defined, for instance, with gap elements.

In this case, one has to know a priori where contact occurs or a precomputation has to be performed to define the contacting node pairs. A more effective approach exists in some codes with defining a contact surface and corresponding contact nodes. The automated way obviously will be the desire of the analyst.

Finite Difference Analysis

Finite difference methods were used successfully for continuous structures, e.g., pipes, vessels, etc. Many efforts were made to use FD also in more complex—i.e., automobile—structures.

Taking advantage of the Kirchhoff Shell Theory, which is valid for thin-shell structures, one can treat the equations of motion of a shell for an automobile body.

In the FD code that has been used(4,5), a regular mesh is formed on the shell, which helps to form these equations in a finite difference form at each mesh station. The spatial differencing requires a regular mesh, and discontinuities such as holes are hard to handle. This is an obvious disadvantage. Complex structures can be computed, however, by means of connecting shells by appropriate shell boundary conditions at corresponding edges.

Figure 8 shows such a body side rail configuration under impact load at 9ms time with computed deformation of three connected shells.

Discussion of Results

As mentioned earlier, analytical methods can be used early in the development process.

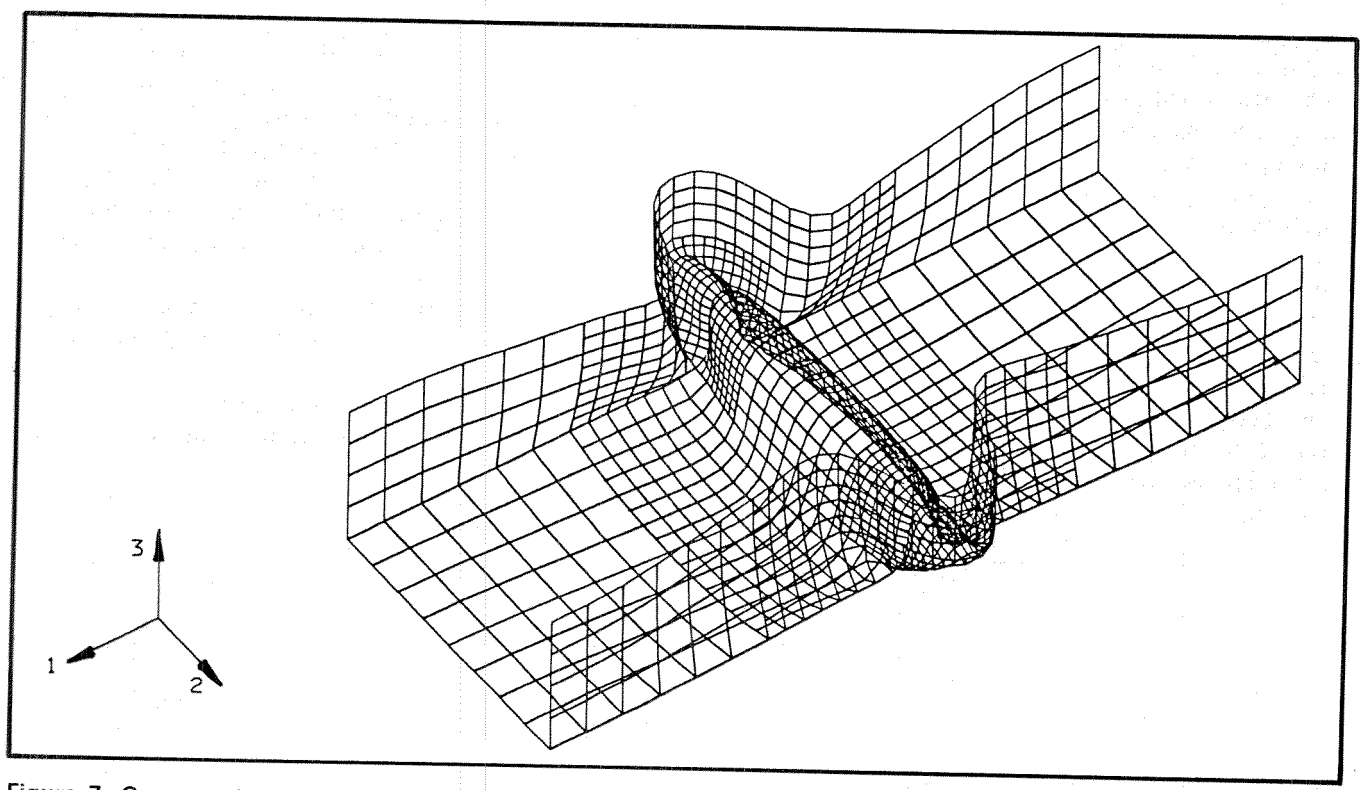

Figure 7. Computation of local fold

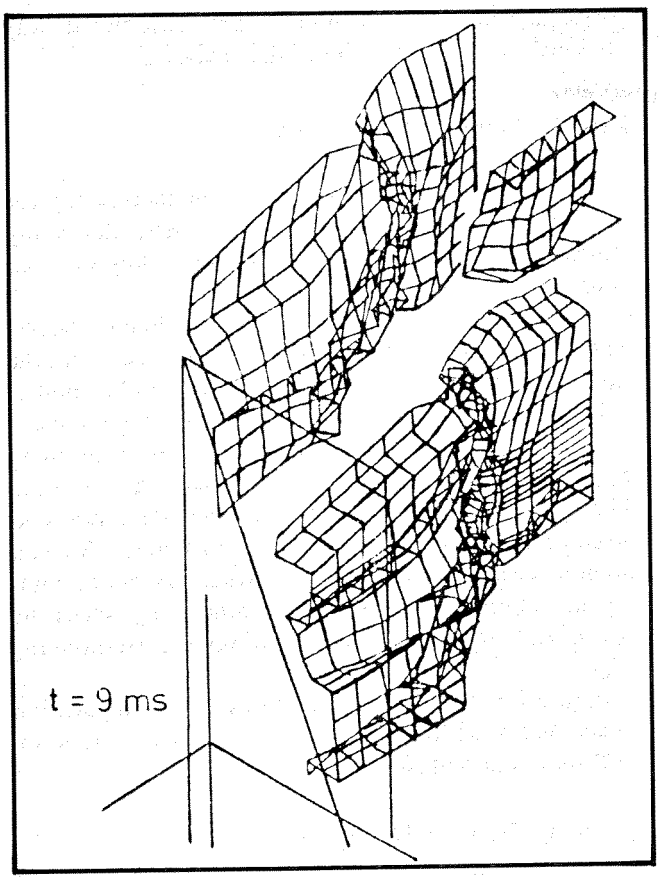

Figure 8. Finite difference shell structure

The determination of energy absorption is ruled by physical events happening in a timespan of a few milliseconds. In other words, the balance of loads needs to be established by comparing the peak load of main energy-absorbing members versus the resistance of the back-up structure. It has been shown that the FE method is providing a tool very helpful in the determination of this balance. Figure 9 shows a comparison of load versus displacement in test and calculation of a Scorpio front side member.

Depending on the use of a filter, one will see that peaks are in a close range (Figure 9). The computation code was the in-house FEM Code WRECKER-F(6).

Beyond 30mm displacement, the computation values need to be established. It must be stated that other computations have been carried out resulting in higher

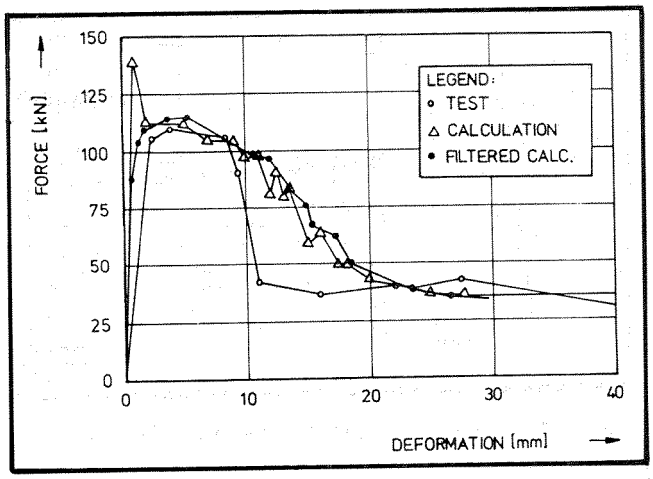

Figure 9. Scorpio front side rail—correlation

deformation. However, one has to study the effect of internal contact carefully in order not to misinterpret the results. Calculations are under way to compute the behavior of full body front and rear ends. The highly iterative computations at the order of 10,000CPU's by using a fast computer require suitable hardware. Our new Cray is yet to be used for this kind of development work.

In summary, it is concluded that analytical tools can partly replace test work.

Advanced Concepts for Driver Air Cushion Systems

G.F. Kirchoff,
R.W. Carr,
R.J. Wheelwright, and
G.V. Adams
Morton Thiokol, Inc.

Abstract

It has long been recognized that cost has been one of the major deterrents to the acceptance of airbag systems in automobiles. This paper addresses some advanced design and development approaches being evaluated by Morton Thiokol's Utah Division toward reducing design, development, and production costs of driver airbag systems. While cost reduction values are not yet available, nor are some of the design concepts proven, the approaches look quite promising.

Introduction

Morton Thiokol, Inc., is evaluating several advanced concepts for driver air cushion systems to develop a lower cost system concept than those offered today. System reduction is a result of (1) fewer components, (2) lower cost of those components, (3) component weight reduction, which reduces cost of support structure, (4) reduction in system installation cost either at the OEM or in the after-market, and (5) reduction in development, qualification, and tooling costs.

The primary ground rule during this cost reduction effort is that there is no degradation in system reliability. This includes failure of the system to function, an inadvertent function, or a failure of the system to perform the specified requirements when it functions (i.e., low inflator, slow sensing bag rip, etc.).

The approach that Thiokol has taken attempts to reduce costs in each of the five areas cited. Component cost reduction has been effected through a simpler inflator design. The reduction in components has been effected by actualization of integrating sensor concepts. Reduction in weight has been accomplished through the use of aluminum and simpler structures. Placing a sensor in the steering wheel and using a pyrotechnic actuation system are being evaluated to reduce installation costs of the airbag system. Reduction in the development cost of the airbag system is accomplished by using baseline-developed and qualified components, and modifying them for each automobile. Testing cost reduction is evaluated by using a pendulum test technique for sensor testing and developing sensor actuation times for various crash pulses. This is supported by computer performance projections to provide a total system design analysis. More details in each of these areas and the status of the Thiokol program are provided with features, approaches, and concepts rather than programmatics or actual costs.

Component Description

Inflator

The new lightweight aluminum inflator, now qualified, certified, and in production by Thiokol, is a key component to this advanced system. It consists of two forged aluminum components, a diffuser and base, joined by inertia welding on three concentric diameters. It uses a high-volume production squib, an ignition/auto ignition cartridge subassembly, sodium azide gas generant pellets, and combustion and diffuser filter and cooling screens. The design is amenable to high-volume production. Quantities anticipated in the near future are less than 300,000 annually. The gas-generating pyrotechnic used in this inflator is produced by a slurry/spray dry/pelletizing technique, which could be developed to a continuous process but is now using batches of 3,000 lb each. Any process for high-volume processing of gas generant must minimize operating personnel contact, due to the toxic and hazardous nature of the intermediate constituents, while still being able to process large uniform batches of the final pelletized product for use in the inflator.

A second inflator requirement is that it be easily tailored to meet future driver system performance specifications and the envelope and interface imposed by the steering wheel and module. Figure 1 shows those parameters established for this inflator. Also this capability must be feasible with a standard inflator and without requalification, tooling, or certification.

Module

The key features of a driver module design must minimize weight and number of components, and simplicity of design.

The module design Thiokol is evaluating features a one-piece, reinforced urethane cover and an aluminum housing, which results in a lightweight, compact unit easily attached to a steering wheel. The total weight for the module (inflator, reaction plate, bag, cover) assembly is 3.3 lb. Figure 2 shows a cutaway of this design. The module housing is stamped from an aluminum sheet and

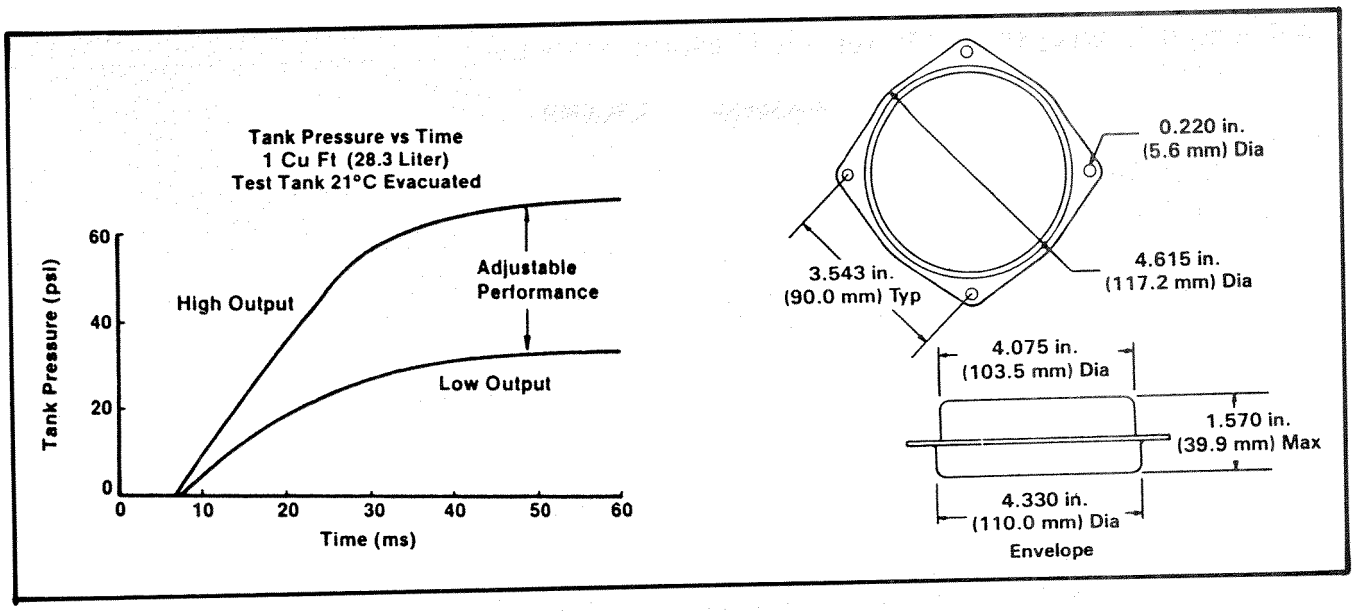

Figure 1. Advanced lightweight inflator

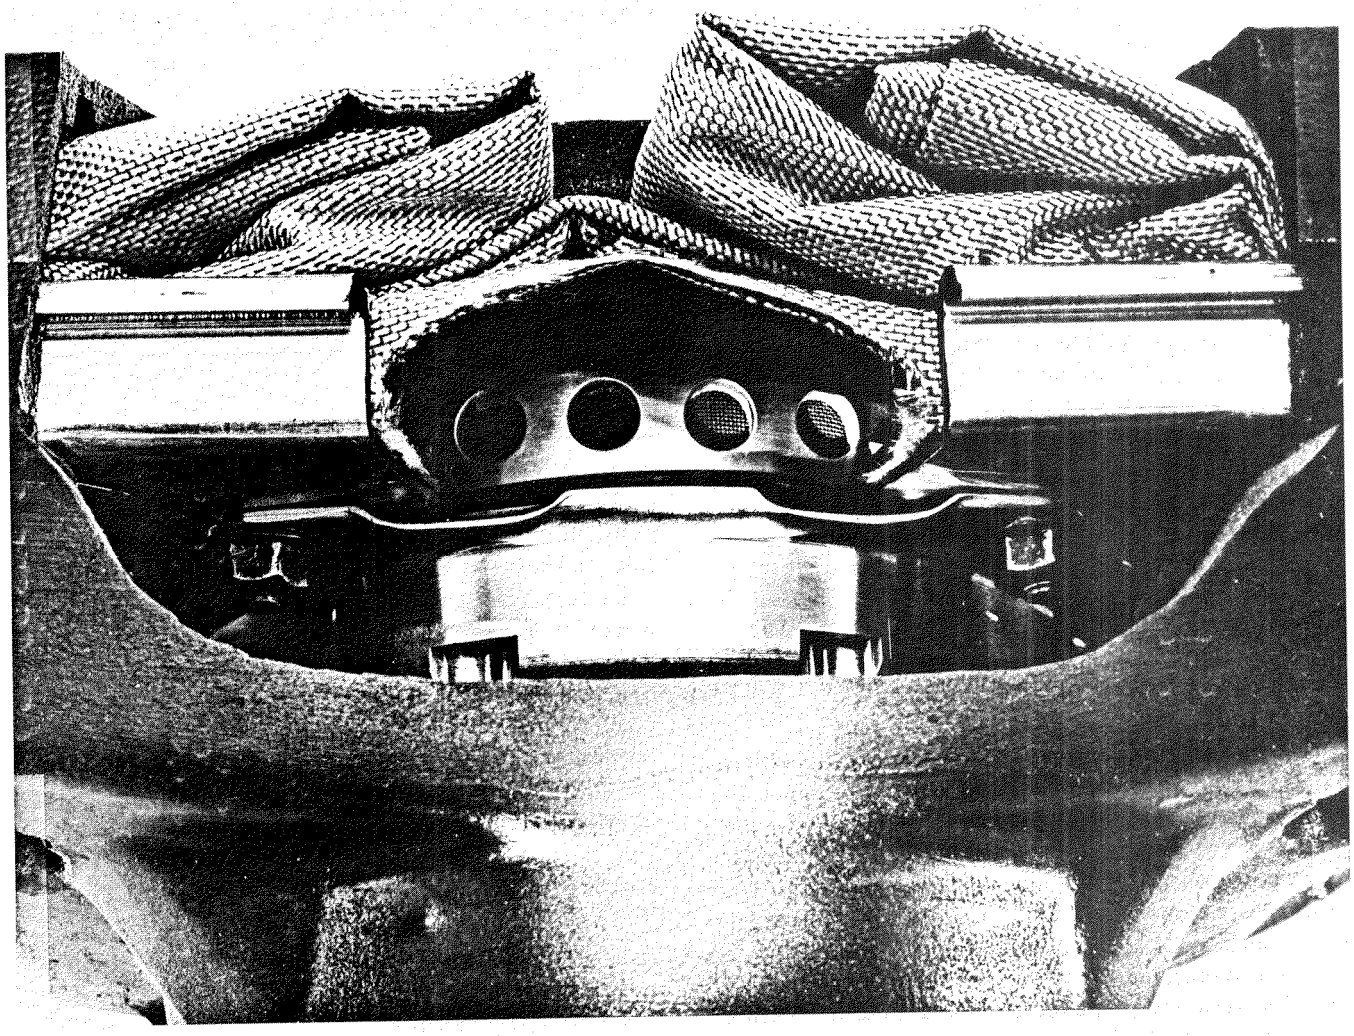

Figure 2. Thiokol module design

provides the attachment features for the remaining module components. Of these, the cover is the most difficult to manufacture. It is a single-piece, construction-reinforced, molded urethane that snaps into place over the cushion and housing and is retained by a continuous lip around the edge of the housing with a steel retainer to hold the two longest sides together. The single cover functions as both a protective cover to the airbag and a decorative cover. An internal, molded-in-place, nylon mesh provides needed reinforcement for the cover panels during deployment. Tear seams exposed just to the interior surface are being examined, however, until test results verify this concept. The more conventional approach of having tear seams on both external and internal surfaces has been selected.

Sensor/Transfer Line

The sensing element we have been evaluating with the module assembly is one of the new pseudo-integrating mechanical sensing elements with either an electrical closure switch or a mechanical firing pin with a percussion primer. The percussion primer initiates a thin-layer explosive (TLX) transfer line, which transmits a pyrotechnic shock wave to the inflator for initiation. The sensing element we have been evaluating is a gas-damped sensor being developed by Technar. A schematic of this sensing element is shown in Figure 3. The integration that takes place is a function of the travel of the "cup and mass" in the forward direction against the spring force and airflow around the cup. These impulse characteristics are shown in Figure 4, plotted to show the functioning and nonfunction regions in relation to the velocity change and time duration of the crash impulse. Other integration sensing elements available in the market are also candidates for this system.

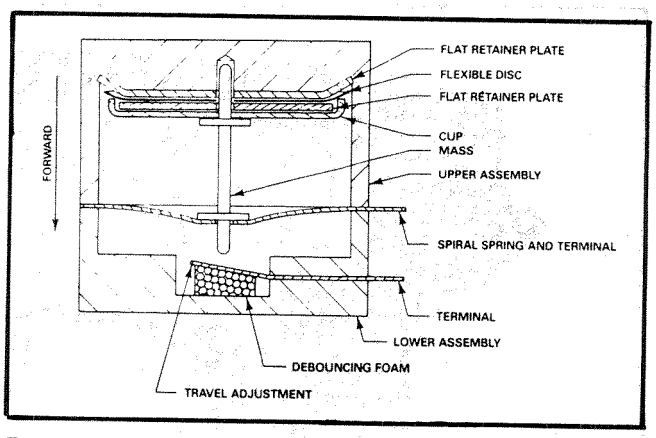

Figure 3. Technar's low-cost gas-damped sensor

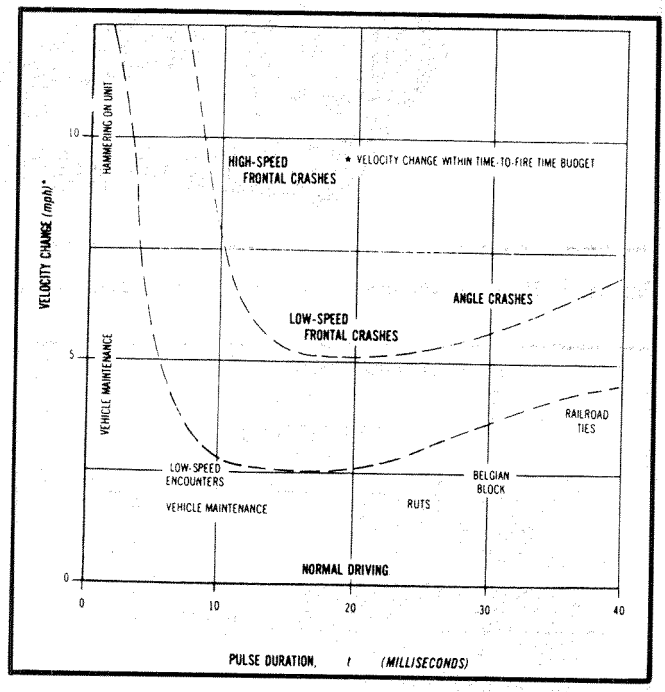

Figure 4. Crash/noncrash impulse map

Module Assembly

We are evaluating both the Pyrotechnic Sensor/Module System and the Electrical Sensor/Module System.

Pyrotechnic Sensor/Module System

The system that employs the pyrotechnic transfer is called a pyrotechnic sensor/module assembly. The sensor detects the crash environment and, through a percussion mechanism, initiates a thin-layer explosive (TLX) transfer line that transmits a pyrotechnic shock wave to the inflator for initiation. The sensor is mechanically attached to the back of the module housing, and the transfer line would be connected directly to the inflator. No changes to the steering column design are needed to accommodate this concept. A very preliminary design layout for this configuration is presented in Figure 5. The TLX transfer line, as shown in Figure 6, consists of a thin coating of reactive material on the inside of a plastic tube encased in a protective coating. When initiated by a brisant primer, a pyrotechnic impulse is transmitted along the transfer line at a velocity of 4,593ft/s. Since the length of the transfer line in this system is about 4in, the time delay between the sensor and inflator is less than 0.1ms. Inside the inflator, the transfer line is terminated adjacent to the ignition charge, so when the pyrotechnic impulse reaches that junction, the inflator fires exactly as it would if initiated electrically.

Electrical Sensor/Module System

The electrical sensor/module assembly incorporates current airbag system technology except that everything

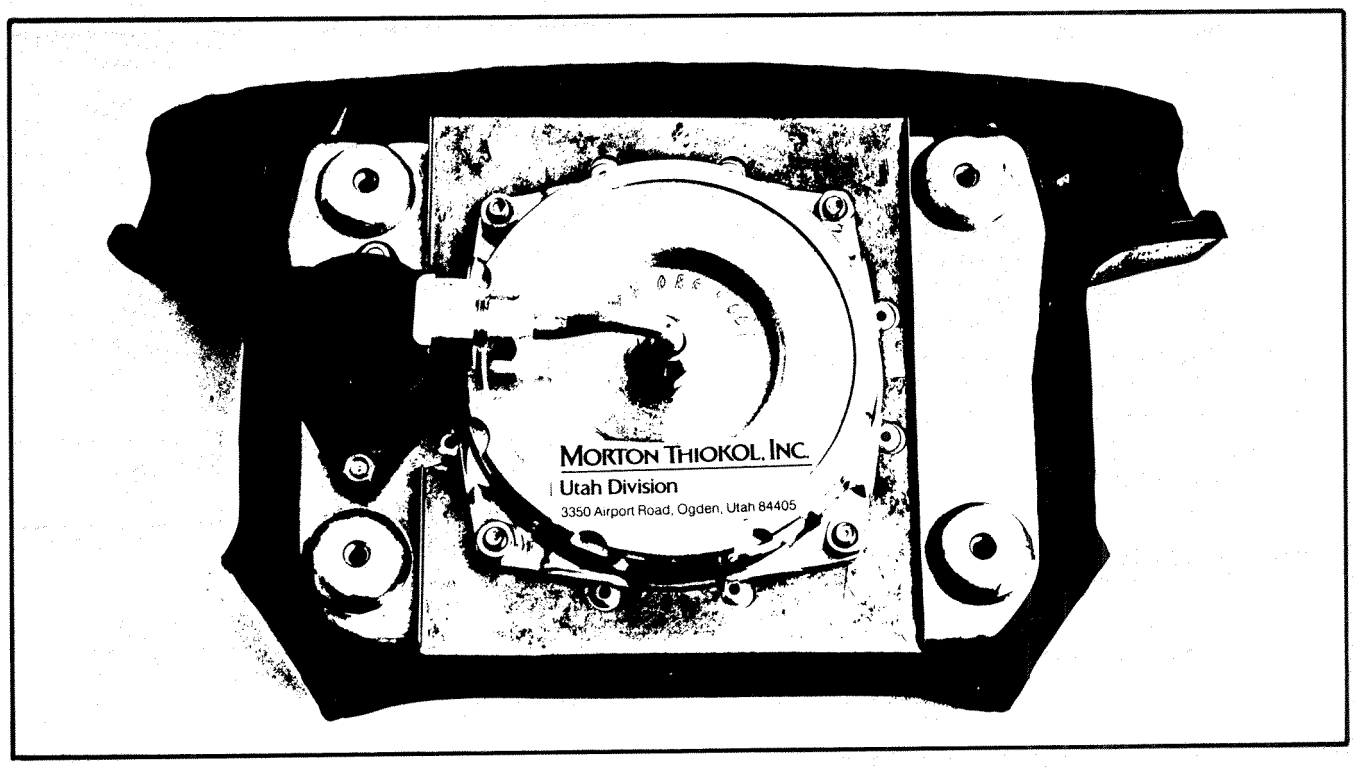

Figure 5. Preliminary design of pyrotechnic sensor/module assembly

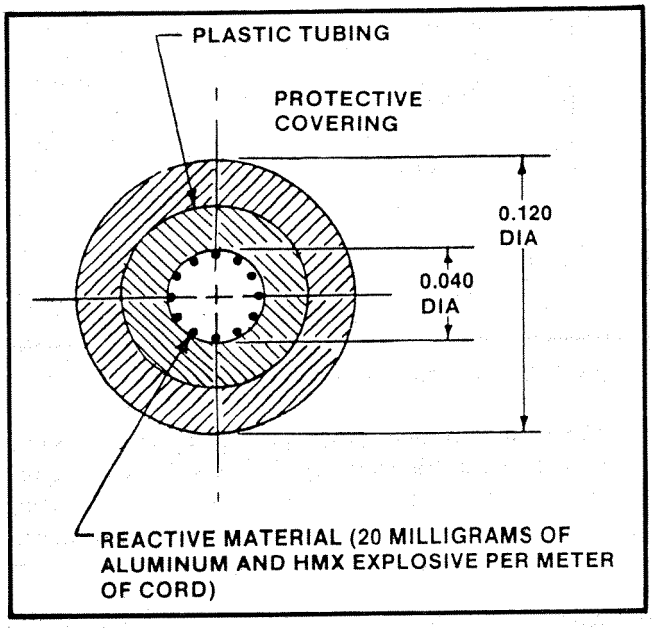

Figure 6. Cross-section view of TLX transfer tube

is contained within the module assembly. This eliminates the need for complicated interconnecting wiring harnesses and a slip ring or rotating electrical connection in the steering column. The sensor is mounted to the module housing next to the inflator (Figure 7), while on the opposite side is a cavity containing the energy storage capacitors. All components are encapsulated in a plastic cover with a foam potting material to maintain position and structural integrity during vibration and shock environments. Power from the horn ring is used to charge the capacitors where the vehicle's electrical system is energized. When the sensor functions in response to a crash impact, it closes a set of electrical contacts, allowing electrical energy from the capacitors to be applied to the electrical squib, which, in turn, fires the inflator. The added weight to the steering wheel for either the electrical or pyrotechnic concept is approximately the same and is shown in Table 1. The total assembly weight is 3.7 lb, which is a substantial reduction over that previously available.

Ease of Installation

There are two key decisions yet to be made for future driver airbag systems that affect the ease of installation. These are (1) location of the sensor—that is, can it be located in the steering wheel—and, (2) whether the inflator initiation element should be electronic or pyrotechnic. Although there are a number of ongoing programs to provide the data needed to make these decisions, the answers are not yet clear. It may be that one design approach can be selected for one automobile, while an alternate approach is suitable for others. Several elements are obvious at this point, if we wish to have a system that can be used for either. These are—

1. The inflator used must be suitable for either pyrotechnic or electrical initiation, without major development, qualification, or tooling costs.

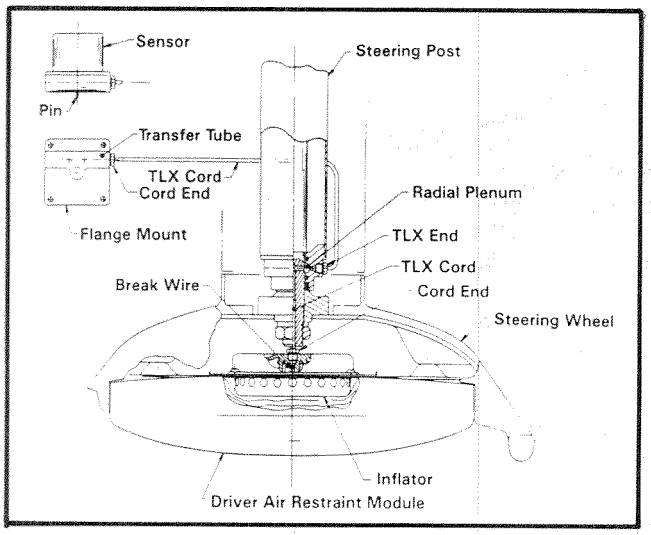

Figure 8. Layout design of driver inflator module with TLX Transfer line

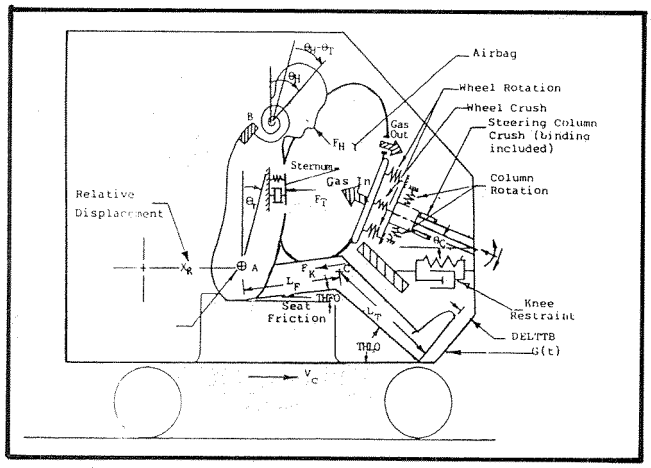

Figure 9. BDRACR computer model

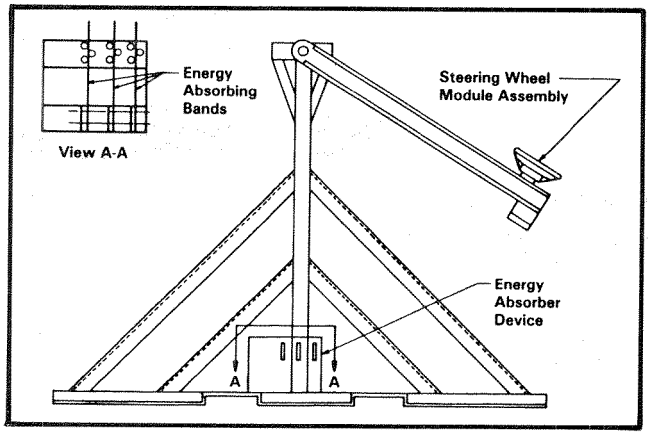

Figure 10. Pendulum test device air cushion system impact test

Development, Qualification, and Tooling

Reduction in development, qualification, and tooling costs is a major factor in selecting a driver airbag system. Further, the costs reflect the lead time required to bring the system to production readiness. There appears to be two keys to accomplishing these efforts with minimum cost. The first of these is to use developed and qualified components where possible. This is particularly true of the items that are very expensive to develop, tool, and qualify, such as the inflator and sensor. Second is the minimization of testing cost through the use of computer modeling and simplified dynamic testing, which can be used to replace more expensive sled and car crash tests.

This paper will not deal with computer modeling, which will be dealt with extensively in other papers, except to say that through the use of the BDRACR Computer Model (Figure 9) by Fitzpatrick Engineering, excellent prediction and design capabilities have been obtained with close agreement between simulated and actual results. Another feature we believe will reduce development costs is a newly devised pendulum test device now being fabricated. This device has been designed to simulate the initial portion of any given crash pulse up to 15mph through the use of a pulse generator with energy-absorbing bands. With the sensor and module assembly mounted on the pendulum (Figure 10) and impacted into the pulse generator, the sensing sequence can be simulated with an inexpensive test versus an expensive sled or car crash dynamic test. Just as in a car crash test, various sensors can be tested to provide comparative data.

In conclusion, we believe that the recent and ongoing efforts to use lighter weight, simpler inflators, simple integrating sensors, potentially simpler installations in the steering wheel, pyrotechnic initiation, and more sophisticated testing, coupled with more accurate computer perform ance modeling, offer lower cost systems than those previously available.

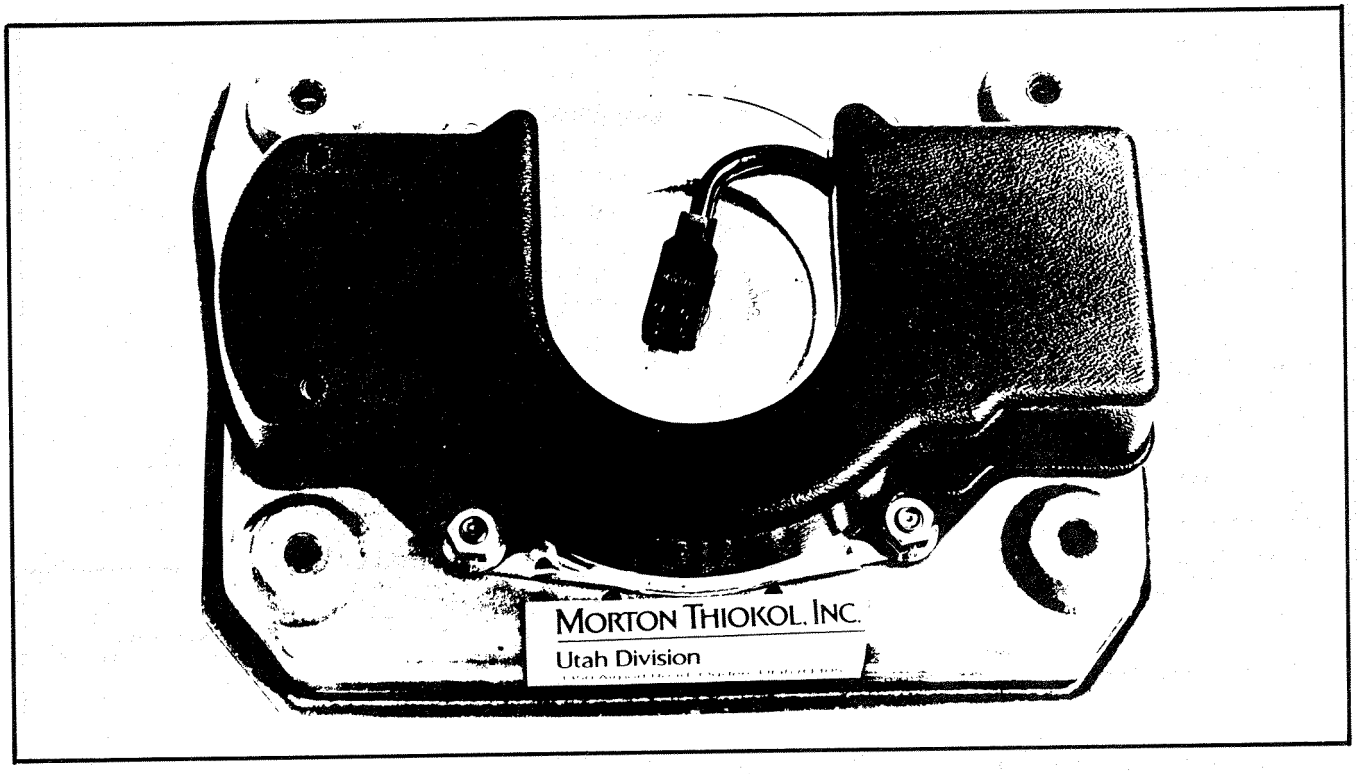

Figure 7. Electrical sensor/module assembly

Table A. Weight summary driver air cushion module

Module Assemblies	Design Description	Weight
Inflator Assembly 95501-01	Lightweight Aluminum Construction	585gms 1.3 lb
Module Assembly Without Inflator	Lightweight Reaction Plate, Bag, Attachment Hardware and Cover	906gms 2.0 lb
Sensor Assembly (No Diagnostics)	Pyrotechnic Mechanical Sensor with Transfer Line or Electrical Sensor	180gms 0.4 lb
Module Assembly With Sensor Assembly		1671gms 3.7 lb
Module Assembly Without Sensor Assembly		1491gms 3.3 lb

Thiokol has done this with the aluminum inflator.

2. There must be flexibility in sensor component placement to locate the sensor other than in the steering wheel, should this be desirable. This is obvious for the electrical system based on existing designs. It is not obvious for the pyrotechnic system. Thiokol has designed and is evaluating a rotating joint transfer line system for pyrotechnic ignition, shown in Figure 8. This concept appears adaptable to a standard steering column with minimum modification. It is not developed or qualified, though it has been conceptually proven.

These decisions will obviously have a major impact on future cost of installation of airbag systems.

Injury Criteria for Combined Restraint Systems

Dr. Lothar Grösch
Daimler-Benz, Sindelfingen

Abstract

The expected improved performance of a combined restraint system where an airbag supplements the conventional safety belt was not reflected in reduced g-values on the dummy's chest. However, by the distribution of forces over the wider area of the airbag and the corresponding reduction of the pressure exerted by the 3-point belt, improved occupant protection is actually produced. Therefore, a new method to measure the deflection of dummy ribs with strain gauges has been developed. The resulting data indicate a significantly reduced chest deflection when a combined system is used.

Similarly, a concentrated load from a steering wheel in the mouth area at a low HIC value means a higher injury risk compared to a widely distributed load from an airbag at an even higher HIC value. Consequently, an additional facial bone injury criterion based on measurements of the specific loading on the dummy's face would be useful, and an alternative calculation of HIC focusing only on that portion of the head acceleration curve assumed to have a brain-injury potential is necessary.

Chest Injury Criterion

Due to the combined effect of two restraints—a 3-point belt and an airbag—the acceleration measured in the chest of an anthropomorphic dummy is greater than with a 3-point belt alone.

Since most of the chest injuries (especially rib fractures) in real-world accidents are due to contact with the belt or with the steering wheel, it is not chest acceleration that is important for identifying the potential injury level but the deflection of the dummy's chest.

A new method, evaluated through extensive tests with different restraint systems, has been developed to measure the deflection of the dummy ribs by means of strain gauges.

Experimental Method

The sled tests were conducted at 30mph. The vehicle was equipped with an airbag, a knee bolster, and a 3-point safety belt (webbing elongation 14 percent) on the driver side.

The test device was a Hybrid II dummy, equipped with strain gauges symmetrically attached on the six ribs near the spine (Figure 1).

The dummy rib can be deflected in the sagittal or lateral direction (Figure 2). In the case of a symmetrical sagittal deflection (a), positive strains of equal magnitude S_{SAG} are measured on both measuring points. In contrast to this, the nonsymmetrical lateral deflection (b) induces a positive strain at measuring point 1 and a negative strain at measuring point 2; both of magnitude S_{LAT}.

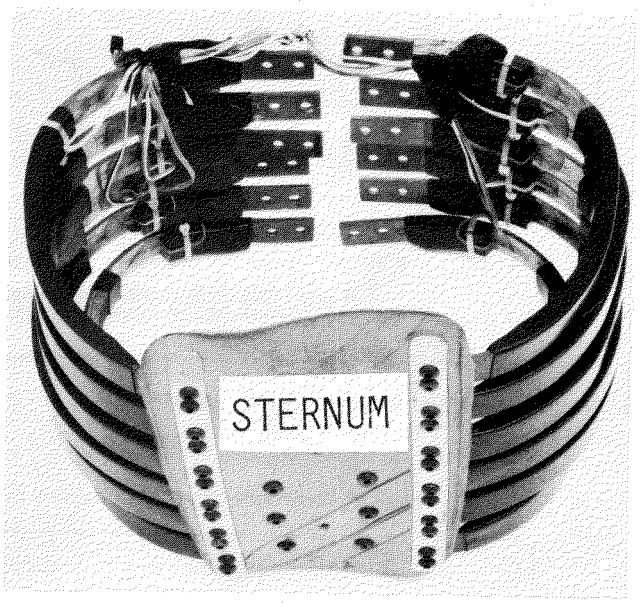

Figure 1. Location of strain gauges on dummy ribs

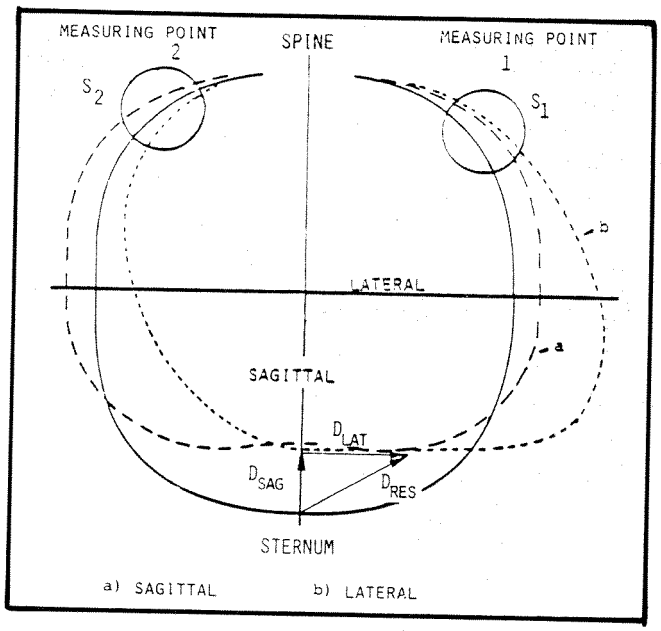

Figure 2. Measured strains if both modes of deflection occur

If both modes of deflection occur simultaneously, the measured strains are:

$$S_1 = S_{SAG} + S_{LAT} \quad \text{and} \quad S_2 = S_{SAG} - S_{LAT} \qquad (1)$$

From this, the sagittal and lateral components, respectively, can be calculated:

$$S_{SAG} = 1/2 \bullet (S_1 + S_2) \quad \text{and} \quad S_{LAT} = 1/2 \bullet (S_1 - S_2) \qquad (2)$$

They are (in linear model) proportional to the corresponding sagittal and lateral rib deflections:

$$D_{SAG} \sim S_{SAG} \quad \text{and} \quad D_{LAT} \sim S_{LAT} \qquad (3)$$

that can be determined by calibration.

The resultant deflection of each dummy rib is given by:

$$D_{RES} \sim \sqrt{S_{SAG}^2 + k^2 \bullet S_{LAT}^2} \qquad k = 0.6$$

determined by calibration (4)

The total of all rib deflections or, alternatively, the average deflection of anterior chest wall, can be regarded as a measure of chest deflection:

$$D_{TOTAL} = D_{RES}^{(1)} + \ldots + D_{RES}^{(6)} \quad D_{AV} = 1/6 \sim \qquad (5)$$

Results and Data Analysis

Three types of restraint systems were evaluated using sled tests:

a) Three-point safety belt alone without emergency tensioning retractor* (3 PT)
b) Airbag combined with 3-point belt alone (AB + 3 PT)
c) Airbag combined with 3-point belt with ETR (AB + 3 PT + ETR)

The resulting chest accelerations (Figure 3) and rib strains (Figure 4) indicate—

- Increased g-values when using the combined system without ETR (b), due to simultaneous restraint forces of belt and airbag in phase with each other
- A reduction of chest acceleration with ETR (c), due to the early restraint effect of the belt and, therefore, delayed contact with the airbag, i.e., belt and airbag out-of-phase
- In contrast to the tendency of increased chest acceleration, significantly reduced rib strains for the combined system

*To eliminate belt slack upon impact

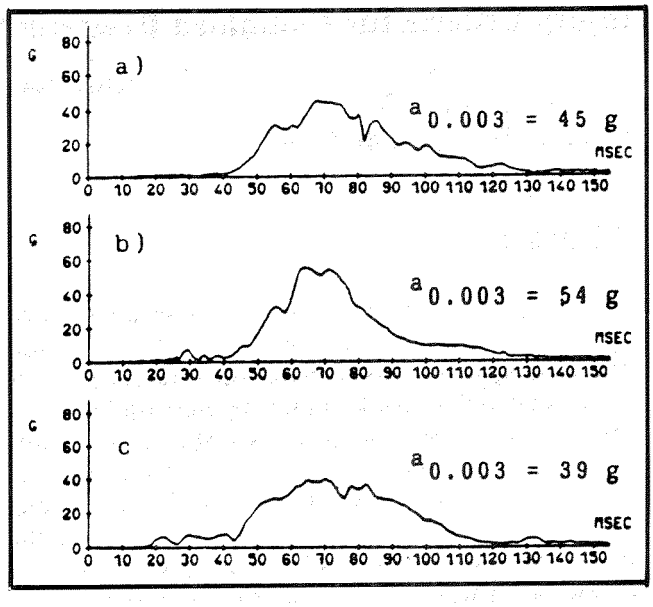

Figure 3. Resulting chest accelerations

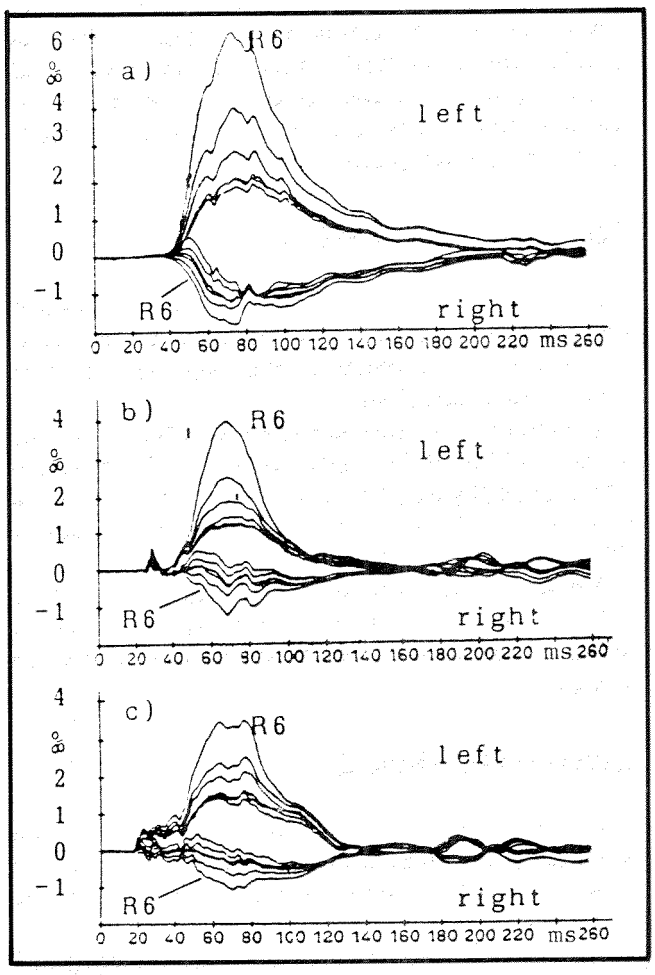

Figure 4. Resulting strain data of different restraint systems

Consistent with this, the upper torso belt load at the shoulder is significantly reduced for the combined system without ETR and slightly increased with ETR because of the delay in belt unloading from the airbag.

The separation into sagittal and lateral components of rib strains indicates—

- Nearly the same total sagittal deflection for all three restraint systems (Figure 5)
- Lateral deflections in each case higher than the sagittal, but a reduction of almost one-half when the combined system is used (Figure 6)

Furthermore, some other important facts:

- Consistent with rib fracture occurrence in real-world accidents, the lower ribs are much more stressed than the upper ones.
- By the combined system, both sagittal and lateral deflection of the lowermost rib are significantly reduced; even more with ETR.

The comparison of rib-deflection data to the chest g-values (Figure 7) indicates contradictory tendencies:

- With the combined system (b), increased chest acceleration but reduced deflection
- With an ETR in the combined system (c), lower g-values but nearly the same deflection

Because most chest injuries in real-world accidents are caused by rib deflection and not internal acceleration, the rib-deflection data are obviously more suitable for

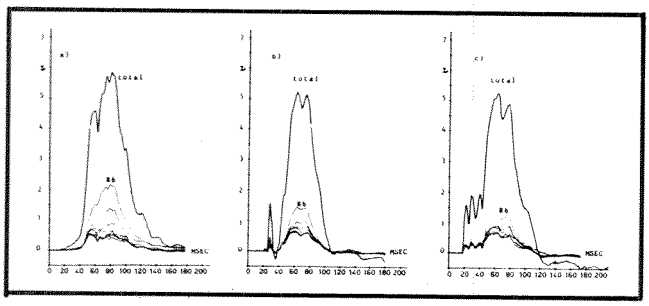

Figure 5. Saggital deflections of dummy ribs

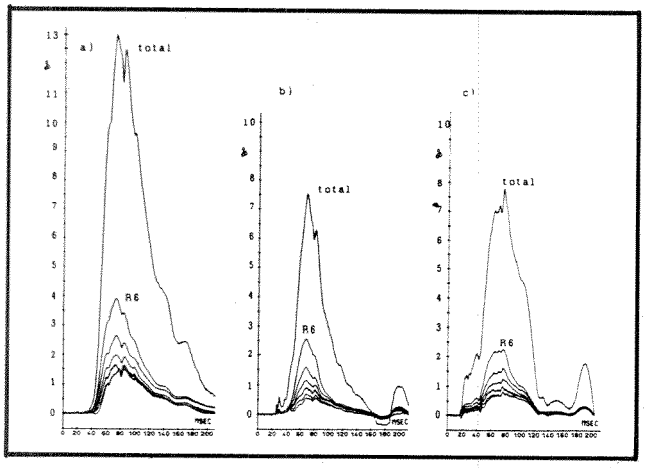

Figure 6. Lateral deflections of dummy ribs

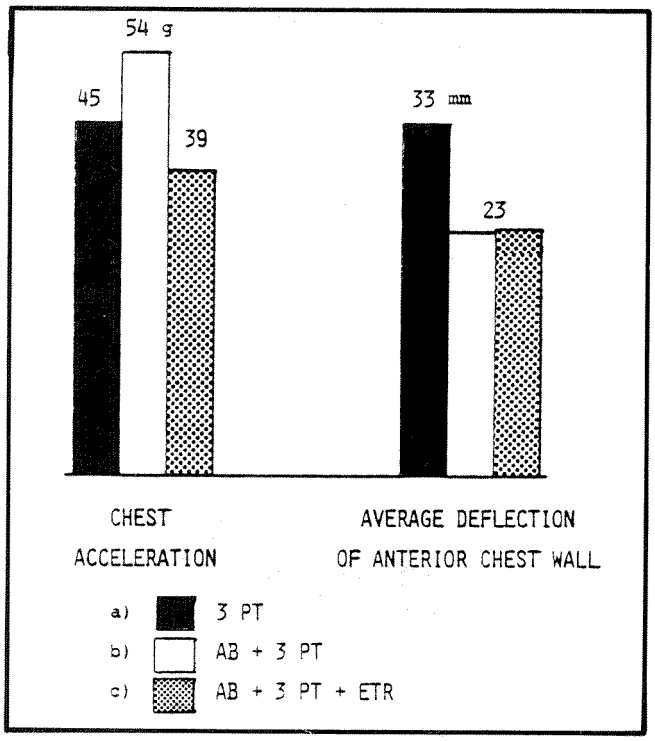

Figure 7. Comparison of restraint systems using either chest acceleration or chest wall deflection

estimating the risk of chest injury than are g-values. Therefore, the need exists for revised chest-injury criteria based on chest-deflection measurements instead of chest acceleration.

Head Injury Criterion

It is not the purpose of this paper to provide an extensive review of the pros and cons concerning the subject of HIC. Suffice it to say that—

- HIC is not adequate to evaluate the potential for facial damages, depending on both the local impact forces and differing strengths of the individual facial bones.
- The current HIC calculation can suggest that an artificially high brain-injury risk exists for a crash that has a relatively low g-level but a long-time duration (e.g., contact to airbag or non-contact events).

Head acceleration data are insufficient to predict localized fracture of the facial structure for two reasons: (1) there are a wide range of load limits for different zones in the face and (2) its incapability to detect localized hard points in the contact surface. Therefore, attempts have been made to apply various devices for pressure indication on the dummy's face (Figure 8).

Due to some difficulties in practical application—in particular where the contacting surfaces move relative to each other during an impact—it is necessary to enclose

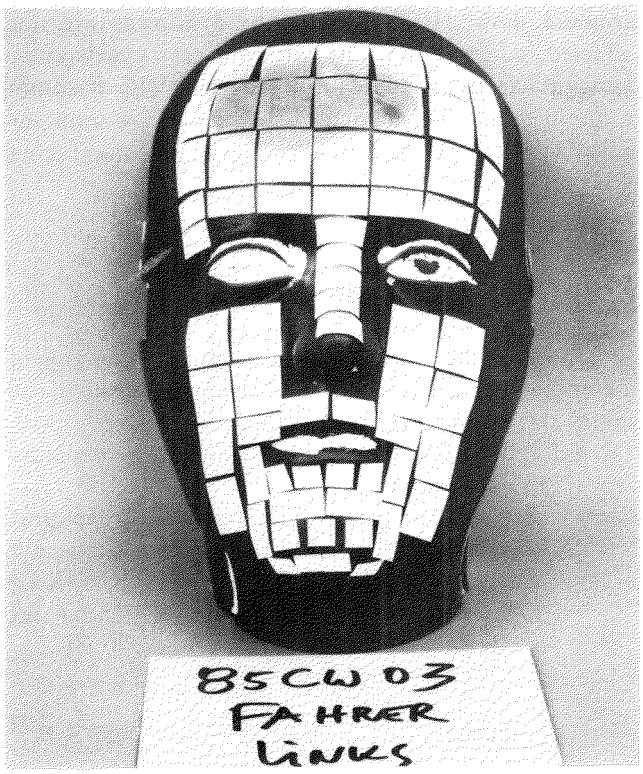

Figure 8. Dummy face with pressure-indication devices

the devices in silicon masks or nylon stockings; further improvements are in progress. The difference between static and dynamic loading makes it necessary to calibrate the device under approximately the same conditions as those under which it is used.

With the help of this pressure-indicating device, facial injury potential could be monitored. When the dummy's head contacts an airbag instead of a steering wheel, in spite of similar head accelerations and HIC values, respectively, a more than fiftyfold reduction of facial pressure was measured.

Modified Calculation of HIC

It is generally accepted that the currently used HIC formula is not able to handle the high tolerance levels in cases of long duration but low-level head acceleration pulses and, therefore, can produce an artificially high HIC. Consequently, HIC appears not to discriminate between hard steering wheel impacts, soft airbag contacts, or noncontacts, as shown in Figure 9.

In spite of similar HIC values, the actual brain-injury risk of the three head acceleration curves would be different, because the existing real-world accident data show no brain injuries with the absence of a head strike or in the case of airbag contacts. Serious brain injuries occur only with evidence of hard surface impacts. The reason for this is that most of the data points defining the Wayne-State-Tolerance-Curve (WSTC) were based on

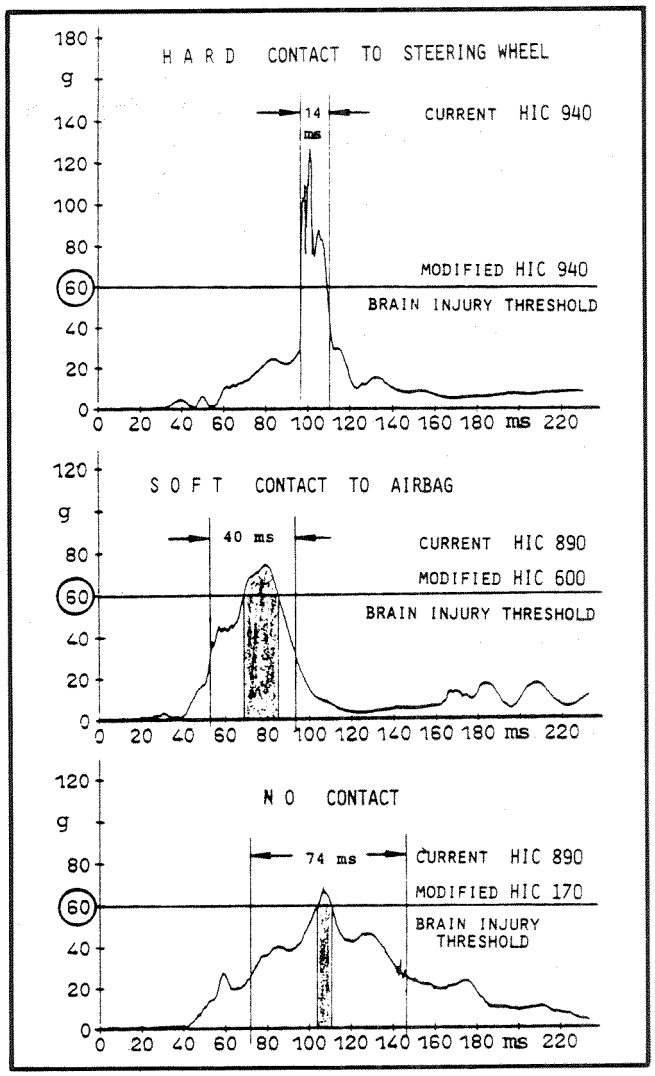

Figure 9. Head acceleration curve of different head loadings

short-duration head impacts up to 15ms, and the level of confidence is lower for those portions of the WSTC, which are analogous to noncontact events of longer duration.

Consequently, the calculation of HIC should be modified, recognizing that there exists a brain-injury threshold set to 60g by the originators of the WSTC; that, of course, simply reflects the fact that if maximum acceleration does not exceed this critical value, insufficient inertial forces are developed to produce injury. It does not matter how long the acceleration persists. Those portions of the head acceleration curve below the 60g level are assumed to be below the threshold at which brain injury occurs and should be neglected. A modified HIC calculation must focus only on that portion of the head acceleration curve assumed to have a brain-injury potential and should be limited to the specific time interval where the 60g injury threshold is exceeded as shown in the shaded portion in Figure 9.

A comparison of current and modified HIC calculations for different head loadings during rigid barrier tests is given in Table 1. It is interesting to note that only the modified HIC values are in line with the real-world accident data: HIC's of truly hard impacts are not affected, whereas those of soft contacts to airbags or noncontacts are significantly reduced. HIC becomes what it should be, namely an effective discriminator between those systems that allow hard injury-producing head impacts and those that do not.

Table 1. HIC of different loadings current and modified calculation

Head	Current		Modified	
Loading	ΔT	HIC	ΔT	HIC
Hard Impact	10ms	2220	13ms	2250
to Steering Wheel	33ms	1240	27ms	1220
or Dashboard	14ms*	940	13ms	940
Soft Contact	40ms*	890	16ms	600
to Airbag	43ms	600	7ms	150
	44ms	470	0ms	0
	51ms	1100	8ms	190
No Contact	74ms*	890	6ms	170
	38ms	630	0ms	0

*Refers to Figure 9

Summary and Conclusion

To ascertain that the improved occupant protection of a combined restraint system will also be reflected in the injury criteria, it is necessary that—

- Evaluation of the chest-injury risk be based on rib deflections
- Pressure-indicating devices be used for monitoring potential facial damages
- Calculation of HIC be limited to the specific time interval where the head acceleration exceeds the 60g level

A Modified Steering Wheel To Reduce Facial Injuries and an Associated Test Procedure

S.P.F. Petty and
M.A. Fenn
Transport and Road Research Laboratory
Department of Transport Crowthorne, United Kingdom

Abstract

Frontal and oblique-frontal impacts are responsible for about two-thirds of car occupant injuries. In those impacts, the steering assembly has been identified as one of the components most frequently hit by the driver. An in-depth study of accident injury data for the Marina car was used to identify the mode of injury. Angled barrier impact tests using an OPAT dummy as driver successfully reproduced the mode of injury.

With a 90 percent plus seatbelt wearing rate in the United Kingdom, it is desirable to develop a simple test procedure to reduce the aggressiveness of the steering wheel to the face and possibly to alleviate the deceleration pulse of the brain. A steering wheel test, based on the standard interior impact test, has been developed and evaluated on seven production car wheels and on a newly designed safer steering wheel. All the production wheels failed the test, but the safety steering wheel passed the suggested test level.

Introduction

Frontal and oblique-frontal impacts are responsible for about two-thirds of car occupant injuries. In those impacts, the steering assembly has been identified as one of the parts most frequently hit by the driver. Internationally, ECE Regulation No. 12 and FMVSS Nos. 203 and 204 were introduced to limit the *rearward* intrusion of the hub of the steering wheel into the occupant compartment in a head-on 30mph frontal barrier test and also to safely absorb the energy of the upper torso of an unbelted occupant, as defined by the SAE J944 body form, from a speed of 15mph. In recognition of the compulsory seatbelt-wearing legislation introduced in Europe with a resulting change in the mechanism and type of driver injury, Regulation No. 12 has been altered to allow the energy-absorbing column test to be optionally replaced by an energy-absorbing steering wheel. The energy absorption required has been changed from that of an upper torso to that of a hemispherical headform travelling at a maximum speed of 24.1km/h (15 mph) as defined in ECE Regulation No. 21.

At the Ninth ESV Conference, a paper by John B. Morris et al.(1) stated that although the post-standard steering system reduced the intrusion of the steering assembly into the passenger compartment by 68 percent,

it was still responsible for 27 percent of all driver serious (AIS 3-6) injuries. The key issues for the continuing injuries were given as—

- The test device does not physically simulate the driver impacting the steering assembly in actual crash situations.
- The test device is not a good human surrogate and the performance criteria are not adequate indicators of injury severity.
- The test and/or performance criteria are not able to distinguish "good" from "bad" design steering assemblies because of these inadequacies.

This paper gives the background to a project that—

- Selected a popular family-sized European car
- Assessed the United Kingdom's accident data to determine the injury mechanism for belted and unbelted drivers
- Compared the accident data with barrier tests using dummies
- Developed a test to evaluate the aggressiveness of steering wheels to the face and produced a safer steering wheel for immediate use

The car chosen for the evaluation was a British Leyland (BL) Marina. This car was nearing the end of its production so there were a sufficient number being driven in the United Kingdom to generate enough accidents to give a sample that could be studied.

Accident Data

To increase the sample size, the studies from the three United Kingdom in-depth accident teams were added together. It must be recognised that doing this gives a sample skewed to the higher energy impacts, but it is these impacts that are more likely to generate occupant injuries. One team based its sample on hospital admittances and the other two teams used accidents to which the police were called with an additional sample of accidents from which a vehicle had to be towed away.

The available sample for the Marina car was then selected for frontal and angled frontal impacts with subsets for drivers using seatbelts and those not recorded as using belts.

Belted Drivers

In the Marina, a lap and diagonal belt is a standard fitting. As there has been no comment on the reports, it is assumed that all the belted drivers were wearing a lap and diagonal belt.

Out of a total sample number of 33, 17 had *recorded* injurious head contact with the steering wheel. Because of the small numbers, the method of sampling, and varying levels of speed and injury, only trends can be considered. The most important is: "In a frontal impact, the seatbelted driver is likely to hit his head on the steering wheel."

Unbelted Drivers

The data given for unbelted drivers relate to all those drivers who could not be identified as wearing belts in the impact and will possibly include a few belted drivers. Table 1 details a relationship of impact speed change, as calculated using the Crash 2 computer program, to the number of *recorded* chest contacts with the steering wheel, to the number of car impacts in which the driver received head injury (face or cranium) from part of the car above the steering wheel, and to the total number of frontal impacts in that speed change group.

Table 1. Unbelted driver's impact data

Δv	Chest Contact with	Head Injury		Number of
mile/h	Steering Wheel	AIS 1	>AIS 1	Impacts
0-5	0	1	0	1
6-10	5	4	2	14
11-15	12	10	1	19
16-20	11	6	9	17
21-25	5	3	1	6
26-30	5	1	5	6
31-35	1	1	2	4
>35	5	0	5	5
Total	45	26	25	72

It should be noted that in seven cases, the driver's head was also identified as hitting the steering wheel. The mean impact speed for the Marina frontal impacts is within 1mi/h of the mean frontal impact speed of 14mi/h for all makes of car as given by Hobbs(2). Thus the Marina can be considered to be representative of a typical car at least in some aspects.

Analysis of the mode of injury shows differences between belted and unbelted drivers. For the belted driver, it is the head that hits the steering wheel giving cranium and/or facial injuries. For the unbelted driver, there is chest contact with the steering wheel but the head hits the A post, header rail, or top of the windscreen generating a more serious injury. With the introduction in the United Kingdom of compulsory wearing of seatbelts by front-seat occupants, the wearing rate rose from under 40 percent to over 90 percent. If the different injury mechanisms are true, there should be a significant increase in injury to the face from the steering wheel. The Rutherford Report(3) on the introduction of compulsory seatbelt wearing confirms this.

Baseline Tests

Two standard Marinas were barrier-impacted to see if the belted and unbelted modes of accident injury could be reproduced. The impacts were head-on into a wood-faced barrier angled at 30° to give maximum intrusion on the driver's side. The drivers were represented by an OPAT dummy.

Seat-Belted Driver

The dummy was restrained using a lap and diagonal inertia reel belt. The impact speed was 57km/h (36mi/h). The lapbelt held the dummy's pelvis in position, allowing its torso to jackknife forward and its head to hit the steering wheel rim, as shown on film and by paint witness marks. Early in the impact, the steering wheel rotated axially through approximately 90°. The left side of the dummy's chest hit the steering wheel rim at its strongest point where it joins the spoke, giving a high chest deceleration. The angled barrier gave some lateral and rotational motion to the car so that during the main impact, the dummy's torso moved toward the door. As a result, its head missed the steering wheel's boss and hit the weakest part of the rim.

Unbelted Driver

The impact speed for the unbelted driver was set at 38km/h (24mi/h). The accident data suggested this was above the critical speed for head injury. At impact, the dummy driver slid forward on its seat until its knee hit the fascia. The chest hit the rising bottom edge of the steering wheel rim, and its torso started to rotate upward. The top of its head hit the header rail and A post before breaking the windscreen, and its chin touched the top of the steering wheel.

The baseline data for both tests are given in Table 2.

The two tests demonstrate it is possible to reproduce the accident injury modes using a barrier test and a dummy to represent the driver. It should be noted that at almost 40km/h, the 3ms exceedance for the unbelted driver is 80g although the HIC value is low.

Facial Impact Into Steering Wheel

Mechanism of Impact

It was necessary to insure that the behaviour of the seat-belted dummy in the Marina baseline barrier test was typical. The angle barrier tests of six small cars at 60km/h (37mi/h) as reported by Penoyre(4) were examined. In these impacts, the dummy's head twice passed to the side of the wheel, twice contacted the rim, and twice went between the rim and the centre. In all cases, the relative motion of the head was perpendicular to the plane of the steering wheel. This is due to a combination of the upper torso of the dummy rotating downward about its hips and the intruding steering wheel rotating upward about a line along the bottom of the windscreen. Making the wheel rotate upward is a simple design solution to overcome the regulation's requirement of limited rearward intrusion in the barrier test. Thus, there is an immediate need to protect seat-belted drivers in high-energy impacts, when their heads are likely to hit the steering wheel.

Head Injuries

The injuries to the head can be divided into two broad but separable types: those to the cranium and brain, and those to the face. The brain injuries normally relate to head acceleration/time history; the facial injuries to the concentrated loading on specific bones. As the facial injuries are not normally life-threatening, they are given a lower AIS rating and have been less researched. It is likely that the low AIS rating does not adequately reflect the severe social and psychological impact of facial injuries. Nahum(5) has listed the impulse loads acting over $1in^2$ ($645mm^2$) required to break different facial bones. The lowest value given is 225 lb (1KN) for the zygomatic bones. Swearingern(6) has demonstrated that with the load evenly distributed over the head, it is possible to produce a deceleration of 300g with no bone fracture.

Thus, apart from lacerations, the head must be protected from concentrated loads and high decelerations (there is insufficient data to include the rotational injury mechanisms).

Steering Wheel Test

It is desirable that to protect unbelted drivers, the present regulations for energy-absorbing steering assemblies should continue despite their problems. In addition, the steering wheel should offer protection when it is hit by the head of a belted driver. Also, after, market wheels should be tested to the original fitment standard. Legislation "Concerning the Approval of Vehicles with Regard to their Interior Fittings" uses a head mass of 6.8kg (15 lb) and its energy is that of a mass travelling at 24.1km/h (15mi/h). For the proposed steering wheel test, the same mass and energy are retained. The hemispherical headform is replaced by a cylinder. The impacting and face of the cylinder is a disc of aluminum honeycomb with a crushing force of 200 lb/in^2. The cylinder is impacted axially square onto the plane of the wheel. The wheel is rigidly mounted or fixed on the rigidly mounted end of the steering column complete with its trim and ancillary controls. The diameter of the cylinder is 150mm (6in) and to avoid edge effects the depth of crush of the honeycomb is measured over a central area of 100mm (4in) diameter. It is proposed that the test is passed by meeting two criteria. One is that the indentations of the honeycomb do not exceed 2mm. The other is that the maximum deceleration does not exceed 80g during the impact for a cumulative period of 3ms. It should be noted this exceedance requirement may produce higher figures than that of the Interior Fittings Regulation, which specifies a continuous period of exceedance.

Wheel Test Results

Eight wheel designs were chosen to use in the test to evaluate their aggressiveness and ability to protect the head; the six from the impact tests as reported by Penoyre,(4) an Austin Metro wheel, and a safety steering wheel being developed by Sheller-Clifford in a joint development contract with TRRL to fit the Austin Metro. Each wheel design was impacted on its hub, at the join of the spoke and rim, on the mid-point of the longest unsupported part of the rim, and on the mid-point of the shortest unsupported part of the rim that did not include a join of a spoke to the rim. The results are given in Table 3. The facial injury potential of the wheels is estimated by measuring the maximum depth of the indentation into the aluminum honeycomb in 2mm steps, using a cylindrical probe 6mm in diameter. For the impacts at the join of the spokes to the rim, the level of crush is tabulated for both the spoke and rim. Where possible, the results of "in car" tests using the Motor Industry Research Association (MIRA) Mk II Free-Flight Headform Impactor has been given for comparison.

It is only on the hub impacts that the peak acceleration is greater than 80g. The channel amplitude class was set at 145g to reduce noise. For some rigid hubs, the peak level saturated giving an unrealistically low HIC value. For simplicity in Test House recording, it is recommended that the cumulative 80g for 3ms should be used. Only the Volvo padded centre spreads the load over the hexacell to give a zero crush reading. An additional 15° angled impact on this hub also gave similar results. This was due to the self-alignment of the wheel and impactor about the Z axis. However, the wheel failed in the exceedance mode.

None of the production wheels passed the proposed facial injury test at the suggested levels. Although the ideal standard should be that of zero crush of the impactor face, it is considered that a maximum crush of 2mm may have to be accepted.

The MIRA Free-Flight Headform Impactor test tends to give lower g results. Allowance must be made for one test being with a rigidly mounted wheel and a flat-faced impactor and the other with a rigid hemispherical aluminum headform hitting the steering wheel as it is fitted in the car for normal use.

The safety wheel passed all the axial impact tests with no deformation of the aluminum honeycomb and with a peak deceleration of 69g on the hub impact. Even when the wheel was angled at 30°, so that the main impulse was through the rim and down one of the most supported spokes, the crush of the honeycomb was only 1mm. Thus it seems to be possible to produce a steering wheel to production standards that protects the head from both brain and facial injuries. Eventual evidence might show that brain deceleration might still be high because for a belted occupant it is the resultant of the facial impact deceleration and head nodding deceleration, which corresponds to the restraint of the head by the neck. Although brain injuries do not seem to occur in cars from this latter deceleration, it is possible that when combined with some facial impact it can be injurious.

Alternative Test

As an alternative to the new test, a load-measuring mat that fits over a dummy's face is being evaluated. This would have the benefit of giving a load-time history at 256 points over the face. Each point is sampled once a millisecond. Such a device need not be restricted to use on a pendulum but could be developed as a standard tool for use on dummies in car crash testing.

Conclusion

1. Frontal and oblique-frontal impacts are responsible for about two-thirds of car occupant injuries. In these impacts, the steering assemblies have been identified as one of the car components most frequently struck by drivers.

#Trim not available in UK for testing

*Low values (see text)

2. An in-depth study identified that the heads of drivers wearing seatbelts hit their steering wheels with injuries to the face and possibly to the brain in moderate-to-severe impacts. The chests of unbelted drivers hit the steering wheels, but their heads were injured by hitting either header rails, A posts, or the tops of windscreens.
3. It is possible to reproduce these two different modes of injury using an OPAT dummy driver and an angled barrier test.
4. With a 90 percent plus front seatbelt-wearing rate in the United Kingdom, it is therefore desirable to discover whether the aggressiveness of steering wheels for facial injuries can be reduced.
5. A simple impact test procedure for steering wheels has been developed, and test levels for it have been suggested. It is based on the standard interior impact test but replaces the solid hemispherical head by a flat circular face of aluminum honeycomb whose crush resistance is matched to that for the weak facial bones. The test has been evaluated on seven production car wheels and on an especially designed safer steering wheel. All the production wheels failed to pass at the suggested level, but the safer wheel did so and showed distinct improvements in several respects.

Acknowledgments

The work described in this paper forms part of the programme of the Transport and Road Research Laboratory and the paper is published by permission of the Director.

The authors wish to thank Mr. Stan Edge of Sheller-Clifford Ltd. for his help in designing and manufacturing a practical safety steering wheel.

Improved Crashworthiness Independent of Belts or Airbags

Richard A. Wilson
General Motors Environmental Activities Staff

Abstract

Impacts to the vehicle interior are the most frequent source of occupant injury in highway accidents and generate the largest segment of the resulting total harm as calculated by the National Highway Traffic Safety Administration. Accordingly, improving the injury-mitigating properties of interior components along with the structural integrity of vehicles has significant potential for providing important safety benefits to occupants of crash-involved vehicles. This paper reviews the relative contribution of various occupant-vehicle contacts to total harm and offers some insight into the benefits that might be realized through component improvements. While such improvements are related primarily to unbelted occupants, their benefits should be considered complementary to those of safety belts and airbags since (1) some degree of nonuse of belts likely will remain even with the growing adoption of belt-use laws in the United States, and (2) belted occupants still can contact the vehicle interior in more severe crashes, as can occupants of airbag-equipped cars involved in crashes below the deployment threshold or in side impacts and rollovers.

Introduction

September 9 of next year will mark the 20th anniversary of the U.S. adoption of the National Traffic and Motor Vehicle Safety Act and establishment of the regulatory

agency now known as the National Highway Traffic Safety Administration (NHTSA). Although a number of crashworthiness improvements were well underway prior to 1966, the enactment of the safety act prompted a considerable increase in the attention given to vehicle safety by government, vehicle manufacturers, and the public. Important gains have come from this increased focus on reducing the number of deaths and injuries caused by highway crashes. However, the direction in which to advance vehicle crashworthiness further has been a subject of on-going debate for nearly two decades.

Much of this debate has been centered on automatic restraints as covered by Federal Motor Vehicle Safety Standard (FMVSS) 208, first issued as a Notice of Proposed Rulemaking in 1970. Although FMVSS 208 is often thought of as "the airbag standard," it actually carries the broader title of "Occupant Crash Protection" and its requirements for future vehicles likely will be met by three candidate approaches. Two of these, airbags and automatic belts, are well known and already have been offered as options on certain models of car. The third alternative, however, has not received as much recognition within the safety community. This approach relies on improved energy absorption and structural integrity, which are built into the vehicle. It would not use add-on systems, such as airbags or automatic belts, to meet the test performance required by the standard.

The purpose of this paper is to examine the potential for increased, built-in safety to reduce the harm to vehicle occupants caused by highway crashes. Specific safety improvements to the steering system and side impact will be discussed as well.

Assessment of Potential

An essential ingredient for any assessment of the potential for built-in safety to improve vehicle crashworthiness is some understanding of which parts of the vehicle are involved with the various body regions of the occupant and what degree of injury was produced by those occupant-to-vehicle interactions. This understanding must come from analyses of accident data, the quality and quantity of which have been improving steadily over the past decade. In February 1982, a detailed analysis of national accident data was published by NHTSA as part of the International Congress of the Society of Automotive Engineers. This significant study(1), "A Search for Priorities in Crash Protection" by A.C. Malliaris, Ralph Hitchcock, and James Hedlund, has provided a wealth of information to help guide the development and implementation of improved crash protection.

The NHTSA paper advanced the concept of total harm as a way to quantify the consequences of various occupant-to-vehicle contacts by including both the frequency and severity of the injuries. Injury severity within the National Crash Severity Study (NCSS) data was rated using the Abbreviated Injury Scale (AIS). The various injury levels ranging from minor through non-survivable (AIS 1-6) were assigned appropriate weighting factors that applied to each injury, and the weighted sum was identified as total harm. The paper provided tables that break down total harm according to a number of key variables, including crash configuration and severity, location of interior contacts, body regions injured, and injury severity.

More recently, in February of 1985, Malliaris, Hitchcock, and Hansen of NHTSA published an update and extension of the earlier work as "Harm Causation and Ranking in Car Crashes." This latter paper(2) used National Accident Sampling System (NASS) data to study what changes in casualty and risk patterns may have occurred from the late 1970's to the early 1980's. The newer study also employed a revised weighting schedule for calculating total harm from the AIS values in the data. However, in light of the conclusions of the authors that (1) no significant changes are noted between the NCSS and NASS results, and (2) no significant change in harm distribution is produced by the revised injury weighting schedule, the assessment of potential that follows will use information from the earlier work because of the more detailed breakdowns of harm distribution it provides.

Distribution of Total Harm

A review of information from the former NHTSA study provides a background for considering the potential for safety improvements. In particular, one of the tables from their paper presented a distribution of human harm according to broad categories of persons involved in highway accidents. Of course, each category of human harm is important in itself and safety improvements are desirable for all. However, as indicated by the general distribution shown in Table 1, about three-quarters of total harm relates to occupants of passenger cars, light trucks, and vans, and most of that is associated with cars.

Table 1. Distribution of harm from highway accidents (excluding property damage)

Category	Percent Total Harm
Passenger Car Occupants	60.9
Light Truck & Van Occupants	15.3
Heavy Vehicle Occupants	2.2
Motorcyclists	9.9
Pedestrians & Other Nonoccupants	11.8
Total	100.1

(From Malliaris, et al., Table 3, SAE Paper 80242)

It is particularly instructive to study in more detail those occupant-to-vehicle interactions involved in more than 60 percent of total harm to all road users. The fourth table in the NHTSA paper took the 60.9 percent total harm associated with passenger-car occupants and gave a further breakdown with respect to (1) which components of the vehicle were contacted by the various occupant body regions, (2) how much harm is related to noncontact injuries, and (3) how much harm is related to exterior contacts. That information has been condensed (see Table 2) to generate four basic categories in which to consider built-in safety improvements.

Potential for Frontal Improvements

The first observation to be made from the distribution shown in Table 2 is that over half (54 percent) of total harm to car occupants is associated with contact to frontal interior components of the vehicle. This priority on frontals is not a new finding, as evidenced by the early attention given to passenger car frontal collisions by FMVSS 208. However, the ability to break down interior contact data by body region and crash severity is more recent, providing a means to make general estimates of the potential for reducing harm through improvements to vehicle interior components. In particular, Table 11 of the Malliaris report gives a cumulative distribution of harm as a function of crash severity. That information can be viewed as upper limits on the total harm available for mitigation within various body-region/vehicle-interior contact areas and below various impact speeds.

To estimate upper bounds on the potential for built-in safety to mitigate total harm within the basic category of "front," the analysis used for Table 3 includes only those rows from Table 11 of Malliaris judged to be related primarily to vehicle interior components contacted by unbelted occupants in a frontal crash configuration. It is recognized that some portion of the values in the column labeled "Harm Pct of Total" might be associated with damage other than front (see Table 5 of Malliaris). However, since the focus of this analysis is on front interior components and component improvements likely would affect other damage directions as well, no adjustment has been made to the line items selected except for head/face contacts with A-pillars and roof edges, which exhibit a more even distribution between front and side involvements.

For convenience, Table 3 reproduces from Table 11 of Malliaris only the 20- and 30-mph columns of cumulative percent of harm. The percent of total harm for each line item is multiplied by the appropriate crash severity cumulative percentage, and the products are shown in the two columns to the right labeled "Added Calculation." The sum of these products represents the percent of the total harm associated with front interior component contacts below the indicated crash severity.

In other words, if vehicle improvements could be devised that assured all harm would be eliminated from contact with front interior components in accidents up to 20 or 30mph, Table 3 indicates a total potential of about 14 or 27 percent, respectively, exists for making reductions in overall total harm. These percentages, when compared to the 47.80 base percentage[1] for front component involvements only, represent front contact harm reduction potentials of about 29 or 57 percent, respectively.

1. The 47.8 percent total harm for front interior component contacts shown at the bottom of Tables 3, 4, and 5 is somewhat lower than the 54.0 percent given in Table 2 for the major category of front because a number of miscellaneous, small-harm value items were not encompassed by the analyses.

Table 2. Percent distribution of car occupant total harm

From Malliaris, Table 4		Basic Category	
All Frontal Interior Contacts	49.37		
A-Pillars (assume 1/2 "front")	2.23		
Roof Edges (assume 2/3 "front")	2.40	54.0	Front
All Side Interior Contacts	15.85		
A-Pillars (assume 1/2 "side")	2.24	19.3	Side
Roof Edges (assume 1/3 "side")	1.20		
Roof	2.35		
All Other Interior Contacts	4.64	14.9	Other
Noncontact	7.91		
All Exterior Contacts	11.83	11.8	Exterior*
Total	100.2%	100.0%	Total

* "Exterior" should not be equal to "ejection." As seen in Table 8 of Malliaris, only 7.4 of the 11.4 percentage points are related to occupants who were ejected.

Table 3. Potential for harm reduction in percent as a function of crash severity in miles per hour (front component contacts only)

	From Malliaris, Table 11			Added Calculation			
Item	Vehicle Contact	Body Region	Harm Pct of Total	Crash Severity 20	30	Harm % up to Crash Severity 20	30
1	Steering Assy.	Chest	11.90	x .21	.40	= 2.50	4.76

17	Steering Assy.	Upper Extr.	1.16	x .46	.84	= 0.54	0.97
18	Mirrors	Head/Face	1.08	x .76	.88	= 0.82	0.95
19	Glove Comp.	Chest	0.84	x .08	.55	= 0.07	0.46
	Totals		47.80%			14.02%	27.20%

*(Related to frontals only — see Malliaris, Table 5)

Since it is unlikely that all harm could be prevented by practicable improvements in occupant protection, some additional considerations for estimating a more realistic harm reduction are indicated. One assumption could be that no injuries at the minor, or AIS 1, injury level would be eliminated. For example, abrasions, contusions, and superficial lacerations are assumed still to occur. The fractions of total harm related only to AIS levels 2 through 6 can be found on Table 12 of Malliaris. Table 4 adds this assumption to the information on Table 3 and shows the harm reduction potential that remains after AIS 1 injuries are dropped from consideration.

If front interior component improvements could be devised that assured all harm having injury levels of AIS 2 or greater were eliminated in accidents up to 20 or 30mph, total harm reductions of about 11 or 23 percent, respectively, might be realized. Using only front component involvements as the base, these estimated percentages represent front contact harm reduction potentials of about 24 or 48 percent, respectively.

Additional information from Table 13 of Malliaris was used in Table 5 to evaluate a further assumption related to estimating the harm reduction potential of changes to front interior components. For each injury beyond the AIS 1's already dropped from consideration, a mitigation of only one level in the AIS rating was assumed to be achievable by improvements. Accordingly, the totals shown at the bottom right represent the percent of total harm that might be eliminated through crashworthiness improvements for unbelted occupant contact to front interior components, assuming those improvements would be successful in reducing each AIS 2 to 6 injury (occurring up to the indicated speed) by one AIS level.

The estimated potentials for reduction in overall total harm from improvements to frontal components are seen to be about 9, 13, or 17 percent for speeds up to 20, 25, or 30mph, respectively. Again, using only frontal component contacts for a baseline, these percentages represent front contact harm reduction potentials of about 19, 27, or 37 percent, respectively.

Potential for Side Improvements

Side interior contacts represent the second largest basic category of car occupant harm, accounting for about 19 percent of overall total harm. Corresponding potentials for harm reduction from side interior component improvements are estimated by Tables 6, 7, and 8, which were constructed in a manner similar to that described above for frontal components.

The nine specific side component contacts selected for Tables 6, 7, and 8 encompass nearly 14 percent of total harm. This is somewhat less than the 19 percent figure noted earlier, because the more general distribution of Table 2 includes a number of miscellaneous body region contacts not separately identified in the NHTSA tables used for the analyses in this paper.

Summary of Potential for Harm Reduction

Tables 3 through 8 have developed general estimates of the potential available for reducing car occupant total

Table 4. Potential for harm reduction in percent as a function of crash severity in miles per hour (front component contacts, AIS 2-6 only)

	From Malliaris, Table 11						Added Calculation	
				Crash Severity			Harm Pct up to Crash Severity

harm associated with contact to front and side interior components of vehicles, and the listing in Table 9 is a summary of those general estimates. The vehicle components included in the analyses are the ones most likely to be involved in nearly two-thirds of the total harm experienced by car occupants in all modes of crashes.

As mentioned previously, these potentials for harm reduction are expressed as a percentage of all the total harm to car occupants experienced for all crash modes. The values in the table would be correspondingly higher if the base for improvement is viewed as being that related only to front, side, or front-plus-side total harm, as appropriate. For example, the 24.3 percent value at the lower right of the table represents about a 40 percent reduction potential for front-plus-side interior component improvements if they could lower all AIS 2 to 6 injuries each by one AIS level.

The values shown for the potential to reduce harm by lowering AIS 2 to 6 injuries up to certain speeds may be conservative estimates. This is because the benefits of improved designs are not likely to be present at 29.9mph and absent at 30.1mph. There can be some additional potential for harm reduction manifested as some injury reduction in higher speed crashes even for the higher level injuries. As Table A-1 of reference (2) reveals, the opportunity for this effect is appreciable, since nearly half of AIS 5's and about nine-tenths of AIS 4's are survivable. Of course, the actual degree to which given improvements

achieve these potentials will have to be observed from accident data acquired in the future.

Specific Safety Improvements

The general estimates developed above have assumed that certain reductions in injury levels actually would be accomplished within the various interior contact situations.[2] Such a hypothetical approach is useful for an overall consideration of the potential for built-in safety to provide safety benefits. However, assessing the harm reduction that might result from implementation of specific and practicable improvements to individual components of the vehicle entails estimating how much the individual crash injuries might be reduced overall through modification of particular design characteristics of the components involved.

2 The assumption that given safety improvements might yield reductions of one AIS level seems particularly reasonable for the case of head impacts which generate about 30 percent (the largest fraction) of total harm from interior contact (see Table 4 of reference 1). This judgment is supported by the basic nature of the Head Injury Criterion (HIC) used to scale the severity of head-to-vehicle contacts. Since calculation of the HIC begins with raising the measured head accelerations to the 2.5 power, even modest reductions in those impact accelerations should produce significant reductions in HIC values, along with the expectation of reduced AIS levels.

Improvements to the Steering System

As seen earlier in Table 2, the basic category of front accounts for over half (54 percent) of car occupant total harm, and a summation of items 1, 2, 7, and 17 of Table 3 indicates that occupant contact with the steering system is associated with nearly half of that (25.6 percent). In other words, about one-quarter of all harm to all car occupants in all crash modes is related to a single group of vehicle components—the steering system. This should not be surprising since most crashes are frontal and each has a driver seated directly behind a steering system. The relative importance of the steering system within the distribution of total harm prompted a more detailed study of the potential for making crashworthiness improvements in this area.

Extensive experience has been gained by General Motors during the past 20 years regarding the design, development, testing, and field evaluation of steering wheels and energy-absorbing steering columns. This experience has generated an increased understanding of the occupant's interaction with the steering system and is providing important guidance for the implementation of improved crash performance as new vehicles are de-

veloped. In particular, a number of design and performance considerations for the steering system are being identified.

The first relates to the force-versus-deflection properties of the steering column. Traditional designs have specified a more or less constant force level to compress the energy-absorption mechanism within the column. Our more recent studies suggest that a compression force that increases with increasing column stroke better recognizes the dynamic nature of the interaction of the occupant with the steering system. During the early portion of column compression, inertial forces are imposed on the torso of the occupant as the mass of the upper column and the steering wheel is accelerated toward the instrument panel. Therefore, a compounding of forces can be mitigated if the column compression force is designed to be lower at the start of the column stroke. Further, a design that provides a higher column force level toward the end of the stroke can help extend the energy-absorbing capability of the system to higher speed crashes.

Another important element in the energy-absorbing steering column system is the manner in which the stroking portion of the column is attached to the instrument panel. While this attachment must be secure enough to meet the demands of normal vehicle usage, it must also disengage readily (from a range of torso impact directions) so the column can compress in a crash. Such a quick-release attachment to the instrument panel should improve the performance of the column system over a wider range of accident configurations.

The overall interaction of the driver with the steering system can be enhanced through several other considerations. The first is maintaining control of vertical and horizontal displacement of the steering system during vehicle crush. Another is designing the knee impact area of the lower instrument panel to provide improved control of driver kinematics, which should promote both loading the column more in line with the stroking direction and reduced abdominal loads. Additionally, proper selection of steering wheel parameters such as wheel dish, hub contact areas, and force/deflection properties of the rim and spokes should, in some crashes, improve the distribution of load between the chest and shoulders of the driver and should mitigate head impacts to the rim. More crush space in the steering wheel hub should reduce the severity of potential head impacts of the belted driver.

Potential Benefits From Steering System Improvements

The Malliaris papers on total harm distribution do not include information on the specific type (i.e., fracture, concussion, laceration, etc.) of the individual injuries that were entered into their analyses using the AIS coding system. An assessment of the potential benefit from specific design changes and performance improvements such as those described above requires this more detailed knowledge, and such injury details are included in the accident data acquired through GM's Motors Insurance Corporation (MIC).

The Safety and Crashworthiness Systems group within GM's Current Product Engineering analyzed steering system improvement potential by separating the steering system total harm seen in the MIC data into cells according to specific injury type, AIS level, and body region. Injury weights used to generate the MIC total harm were identical to those used by NHTSA in its earlier study of the NCSS data. Estimates were made for how much of the harm in each cell might be mitigated by the steering system improvements under consideration. The data for drivers were analyzed separately for both the belted and unbelted conditions, and Table 10 gives the results.

The potential reductions shown in Table 10 used only steering system contact harm as the 100 percent baseline. If these steering-system-only improvements of 28.6 percent and 34.9 percent for the belted and unbelted cases are

Table 10. Potential driver harm reduction from steering system improvements (using MIC data).

Body Region	Current Percent of Steering System Harm		Portion Estimated to be Reduced	
	belted	unbelted	belted	unbelted
Head	13.4	14.9	4.2	5.4
Neck	0.4	1.5	0.0	0.0
Torso	52.4	56.4	19.8	23.6
Abdomen	16.9	15.8	4.6	4.5
Upper Ext.	7.3	4.2	0.0	0.0
Lower Ext.	2.4	2.6	0.0	0.0
Whole Body	7.2	4.6	0.0	1.4
Totals	100.0%	100.0%	28.6%	34.9%

multiplied by the 25.6 percent of total harm noted earlier for only steering system contact, a reduction in overall total harm of from 7 to 9 percent is indicated to be potentially available from steering system improvements such as were described above.

Improvements for Side Impact

Referring again to the broad distribution shown in Table 2, the basic category of side represents the second highest portion of total harm to car occupants, accounting for about 20 percent. If more specific occupant-to-vehicle contacts are examined (as in Table 6), nearly 14 percent of all harm to all car occupants in all crash modes is indicated.

In October 1980, a paper was published by Mehta, Pearson, and Wilson entitled "Side Impact Insights From General Motors Field Accident Data Base." This study(3) provided overview statistics and in-depth, case-by-case analyses of side impacts involving fatal and life-threatening injuries. The in-depth studies focused on how injuries were produced in side impacts and in what areas countermeasures might help mitigate those injuries. In general, two primary categories for countermeasures were suggested: improved energy absorption for side interiors and improved side structural integrity. Side interior improvement might allocate more space for energy-absorbing materials and/or structures in the areas of torso-to-door and head-to-roof-rail impact. Improved integrity of the side structure might include further strengthening of door hinges and latch/strikers, improved attachment of body pillars, body joint redesign, and improved welding.

Potential Benefits From Side Interior Improvements

General estimates of the potential for mitigating life-threatening and fatal (AIS 4 to 6) injuries were made during the Mehta analysis of 216 occupants in non-rollover, nonejection side impacts. Injuries to the head, torso, and lower extremities were included in the study. For 23 percent of the fatalities and 41 percent of the AIS 4 to 5 occupants, potential for injury reduction from practicable changes to the vehicle was judged present. In particular, improved interior energy absorption was estimated to have mitigation potential for 11 percent of the fatally injured and 20 percent of the AIS 4 to 5 occupants. Side structural integrity improvements were judged to have the potential to help 2 percent of the fatally injured occupants and 1 percent of those with AIS 4 to 5 injuries. Again, these judgments were very general (no specific countermeasures were identified) and injuries to all body regions were included to formulate the estimates.

Concerning a more specific benefit projection, the Field Accident Review group within GM's Current Product Engineering analyzed side impact data from the 1980-84 MIC accident files to determine what the potential reduction in total harm might be from increasing the energy absorption of the side interior. This study of MIC data, however, was limited to chest and abdomen contacts only. Specifically, the included injuries were to the chest region, the liver, the spleen, and the kidneys. The assumed modification to the side interior consisted of providing improved energy-absorbing construction in the area of occupant impact, including contoured armrests of limited protrusion. Based on earlier testing using dummies in car-to-car side impacts, an initial assumption was made that such interior changes might reduce AIS 2, 3, and 4 chest and abdomen injuries, each by one AIS level.

When the above assumptions and limitations were applied, a preliminary, computer-only data analysis indicated a potential for reduced, overall total harm of about 4.7 percentage points (a change from 9.5 to 4.8 percent). To verify the validity of the initial injury-reduction assumption, an in-depth study of those cases likely to have the greatest influence on harm reduction estimates was performed. As a result of the case-by-case review, the injury-reduction assumption was changed. The "one AIS level" reduction would still apply to all AIS 2 and 3 injuries; however, the probability of reducing AIS 4 injuries was limited to about 4 chances in 10. Also, since there is some harm reduction potential for injuries above the severity range of the first assumption, the 0.4 probability was assumed to apply also to AIS 5 injuries.

When the data were analyzed again but with the revised injury-reduction assumptions, the estimated potential for reduction in total harm from the improved energy absorption as outlined above was seen to be 2.9 percent overall. Using the original 9.5 percent value as a base, this potential reduction would represent a 30 percent improvement. As mentioned previously, only chest and abdomen contacts were included in this particular study. Any improvement for head impact from other modifications would represent additional potential for reduced harm.

Summary of Steering System and Side Interior Potential Benefits

Table 11 is a summary of the estimates of potential reductions in total harm that might be realized from improvements to two areas of the vehicle interior associated with injury to car occupants. Referring back to Tables 3 and 6, the percentages of all occupant harm produced by contact with front and side interior components in crashes below 30mph are about 27 percent and 11 percent, respectively, for a total of 38 percent. If

Table 11. Estimated harm reduction potential from interior component improvements.

Vehicle Component	Body Regions Considered	Harm Reduction for Contacts Considered	Overall Reduction in Total Harm
Steering System	All	35 percent	9 percent
Side Interior	Chest and Abdomen	30 percent	3 percent

specific improvements to just two component systems were successful in accomplishing the various AIS reductions that were judged potentially achievable, Table 11 would project nearly a one-third reduction from that total (12 parts out of 38).

Summary

This paper has reviewed car occupant harm distributions as originally developed by Malliaris, et al., of NHTSA and, by selection of appropriate line items from those distributions, has generated overall estimates of potential reductions in total harm that might be realized through vehicle crashworthiness improvements. The overall potential for harm reduction from front- and side-interior improvements alone was seen to be as much as 24 percent if those improvements were able to reduce AIS 2 to 6 injuries each by one AIS level up to crash speeds of 30mph. A general view of which occupant-interior interactions present the primary opportunities for improvement is implicit in the harm distributions themselves. In addition, specific safety improvements to the steering system and the side interior were outlined and their potential benefits discussed. About a 12 percent reduction in total harm was estimated to be potentially available from the particular countermeasures considered.

Changes to the components involved in the various safety improvement areas likely can be developed as part of the built-in crashworthiness of the vehicle's design. As such, they offer potential benefits complementary to those of add-on safety equipment such as manual belts, automatic belts, or airbags. This is important because (1) some degree of nonuse of belts likely will remain even with the growing adoption of belt-use laws in the United States, and (2) belted occupants still can contact the vehicle interior in more severe crashes, as can airbag-restrained occupants in crashes below the deployment threshold or in side impacts and rollovers.

An Impact Test Programme Using Six Models of Lower-Medium-Sized Care

S. Penoyre
Transport and Road Research Laboratory, Department of Transport, Crowthorne, Berkshire, United Kingdom

Abstract

This paper describes a test programme in which examples of six models of popular 1983 lower-medium-size four-door cars were subjected to front, side, and interior headform impacts to assess occupant protection.

The frontal test was a 30° angled impact into a wood-faced barrier at 60km/h using restrained OPAT dummies. The side test was a 90° impact from a CCMC deformable mobile barrier at 50km/h, using a prototype Eurosid dummy to represent the driver. The interior headform tests used a 6.8kg free-flight headform launched from an air gun at 24km/h to impact 21 points that occupants are likely to strike in an accident.

The results of these tests are summarised and used to compare the occupant protection offered by the different car models and also to see whether the average level has changed since a previous set of similar TRRL tests on 1976 cars. The more recent cars appear to provide considerably better protection in frontal impacts, mainly because of reduced intrusion and lower occupant head accelerations, but little progress has been made on improving side impact protection.

It is suggested the current levels of occupant protection could be further improved by simple, cheap design changes, e.g., fitting energy-absorbing door trims in place of standard armrests and using less aggressive steering wheels with better padding over the end of the steering column. Improvements to standard lap diagonal seatbelts, for example by fitting pretensioners, would also be worthwhile for cars sold in countries like the United Kingdom that have a high belt-wearing rate.

Introduction

This paper describes an impact test programme recently carried out on six models of European and Japanese lower-medium-size four-door cars bought new in 1983: the Renault 9, Vauxhall (GM) Astra, Volvo 340, Toyota Tercel, Austin Rover Maestro, and Ford Escort. The tests were carried out by MIRA under contract to TRRL. The purpose of the programme was to assess and compare how well these cars protect their occupants in crashes and to some degree compare the results with those from tests on 1976 cars. The tests were also intended to identify any particular strengths or weaknesses in the individual models and to suggest practicable and cheap ways in which they could be made safer. Since the tests were more demanding than those used in current safety legislation, it was hoped their results would also show whether recently designed cars are providing better occupant protection than the basic minimum required by law.

Test Procedures

The impact test procedures used in this programme were based on those TRRL has been advocating for many years(1,3); a 30° angled 60km/h frontal barrier impact, a 90° side impact mobile barrier test representing a 50km/h collision, and a set of interior tests with a free-flight headform of 6.8kg at 24km/h.

The frontal angled barrier test used OPAT dummies wearing seatbelts in both front seats of each car, the same dummies being used for each of the six tests. These tests were assessed on the same criteria as before(1,3), i.e., dummy head and chest accelerations and femur forces, and passenger compartment survival space measurements from ECE Regulation 33 (instrument panel to R point, front of passenger compartment to R point, and width of footwell through the brake pedal). OPAT dummies were used because it is felt their chest and shoulder design gives a more human-like response than the Part 572 dummy. In future frontal tests, it is likely that Hybrid III dummies will be used. However, for the reasons given in (1), it is unlikely a change from the angled barrier test to a perpendicular one will be made.

The side impact test was an updated version of the procedure previously used at TRRL(2) with a CCMC deformable barrier(4) of mass 950kg moving at 50km/h instead of the TRRL rigid barrier of mass 1,100kg moving at 35km/h. The test was a 90° impact into the driver's side of the stationary car, with the barrier face centered on the R point. The TRRL side impact dummy previously used to represent the driver was replaced with an Interim Eurosid, a prototype version of the European side impact dummy now being developed by EEVC(5). The test was mainly assessed on the dummy measurements of rib deflection and pelvis load, although the barrier's peak deceleration was also measured to give an indication of the stiffness of the struck side of the car. The Eurosid dummy is designed to give a better representation of the stiffness of the human chest than the TRRL side impact dummy, while keeping the earlier dummy's ability to measure pelvis force. The new dummy predicts chest injury from rib deflection measurements. In future tests,

it is planned to use the final Eurosid dummy rather than this interim version and to change to the EEVC deformable mobile barrier(6) rather than the CCMC design.

The interior headform impact test was also slightly updated from that previously used(1,3) since the MIRA Mark 2 Free-Flight Headform Launcher was available in place of the more awkward and bulky Mark I air gun. The new launcher is described in (7). The number of interior impact points in each car was also reduced from 25 to 21. The impacts are of the same severity as now used in ECE Regulation 21, i.e., a 6.8kg headform impacting at 24km/h and having a rigid face that is a segment of a sphere of diameter 165mm.

Frontal Impact Test Results

Table 1 summarises the results of the 60km/h frontal impact barrier tests and also gives proposed critical or tolerance values for the various parameters; figures from current or proposed legislation have been used where applicable. For head injury, the simple criterion of peak deceleration (3ms cumulative) has been used rather than HIC because it is easier to understand while (in the view of some authorities(8) being quite as good a predictor of brain injuries. A femur load tolerance value of 4kN has been used as previously; since then higher levels have been suggested but for the sake of continuity these have not been used here.

It is clear from Table 1 that Car C performed best of the six cars in this frontal impact test, with none of its measured parameters exceeding the critical values. Car F also did well, but had a passenger head acceleration of 102g, apparently due to a combination of excessive seatbelt stretch, spoolout, and too stiff a facia. Car B also had a similar though less severe (90g) passenger head to facia impact, and Cars B, D, and E all had driver's head to steering wheel rim impacts giving 87 to 95g head accelerations. Cars A, B, and D also had driver left femur loads above the 4kN level, probably from contact with the steering column or its supporting structure.

The performance of all these cars would have been improved by reducing spoolout and possibly by reducing seatbelt stretch. This might be done by using stiffer webbing, and either a web locker at the upper belt anchorage or a seatbelt pretensioner. Further improvements could be made by providing better energy-absorption capability in the areas that the occupants hit when the belt does allow such contact.

Side Impact Test Results

Table 2 summarises the results of the 50km/h side impact mobile barrier tests, with proposed critical values for the Interim Eurosid dummy used to represent the driver. These critical values are even more uncertain than usual, because the dummy was an interim version and had not been thoroughly tested to correlate its measured outputs with other side impact dummies or cadavers. A direct translation from TRRL SID to this dummy is not possible because the former has four load-measuring ribs while the latter has only two transducers measuring rib deflection. However, an approximate translation can be made, which suggests a tolerance value of 20mm for allowable rib deflection. For the pelvis, the position is even less satisfactory. Limited drop testing onto surfaces representing car doors has suggested that although the pelvis stiffness of the TRRL SID and this Eurosid are similar, the Eurosid appears to give higher measured pelvis forces than the TRRL SID. Also, work done since the pelvis tolerance load of 6kN for TRRL SID was derived(9) has suggested that this 6kN is perhaps too low; for example, cadaver tests on Onser(10) indicate a figure of 10kN for 50 percentile male subjects, and perhaps 30 percent less for females. For these six tests, a provisional critical value for pelvic load of 9kN in this Interim Eurosid dummy has been chosen.

Another difficulty arising from the use of this prototype dummy was that in one of the tests (Car A), the rib deflection measuring instrumentation failed, while in another (Car D) the ribs jammed mechanically. Chest acceleration resultant measurements can be used as a backup in such cases, although this is felt to be a worse predictor of chest injury than rib deflection. Then there is a question as to whether 3ms exceedence or Gadd Severity Index should be used. Table 2 gives values of all these quantities for all the cars.

The mobile barrier peak decelerations measured in these tests were very similar (15 to 16.7g, after filtering to 180Hz and then digitally to 60Hz). These values correspond to forces of 140 to 155kN on the 950kg barrier. They are significantly less than the force of 220kN required to deform the CCMC barrier (intended to represent the front of a typical European car) by 200mm(6). The sides of these cars, therefore, appear to be too weak to make the front of a car hitting them deform enough to absorb much of the energy in a front to side crash. Car F was the only car of the six fitted with door beams, and these do not seem to have been very effective in stiffening its side; its peak barrier deceleration of 16.7g was the same as that of Car C without beams, and measurements of intrusion in these two cars were similar.

The Car F figures for pelvis force and acceleration were satisfactorily low, better than all the other cars except Car D (where the jamming ribs probably increased the load carried by the chest while reducing the pelvis load). Car F is the only one of these cars fitted with energy-absorbing door trim at pelvis level, as an armrest, and this suggests that such trim can be effective in reducing pelvis forces. However, the Car F rib deflections and chest acceleration are not particularly low, which confirms that door beams do not necessarily reduce chest injury. This

Table 1.

agrees with previous TRRL work(2), which indicated that door beams produce hard areas in the door that can cause injuries, and also with more recent American work(11), which suggested that the space door beams occupy would be better used as energy-absorbing crush depth. An interesting possibility would be to use a door beam low down in the door just below the level of the driver's pelvis, where it would provide an increased side stiffness without taking up useful crush distance. Such a low beam (running back from the lower door hinge rather than the upper one) could also perhaps be supported in a side impact by a stronger seat frame and mounting to provide a worthwhile increase in occupant protection at acceptable weight and cost.

Table 2 shows that none of the cars did well in this side impact test; each car exceeded several of the proposed injury criteria, and Car E exceeded all these criteria. The consensus is that radical design changes are needed to solve this problem. These would include strengthening the side structure to resist impact, but this alone is unlikely to be effective, and it is desirable that car front structures should be softer than at present for car front to car side impacts. Finally, however, extensive energy-absorbing padding is needed to attenuate side impact loadings.

Interior Impact Results

Table 3 summarises the results of the interior free-flight headform tests. The figures given are the peak headform resultant accelerations after filtering to Channel Class 60 (i.e., 60Hz). This was chosen after a trial in which headform test results were filtered to different channel classes and their peak accelerations compared with the 3ms exceedence level. Class 60 was the frequency whose maxima corresponded most closely to the 3ms figures. Use of this 60Hz peak level is intended to overcome the well-known problem of applying the 3ms exceedence criterion (whether continuous or cumulative) to an oscillatory or spikey signal, where tiny differences in the shape of the signal can make large differences in the figure produced. It should also insure that a headform impact with a very rigid surface (e.g., the unpadded top of a steering column) cannot give an apparently safe result because the very high acceleration peak does not last for 3ms.

All the cars produced good results in the impacts with the facia top and the lower facia. The steering wheel rim impacts also gave fairly low decelerations (37 to 55g). As explained in(12), this present test with a rigid headform is not a good measure of the potential of a steering wheel for causing fracture of the facial bones. For example, a deceleration of only 40g on the 6.8kg (15 lb) headform is a force of 2.7kN (600 lb), which, if applied to a face by a narrow wheel rim over a contact area of perhaps 75x12mm (3x½in), produces a local pressure that is about twice what the facial bones can withstand(13). A test using a deformable or frangible face form (e.g., a piece of aluminum honeycomb of the correct crush strength) would therefore be preferable for measuring the safety of a steering wheel rim. The test could insure that the wheel centre, steering column end, and rim are padded to reduce face bone fractures.

The other five areas tested (header rail, cantrail, A post, B post, and steering wheel hub) all gave poor results with high headform decelerations, although there are wide variations between car models. For example, the header rail on Car A gave a mean value over five impact points of 63g, while Car E gave nearly double this at 121g. Similarly, the A post results vary from 66g (Car F) to 99g (Car E), and the steering wheel hub from 75g (Car F) to 111g (Car E). These high values for steering wheel hubs are important because these may be struck by the faces of drivers wearing seatbelts.

On all six cars, the B posts and cantrails (over the doors) gave very high levels of headform acceleration, and design changes to improve energy absorption in these areas would be very desirable. The seatbelt anchorage point on the B post might possibly be protected by using foam-filled plastic or deformable metal trims clipped to the anchorage. It may be more difficult to protect the cantrail area without unacceptable reduction of the space

Table 3.

beside the heads of occupants. Sideways head space does not usually seem to be a critical design area. Grab handles are often fitted there in the up-market versions of small cars, and several luxury saloons offer very limited head space in this direction.

Comparison With Results on Previous Cars

Although exact comparisons cannot be made with the similar tests(1,2,3) on cars produced in 1976, some trends are apparent.

In the frontal impact test, Table 1 shows the 1983 cars gave no infringements of the ECE Regulation 33 survival space requirements and lower values for dummy head accelerations (an average of 81g rather than 105g). Dummy passenger head impact levels were similar. Deceleration levels for headforms on facias have improved and so has the softness of the rims of steering wheels. However, the rigidity of the other likely head impact areas is little different.

Overall, the results of Table 1 show a fairly good level of occupant protection at 60km/h angled impact. This suggests that the 30° angled barrier test proposal at 50km/h has been largely overtaken by events.

An alternative is the U.S. New Car Assessment Program test head-on into a barrier at 35mi/h (56km/h)(14), but this does less to improve resistance to corner impact and subsequent intrusion.

For side impact protection, the introduction of European legislation is long overdue, and this may partly account for the lack of energy-absorbing door trims and other measures for protection.

Although car manufacturers can be justifiably proud of the improvements achieved in frontal barrier test results between 1976 and 1983, the fact that large numbers of car occupants are still being killed or seriously injured even when wearing seatbelts in modern designs of cars should remove any grounds for complacency. There is a wide range between the best and worst results in many of the tests, so a very significant improvement in occupant protection would result if all cars approached the levels that the best are already achieving in the various tests. It should also be possible to achieve a further improvement by using safety ideas that have not yet been introduced widely into production cars but whose value and feasibility have previously been demonstrated on experimental safety vehicles, e.g., safer steering wheels, energy-absorbing armrests and door trim, and head impact area padding. Seatbelt pretensioners are a more recent innovation of great promise.

Conclusion

1. Six models of European and Japanese 1983 lower-medium-size four-door cars have been tested in front, side, and interior impacts: the Renault 9, Vauxhall (GM) Astra, Volvo 340, Toyota Tercel, Austin Rover Maestro, and Ford Escort.
2. The results of the frontal impact tests were on average considerably better than those of similar tests carried out on 1976 cars. The most important improvements in the 1983 cars were reduced intrusion into the passenger compartment and lower occupant head decelerations. However, little progress appears to have been made in improving side impact protection.
3. A comparison of the results for the six models of car suggests that five are very similar in overall performance while the other appears to be designed to slightly less demanding standards. It is noteworthy that no one design has the best performance in many of the different aspects of safety for its occupants. In fact, a new car built with the best features from these six models would be a distinct advance on the six. Further improvements in safety can therefore be gained by attention to detail design.
4. The good average performance of these 1983 cars in this 60km/h frontal barrier impact suggests that current legislation based on 50km/h impacts is no longer having a major influence on the designs produced by competent teams, who are providing more occupant protection than the minimum standard required. Since the number of car occupants being killed is still unacceptably high, there is a clear need for a more demanding and realistic frontal impact legislative test. The long overdue introduction of European side impact legislation, and the more realistic testing of likely interior head impact areas, are also needed if legislation is to make a further contribution to car occupant safety.
5. The main safety problems for belted occupants in nearly all the six cars are—
   - In the frontal impact test, driver head injury from the steering wheel and passenger head injury from the facia
   - In the side impact test, high chest and pelvis loads
   - In the interior impact tests, excessive stiffness and lack of padding on the steering wheel hub, the header rail, and cantrails (i.e., above the windscreen and doors), and on the windscreen A post and central side pillars
6. Simple ways of reducing these safety problems would be to—
   - Improve the steering wheel design
   - Use energy-absorbing armrests and trim on the doors
   - Improve padding in the head impact areas

A more expensive safety improvement would be to use seatbelt pretensioners. However, side impact appears to be the least tractable occupant protection problem, and a

concerted effort backed by regulations is needed to improve the situation.

A Free-Flight Headform Impact Device for Evaluating the Energy-Absorption Characteristics of Vehicle Interiors

K.J. Dale and
K.C. Clemo
Motor Industry Research Association

Abstract

This paper reports on the design, development, and use of a test rig that enables the analysis of the aggressivity of vehicle interiors to the heads of occupants. The equipment comprises a pneumatically controlled free-flight headform device. It can be positioned inside the passenger compartment of any passenger car via any normal window or door aperture. The device fires a simulated headform prescribed in SAE J984 at speeds from 10 to 30mph. The enormous degree of flexibility in positioning enables impacts to be conducted on almost any part of the vehicle interior.

Currently, energy-absorbing characteristics of the interior of passenger cars are assessed using drop rigs or pendulums, which necessitate the dismantling of the vehicle body. This has implications for representativeness in terms of the validity of the stiffness characteristics of the section of the vehicle being tested.

The results of testing standard specimens, using all three test devices, are presented and discussed.

Introduction

In vehicle crashes, injuries to occupants are frequently sustained by the head striking the interior surfaces of the

passenger compartment. The design of the passenger compartment has a significant effect on the injuries that result from a given impact. In particular, the injury level is reduced where the impact acceleration of the head is limited by provision of resilience or energy absorption in the impact area.

A number of test methods exist to compare the ability of different vehicles to limit head injury. One method of simulating a real impact is given by a full-scale crash test using anthropomorphic dummies, such as the U.S. FMVSS 208 regulation. This comprises a variety of impact conditions, including frontal barrier, angle barrier, side impact, etc., with restrained 50th percentile male dummies in the vehicle, the dummies being fitted with accelerometers in various locations, including the head, to measure the impact accelerations.

However, this test can only mimic the behaviour of a human subject for—

- The trajectory of the dummy head
- The point of impact on the car interior for this accident configuration only

Studies of real accidents, however, show a wide variation in impact location(1). Clearly, it is impractical to carry out a full crash test at each possible head impact point and, therefore, it is necessary to supplement these with a simpler test, which can be repeated at a large number of positions on the vehicle interior.

One such test is laid down in the FMVSS 201(2) and ECE 21 regulation(3). These define the parts of a vehicle interior that must limit head acceleration during impact. They specify a test using a smooth rigid hemisphere conforming to SAE J984(4) of 6.8kg mass and 165mm diameter, striking the vehicle surface at velocities up to 24.1km/h. The impact velocity is related to the angle at which a head, connected to an imaginary torso pivoted at the H-point, strikes the surface. One established means of propelling the hemispherical headform is by mounting it on a pendulum rig or alternatively by guided drop weight rig.

The principal disadvantage using these approaches is that the vehicle to be tested must be dismantled to enable access to the selected impact positions. When dismantled, the vehicle components are mounted separately on the rig simulating as near as possible the mounting in the vehicle.

Once the component is prepared in this way, the structural integrity of the test sample is compromised, to the extent it may have a different stiffness characteristic than when it was incorporated into the vehicle body.

The MIRA Free-Flight Headform Impact Device has been designed in an attempt to provide a solution to these problems, which have also been addressed by rigs of the compressed air nodding hammer type. The device is basically a pneumatically controlled launcher of a headform conforming to SAE J984. It can be positioned inside the occupant compartment of any passenger car via any normal window or door aperture. The enormous degree of flexibility provided in positioning enables impacts to be conducted on almost any part of the vehicle interior.

One important factor in the establishment of a new piece of equipment is its correlation in performance with equipment already accepted as suitable for compliance testing to legislation requirements by the regulatory authorities.

MIRA has conducted tests using two more common rigs and the Free-Flight Headform Impact Device to access the correlation of headform deceleration characteristics between the different devices.

The MIRA Free-Flight Headform Impact Rig

Description of Equipment

The MIRA Free-Flight Headform Impact Rig consists of an instrumented headform with its associated launching apparatus and signal processing equipment. The headform is in the form of a piston and is fired from an open-ended pneumatic cylinder by a charge of low-pressure air. The rig is illustrated in Figure 1 and the launcher system in Figure 2.

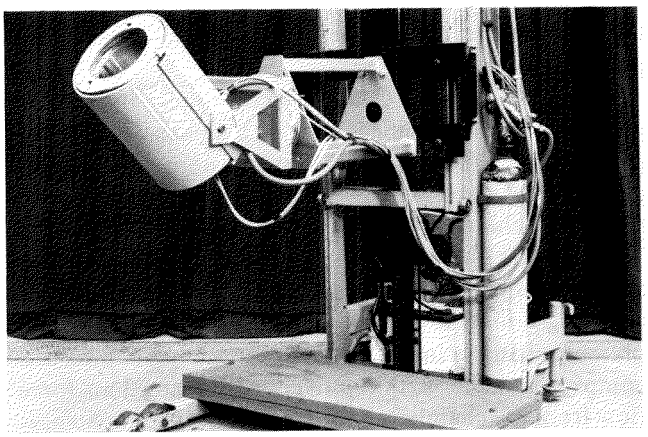

Figure 1. MIRA free-flight headform impact device

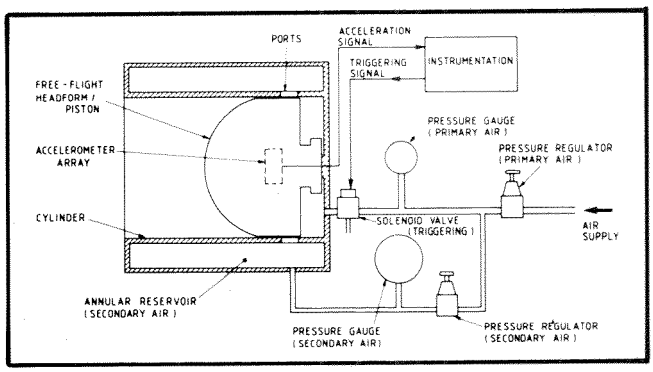

Figure 2. Schematic diagram of headform launcher system

The headform is in three parts, enclosing a central cavity that houses an accelerometer array. The central part is a steel piston of 158mm diameter, carrying two pneumatic seals. Onto the front face of this is bolted an aluminum block whose front surface forms a segment of a 165mm diameter sphere. This spherical surface subtends an arc of 140° about the piston axis.

The rear part of the headform constitutes an aluminum ballast plate designed to place the combined centre of gravity of the headform at the centre of the sphere. An array of three accelerometers is bolted to the rear face of the spherical segment with their axes aligned with the axis of the piston and two other mutually perpendicular axes, intersecting at the centre of the sphere. The combined mass of the headform and accelerometers is 6.8kg. The signal from the accelerometers is carried by an umbilical multicore cable that passes through a slot in the rear face of the headform.

The launcher consists of a cylinder of 158mm diameter and 330mm length, open at both ends. The rear end of the cylinder is fitted with a sealed plug held in position by quick-release clamps to allow the headform to be loaded from the breech. The accelerometer cable passes through a sealed gland in this plug, with approximately 2m of cable between this and the headform, the cable being wound into the space between the headform and plug. When correctly installed in the cylinder, the piston is located against a stop on the plug and held by a permanent magnet.

The outside of the cylinder incorporates an annular pressure chamber connected to the cylinder via a ring of ports in the cylinder wall. When the piston is in the firing position, the ports lie between the two piston seals, with the space behind the piston ventilated to the atmosphere. The pressure chamber may therefore be charged to the firing pressure of up to approximately 5 bar without applying a load to the piston. The arrangement of the pressure chamber in this form offers the combination of a compact launcher with relatively unrestrained air force flow from the chamber to the cylinder. The compactness of the launcher, in particular, allows impacts to be made downward onto the top of the facia panel. The piston is fired by closing the connection to the atmosphere and introducing a pulse of pressurised air onto the rear face of the piston. This moves the piston off its stop, opening the ports and allowing the air to flow from the pressure chamber into the main cylinder, firing the piston from the open end.

The pressure chamber is charged via a precision regulator from a supply of bottled nitrogen, the regulator setting being used to control the firing velocity. The air used to trigger the firing is taken from the same supply via a second regulator and an electro-pneumatic solenoid valve mounted on the plug.

The launching cylinder is mounted on an apparatus that allows it to be positioned inside a complete vehicle to simulate a wide variety of head-impact positions and directions. This is in the form of a trolley carrying an extension arm on which the cylinder is mounted, the arm being adjustable for height, using a hydraulic mechanism. The trolley is wheeled to the vehicle and the arm inserted through a suitable door, tailgate, or window aperture. A pivoting cradle on the end of the arm allows the cylinder to be aligned with the chosen impact position at a suitable firing distance. Clamps on the cradle pivots and trolley wheels and ballast on the base of the trolley minimise movement of the cylinder during firing. The trolley carries a $44ft^3$ cylinder of nitrogen that supplies the cylinder during firing, which is capable of providing a supply pressure for over 80 impacts.

The signals from the three accelerometers are passed to a MIRA instrumentation trolley where they are amplified and recorded on a Hewlett Packard HP 6942A Multi-programmer incorporating high-speed analogue to digital converter with the associated I/O circuitry and configured with HP 9816 S microcomputer.

The circuits of the three accelerometers incorporate fixed resistors inserted during calibration to represent fixed-scale values. These may be switched into the circuit and recorded before the test to enable the scale of the output signal to be determined. The switching and firing of the headform are controlled by the instrumentation trolley.

The firing velocity of the headform is generally derived from the accelerometer signal, but may also be determined by means of an extension of the rear ballast plate passing between a light source and photocell mounted on the front face of the cylinder. The extension incorporates two trailing edges a known distance apart. The output from the photocell is monitored and the time elapsed between the passage of these two edges recorded on a digital-output timer.

Test Equipment Operation and Performance

The appropriate impact point inside the vehicle is selected from the array of positions to be tested. Figure 3

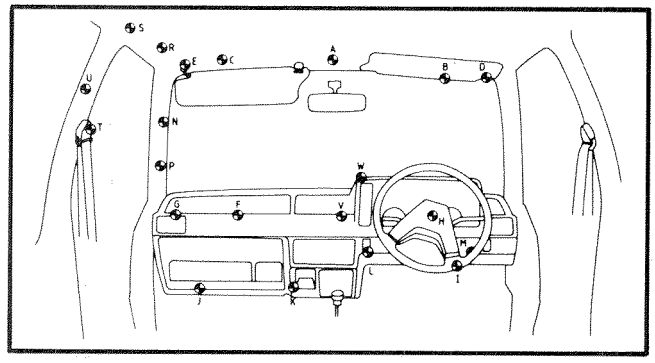

Figure 3. Typical positions selected for impact

illustrates a variety of positions where impacts can be directed.

The test rig is manoeuvred into the car to give the correct impact alignment, with the first contact of the headform on the impact point. This is checked with a small gauge that fits into the end of the cylinder and carries a two-dimensional template representing the headform. The distance of the cylinder from the impact point is selected to allow the headform to clear the cylinder before impact and prevent damage on recoil, and is normally in the range of 300 to 400mm. A small correction is made to allow for the effect of gravity on the headform in flight. With the cylinder aligned, the clamps on the support structure are tightened and the angles of the cylinder in relation to the car noted.

The cylinder is then lubricated and the headform loaded to the rear of the cylinder with the axes of the accelerometers in vertical and horizontal planes. The plug is then located on the rear of the headform and the cable wound into the annular space between them. The whole unit is then slid forward into the end of the cylinder, taking care not to trap the cable, and the plug clamps tightened. The engagement of the headform on the plug (and its correct positioning in relation to the ports) is then checked with a small gauge.

Guards are then fitted to the door apertures of the vehicle, if doors have been removed, and the cylinder charged up to the firing pressure. The firing sequence (with its safety override) is initiated, putting the calibration steps on the computer and firing the headform and recording data. The air supply is automatically disconnected and the damage noted. The headform is then fed back through the cylinder and the procedure repeated for the other impact points.

The graph of headform fore and aft acceleration shown in Figure 4 illustrates the phases that the headform

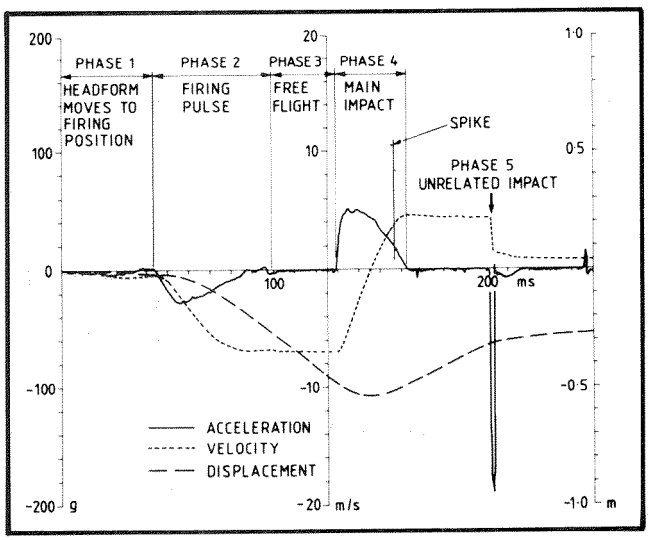

Figure 4. Various phases of headform acceleration traces

undergoes during the test. Beginning at the point where the solenoid valve operates and air is admitted behind the piston, Phase 1 represents the slow movement of the headform as the restricted airflow through the valve displaces it from its initial position toward the ports.

Phase 2 shows the increasing acceleration as the piston uncovers the ports and air transfers rapidly into the cylinder. After reaching a maximum of approximately 25g, the acceleration declines as the air charge expands.

Finally, at a displacement of 270mm, the headform emerges from the end of the cylinder and begins Phase 3, which represents the free flight of the headform to its target. The distance travelled in this phase depends on the test configuration but is generally between 200 and 500mm. The headform is subject to the effects of gravity during this phase, but this may be compensated for in setting up the test.

Phase 4 begins as the headform first decelerates as it strikes the impact point. Up to this point, the alignment of the headform has been maintained by the launcher, but during this phase the headform may rotate and cause the original alignment to be lost. Therefore, we cannot derive any useful information from the fore and aft channel beyond this point and must turn to the graph of resultant acceleration, which is not affected by the rotation of the axes. Despite this, however, analysis of high-speed cine shows most impacts appear to undergo little, if any, angular deflection during impact, so that the fore and aft trace gives an approximate indication of the penetration of the headform and the recoil velocity.

After impact, the headform falls back into the interior of the car. In doing this, further impacts occur as it strikes the launcher or the vehicle, and these often fall within the timespan of the analysis. These impacts are generally of lower severity than the main impact due to the lower velocity and can be readily distinguished. One such impact is shown on the graph as Phase 5.

The principal method of measuring headform velocity in these tests is the technique of integrating the fore and aft accelerometer signal. This is an established method used in MIRA for measuring velocity and displacement of vehicles in crash tests.

However, as a backup, a second technique is employed, using a light beam on the front face of the launcher, intersecting two surfaces on the rear of the headform. This provides a readout on a digital display from which the speed may be calculated.

However, this method proved very unpredictable in use due to the interaction of the trailing umbilical cable with the beam, and, in approximately 25 percent of the tests, this measure of velocity has been lost due to interaction of the cable before or during the timing interval.

In addition to this, the velocity calculated by this method has proved to be generally of the order of 15 percent lower than the value obtained by integration.

Examination of high-speed cine films of various impacts suggests that this may be due to the displacement of the launcher due to recoil. This displacement has a maximum amplitude of approximately 12mm and the launcher is beginning to move forward during the timing interval, so the timer speed represents only the relative velocity between the launcher and headform at this point.

The aiming of the device is good and not seriously affected by the slight distortion of the support upon firing. In a situation representing the worst possible case, with a flight distance of 430mm and the launcher axis at right angles to the arm, the headform struck a point 12mm away from its original target. Given the benefit of these tests, it is possible now to compensate for this effect in aiming the device. Clearly, it would be an advantage to have a mounting that constrains the launcher most effectively. However, this is the first of its type and the maneouverability proved extremely useful. Future models could incorporate a mounting with stiffer supports and fewer moving parts while retaining accessibility.

Signal Analysis

The results are analysed using MIRA's impact test analysis computer program. The recorded signals are variously filtered to Channel Frequency Classes (CFC) 1000 and 60 as defined in SAE Technical Report J211(5). The signals are then passed through an analogue to digital converter for analysis at a nominal sampling rate of 33 samples/ms of real time record and loaded onto disc. The accelerometer signals are recalled from disc for the period corresponding to 250ms after activation of the solenoid valve. This period includes the acceleration from the launcher, the main impact, and, in some cases, a further impact as the headform strikes other parts of the car interior.

Headform Speed

This is computed from the integration of the headform's acceleration in the firing direction, starting just before the release mechanism is operated, when the headform is known to be stationary. This may be expressed as follows:

$$v = \int_{o}^{T} a_f \cdot dt$$

Where:

a_f = acceleration in the direction of impact
t = time from a point just before release

v is drawn out as a graph against t over the time scale 0 to 250ms. The velocity of the headform just before impact may be read from the graph. Note that the graph ceases to be valid during the impact after rotation of the accelerometer axes.

The graph also computes the displacement of the headform, along the impact axis from the second integral of headform acceleration with respect to t.

The headform's velocity may also be determined by the time taken for the two trailing edges on the headform and its extension (a distance of 30mm apart) intersecting the timing light beam.

Resultant Acceleration (Magnitude of Acceleration Vector)

This may be expressed by the formula:

$$a_r = a^2_f + a^2_v l + a^2_l$$

where:

a_f = acceleration in the direction of impact
a_v = acceleration at right angles to the direction of impact and in a vertical plane
a_l = acceleration at right angles to the direction of impact and in a horizontal plane

This quantity is expressed as a graph against t, over the time scale 0 to 250ms, and, when computed, forms the basis for head injury predictions.

Head Injury Level

The computer programme conducts analysis on the normally accepted indices of head injury level required by current international legislation. These comprise the following:

80g for 3ms exceedence
Gadd Severity Index 1000
Head Injury Criterion HIC 1000

Test Equipment Used To Quantify Correlation

The most important aspect, in terms of performance, of any new device used for testing components is the correlation of the output function with other currently accepted equipment. Headform impact testing has been conducted for many years using both pendulums and drop weight rigs.

The performance comparison of the MIRA Free-Flight Headform Impact Device was conducted against that of the MIRA Head Impact Pendulum Rig and the MIRA Head Impact Drop Weight Rig. All three devices incorporate headforms to the legislative requirements, and all impacts were conducted using a standard test specimen.

Description of the Head Impact Pendulum Rig

This rig comprises a hemispherical headform mounted on a pendulum arm to simulate occupant head impacts on items such as facias, seats, etc., and is illustrated in Figure 5.

The headform is a hollow aluminum hemisphere of 165mm diameter and having an effective mass of 6.8kg. This is made in two parts and carries two accelerometers mounted symmetrically on either side of the centre-line,

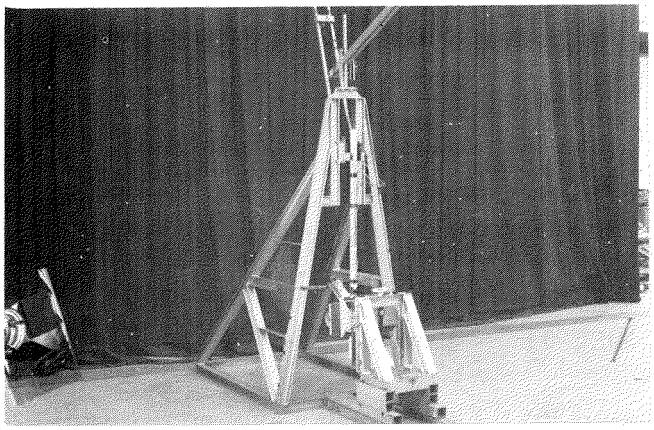

Figure 5. MIRA head impact pendulum

measuring the tangential acceleration of the headform about the arm pivot. The radius of the centre of the headform from this pivot is 1.21m.

The pendulum beam is of rectangular section and designed with counterweights below the headform and above the pivot axis to place the centre of percussion exactly at the centre of the headform.

The beam is hung from a welded steel framework via a ball bearing pivot. The frame incorporates an extension for mounting specimens and also a pivoting arm carrying an electrical release mechanism. By altering the position of the arm, the position of the pendulum and thus the drop height can be varied, allowing the impact speed to be controlled up to a maximum of approximately 24.1km/h (15mi/h).

The specimen to be tested is mounted on a support frame and positioned on the rig so as to just touch the headform when hanging free. The frame is bolted to two rails projecting from the rig to prevent movement of the specimen on impact and incorporates adjustment whereby the specimen may be raised, lowered, and tilted in the plane of the pendulum.

The speed of the pendulum immediately prior to impact is measured by a slotted blade mounted on the beam, passing between a light source and photocell fastened to the rig frame. The spacing of the leading edges is known accurately, and the signal from the photocell is amplified and fed to a timer and one channel of the instrumentation.

Description of the Head Impact Drop Weight Rig

The rig consists of a hemispherical headform that falls onto the test specimen from a given height. The headform is guided by two parallel rails and illustrated in Figure 6.

The headform is a smooth rigid aluminum hemisphere of 165mm diameter. The central cavity of the headform houses an accelerometer, measuring the acceleration in the vertical direction. The headform is bolted to a small framework supporting the guides that locate the headform in its guide rails. The headform, accelerometer, frame, and guides have a total mass of 6.8kg.

The rails are set parallel and vertical to insure precise guidance of the headform while eliminating any frictional resistance on the falling weight.

The headform is raised to the appropriate height for the chosen impact speed. An electromagnetic release mechanism is incorporated to allow the weight to be released remotely.

An accelerometer is mounted in the headform to measure the impact decelerations. Test specimens are positioned beneath the rig.

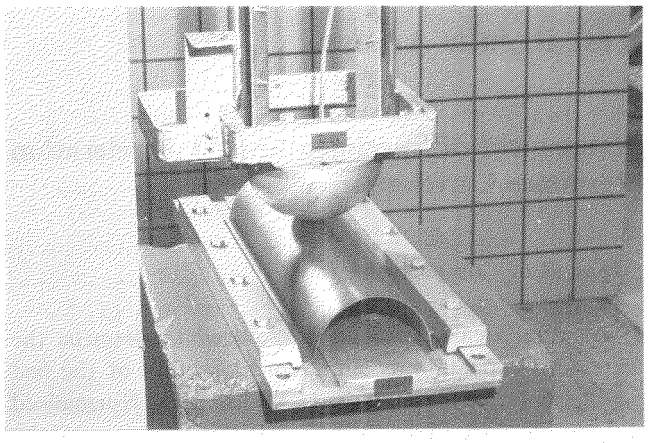

Figure 6. MIRA head impact drop rig

Description of the Calibration Specimen and Fixture

The specimens are designed to collapse as the result of impact by a standard headform to enable impact acceleration signals to be compared.

The specimens are pressed from a sheet of cold-reduced steel sheet of 0.76mm thickness and formed into a half-cylinder section. On removal from the press tool, the elasticity in the material causes the specimen to open slightly, and this elasticity is used to locate the specimen in the test fixture.

The fixture consists of a steel plate with a shallow longitudinal cavity to accept the specimen. The specimen

is constrained within the fixture by the two outer edges of the flanges pressing against the vertical walls of the cavity. Clamping plates held by four bolts secure the specimen to the fixture surface at each side. The fixture is mounted so the impact axis is perpendicular to the base at the centre of the specimen for the impact to be conducted. The arrangement is illustrated in Figure 7.

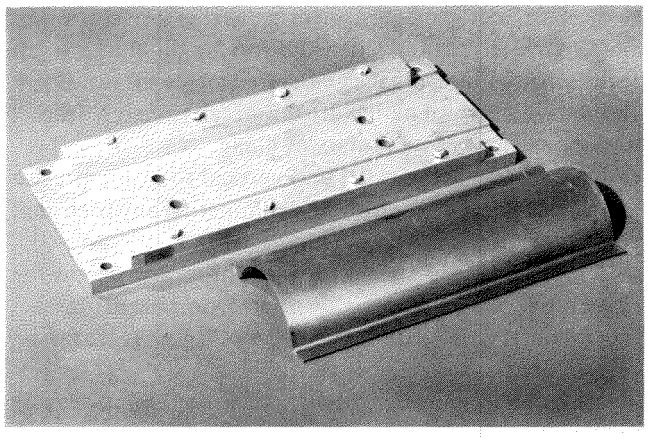

Figure 7. Calibration specimen and fixture

Test Results Analysis

Assessment of Specimen Impact Acceleration Response Correlation

Measure of Comparison

An analytical approach is required to describe the extent of repeatability and reproducibility of the test equipment. The measure used is known as the Normalised Integral Square Error (NISE). NISE is a measure of the difference between two time histories and is able to divide total NISE into phase shift, amplitude differences, and shape difference.

The equations by Donnelly et al.,(6) for NISE are:

$$NISE = 1 - \frac{2Rxy\ (o)}{Rxx\ (o) + Ryy\ (o)}$$

$$\text{where } Rxy\ (o) = \frac{1}{N} \sum_{i=1}^{N} (Xi)(Yi)$$

$$\text{where } Rxx\ (o) = \frac{1}{N} \sum_{i=1}^{N} (Xi)(Xi)$$

$$\text{where } Ryy\ (o) = \frac{1}{N} \sum_{i=1}^{N} (Yi)(Yi)$$

Xi = a digitised point of one data set
Yi = a digitised point of a second data set
N = number of digitised points in each data set

The portion of the NISE due to a phase shift between the two data sets is:

$$NISE\ (Phase) = \frac{2xy\ (t)\ max}{Rxx\ (o) + Ryy\ (o)} - \frac{2xy\ (o)}{Rxx\ (o) + Ryy\ (o)}$$

where t = a time lag

$$Rxy\ (t) = \frac{1}{N-a} \sum_{i=1}^{N-a} (Xi)(YI + a)$$

$$a = \frac{t}{\Delta t}$$

Rxy(t)max = maximum Rxy(t) for any (t)

The portion of the NISE due to a difference in amplitude only, after the phase shift has been eliminated, is:

$$NISE(0) = Pxy(t) - \frac{2\ Rxy\ (t)\ max}{Rxx\ (o) + Ryy\ (o)}$$

where Pxy (t) = correlation coefficient

$$= \frac{Rxy\ (t)\ max}{Rxx\ (o) \cdot Ryy\ (o)}$$

The portion of NISE due to a difference in shape after phase shift has been eliminated is:

NISE (Shape) = 1 - Pxy(t)

The sum of the three apportioned NISE's is then total NISE.

This approach was judged to be suitable because it is based on the principle of cumulative variance and treats each data set as a continuous whole and quantifies the difference between the two data sets over their duration.

Acceptance Criteria

Donnelly et al., reviewed the previous work on this topic and determined that a coefficient of variation of 6 percent or less was generally considered good. Using simple cases as examples, they derived allowable NISE limits of acceptability for phase, amplitude, and shape. The results of these calculations are shown in Table 1.

Table 1. Allowable NISE

	Limit of Acceptability (6%)
Phase	0.0300
Amplitude	0.0017
Shape	0.0291

For the Free-Flight Headform Impact Rig, limits of acceptability of 6 percent were adopted for both repeatability and reproducibility.

Test Result Comparison

Repeatability

The recordings of five example impacts were selected at random from a range of tests on the specimens using the Free-Flight Headform Impact Device. The acceleration data were recorded over a 100ms sample period at 33kHz sampling rate and filtered to CFC 1000. The output from three tests, for clarity, was plotted on a reduced common time base and is shown in Figure 5. The mean curve was calculated from the set of randomly selected impacts and then, to calculate the NISE, each impact was compared with the mean. The NISE was calculated for phase shift, amplitude, and shape, and the results, from these comparisons, are shown in Table 2.

Table 2. NISE comparisons for free-flight headform

	Free-Flight Headform Impact Tests			Limit of Acceptability
NISE	Sample 1	Sample 2	Sample 3	(6%)
Phase	0.00011	0.00024	0.0019	0.0300
Amplitute	0.00002	0.00021	0.00012	0.0017
Shape	0.00035	0.00011	0.00127	0.0291

The calculations for NISE (amp) and NISE (shape) were conducted without phase shift adjustment but are still well within the acceptability limits adopted. A visual comparison of the time history curves in Figure 8 shows good repeatability.

Reproducibility

The results of specimen impact tests from the MIRA Free-Flight Impact Device were compared with tests on identical specimens using the MIRA Head Impact Pendulum Rig and the MIRA Head Impact Drop Weight Rig.

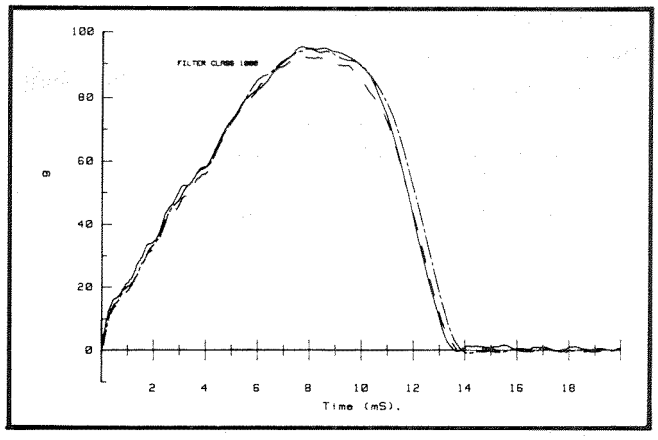

Figure 8. Curves illustrating the repeatability of the free-flight headform impact device

To enable the comparison of the different test devices, a mean curve was calculated from a set of five tests for the pendulum and drop weight rigs. The accelerations were recorded over the same sampling period and sampling rate, and filtered to the same channel class as for the Free-Flight Headform Impacts.

The NISE calculation was then conducted, comparing the mean acceleration time histories for each test device.

The calculations for NISE (amp) and NISE (shape) were conducted both with and without phase shift adjustments, and the results were well within the acceptability limit and are shown in Table 3. The curves plotted in Figure 9 are of phase shift adjusted time histories.

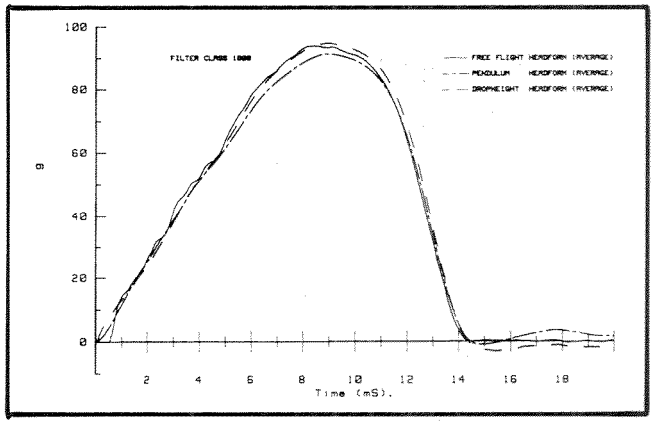

Figure 9. Curves illustrating the reproducibility of the free-flight headform against both pendulum and drop rig headforms

Table 3. NISE comparisons between different rigs

	Phase	Amplitude	Shape
Acceptability Limit (6%)	0.0300	0.0017	0.0291
Free-flight Headform vs. Pendulum	0.00015	0.00035	0.00151
Free-Flight Headform vs. Drop Weight	0.00075	0.00005	0.00288
Pendulum vs. Drop Weight	0.00087	0.00066	0.001

Therefore, the MIRA Free-Flight Headform Impact Device gives repeatable and reproducible acceleration time histories within the rigorous acceptability criteria chosen.

An additional successful aspect of the headform performance can be seen in the shape of the accelerometer traces. In designing a headform impactor of this type, it is essential that the structure be sufficiently rigid to place the natural frequency of all possible modes of vibration well above the attenuation level of the filters (i.e., 1,000Hz). Failure to achieve this causes ringing in the form of a regular ripple on the acceleration signal. Examination of the traces shows the accelerometer signals are entirely free from this effect.

Impact Velocity Variations

The Free-Flight Headform Impact Device was used when conducting a research programme in relation to head impact. The device was fired on over 100 occasions at nominally identical impact velocities, i.e., 7.2m/s. The annulus pressure required to provide this impact speed was 1.2 bar.

The pendulum and drop weight rigs have been used at MIRA for many years and, by virtue of their gravity power, have adjustable impact velocities on the basis of the release height of the headform. A series of 20 tests was conducted to verify impact speed repeatability on both the pendulum and drop weight rigs.

Table 4 shows the means and standard deviations of the tests conducted on all three rigs.

Table 4. Variations in impact velocities

	Nominal m/s	Mean	Standard Deviation
Free-Flight Headform	7.2	7.289	0.25
Pendulum Headform	6.9	6.754	0.045
Drop Weight Headform	7.2	7.317	0.017

Clearly the gravity-powered rigs show better speed control than the Free-Flight Headform Impact Device. The Free-Flight Headform produces a mean speed very close to the intended value, but there is a scatter of some 3.4 percent. Although larger than the figure for the speed variation on the gravity-powered rigs, it appears to be within acceptable limits and may well be reduced in the future by improvements in launcher design.

Discussion

The objectives in the design of the MIRA Free-Flight Headform Impact Device were to enable easy access to the interior surfaces of a passenger car and, without dismantling, conduct a series of tests to evaluate the aggressiveness of the surfaces. The characteristics of the acceleration time histories generated from these impacts were to show a close relationship to equipment currently used for the same purpose.

On completion of the commissioning trials of the device, it was used successfully in testing six saloon cars at more than 20 impact positions on their passenger compartment interiors(7). The device demonstrated its flexibility in positioning during these tests, being free to rotate up to 360° in the vertical plane and 245° in the horizontal plane.

Using the standard specimens, the tests gave extremely good correlation with the alternative test rigs used for head impacts. The repeatability and reproducibility of the deceleration pulse in terms of phase shift, amplitude, and shape were well within the coefficient of variation of the 6 percent chosen as an indication of good correlation.

The results of the work conducted to date are very encouraging, and the main objectives of the design were achieved successfully. There is, however, room for minor improvement in the repeatability of firing velocity. Design modifications have been identified, and analysis of the benefits of the proposed changes are underway.

Conclusion

The results of the tests using the MIRA Free-Flight Headform Impact Device on the interiors of a range of current vehicles(7) has illustrated the flexibility of the subsystem approach. In the area of developing improved energy-absorption characteristics of these structures, this is a tool around which test procedures could be developed, based on the analysis of accident data, and which may yield useful benefits.

Acknowledgments

The opinions, findings, and conclusions expressed in this paper are those of the authors and do not necessarily reflect the views of MIRA.

The authors wish to extend their thanks and appreciation to Mr. Phillip Degg, who conducted much of the testing.

New Car Assessment Program Results and the Risk of Injury in Actual Accidents

Ian S. Jones,
R.A. Whitfield, and
Diane M. Carroll

Abstract

The risk of injury for particular car makes and models was examined in relation to their corresponding crash performance in the 35mph New Car Assessment Program's (NCAP) frontal barrier tests. Texas State accident data for the years 1980 to 1982 were used to determine the risk of driver injury in single-vehicle, fixed-object car collisions. The risk of fatal or incapacitating injury was modeled using logistic regression techniques so the effect of confounding factors such as car mass, age of driver, crash severity, and restraint use could be effectively controlled. The NCAP test results were entered in the model by using the values of Head Injury Criterion (HIC), chest deceleration (CD), and femur load as independent variables. Separate results are presented for restrained and unrestrained drivers. After controlling for the confounding effects, for restrained drivers the risk of driver injury was reduced by between 80 and 87 percent for cars with the best NCAP test results compared to cars with the worst results. The corresponding reduction for unrestrained drivers was between 21 and 36 percent. To examine the possible biomechanical causes of these statistical results, the 16mm films from the NCAP crash tests were analyzed to determine whether there were discernible differences in the trajectories of drivers for cars with good NCAP test results compared to cars with poor results. This analysis showed an obvious pattern of increasing interaction with the steering assembly with increasing HIC and CD values.

Introduction

The NCAP of the National Highway Traffic Safety Administration (NHTSA) was established in 1979 to provide consumers with comparisons of the crash protection offered by new production vehicles of the same size class. The program uses the results of full frontal barrier crash tests at 35mph with restrained anthropometric dummies in the driver and right-front passenger seat position(1). Although the program is designed to measure vehicle crashworthiness, the relevance of the single crash test and the applicability of the results to real-world crashes have been repeatedly questioned.

Previous studies have attempted to assess the relevance of the NCAP test results to real-world crashes with different degrees of success(2,3,4,5). These studies have all been criticized because they have not restricted their analyses to impacts comparable to the NCAP test configuration, and they have not been controlled sufficiently for other confounding variables.

The frequency and severity of injuries to occupants in crashes are influenced by many factors; the strongest effects include crash speed and configuration, car size or mass, and restraint use. Differences in vehicle crashworthiness are likely to have less effect on the probability of occupant injuries than some of these factors. Therefore, to assess the relevance of the NCAP crashworthiness ratings to actual crash injuries, it is necessary to separate differences in injury outcomes due to factors such as crash speed and configuration from differences due to crashworthiness. One way to do this is to identify a relatively homogeneous set of real-world crashes with characteristics similar to the 35mph frontal barrier NCAP tests and to examine—while controlling for other confounding factors—whether the various anthropometric dummy responses measured in the tests are related to the likelihood of crash injuries.

Selecting a sample of accidents that are similar to the NCAP tests makes it more likely that a relationship between crashworthiness ratings and the risk of injury will be found. At the same time, if the ratings are to be useful to consumers, it is important to establish relationships between the NCAP crashworthiness ratings and as wide a range of actual crashes as possible. Because the NCAP tests use a full frontal barrier crash configuration, it is logical to compare the test results with real-world crashes with frontal damage. An earlier analysis examined the relationship between anthropometric dummy per-

formance in the NCAP tests and risk of fatality in collisions between passenger cars(6). In the present study, these results are summarized together with other relevant literature, and the range of applicable real-world crashes is extended by examining relationships with single-vehicle, fixed-object crashes. This analysis looks at the relationship between each of the dummy response parameters measured in the NCAP tests, Head Injury Criterion (HIC), chest deceleration (CD), and femur load, and the odds of incapacitating injury or death for drivers in a sample of single-vehicle impacts of passenger cars into fixed objects.

In addition, to better understand some of the reasons for these results, a frame-by-frame analysis of driver trajectories from films of the NCAP tests was performed. The trajectory of the drivers in cars with high HIC and CD values were compared to those in cars with low values.

Literature Review

Campbell(2) examined serious and fatal injuries as a proportion of all injury for five groups of cars rated from best to worst in terms of the crashworthiness ratings published by *Consumer Reports*, which are based on the NCAP tests. Car sizes were aggregated to insure adequate sample sizes; the data base consisted of 32,602 drivers and front-seat passengers involved in crashes in North Carolina. Separate analyses were presented for drivers and front-seat passengers and for belted and unbelted occupants. No discernible relationship was detected between the crashworthiness rating based on the NCAP tests and the proportion of serious injury in highway crashes for unbelted occupants. There was a suggestion of a possible upward injury trend associated with the poorer crashworthiness ratings for belted occupants, but the results were not significant. However, as the authors point out, the data were not limited to frontal collisions, and major confounding factors such as crash severity, car mass, or driver age were not taken into account.

Jones(3) used the Fatal Accident Reporting System (FARS) data sets for 1979 through 1980 and R.L. Polk vehicle registration data to examine the fatality rates for individual car models. In that study, fatal injuries to drivers and front-seat passengers per vehicle years registered were correlated with HIC's and chest decelerations. The effects of car size were controlled by analyzing subcompact, compact, and intermediate size cars separately. Correlations bordering on statistical significance were found for subcompact cars, but the relationship disappeared with increasing car size. Similar results were found using the Highway Loss Data Institute (HLDI) relative injury claim frequencies for injury claims in excess of $500. Unfortunately, it was not possible to control for type of impact, size of car struck, age of driver, or restraint use, and the author concluded that the effects of these variables were overwhelming any possible relationships with the NCAP results.

A similar study was reported by Grush et al.(4), who used the FARS data sets for 1979-1981 and R.L. Polk vehicle registration data to compute fatalities per registered car year. HIC values, the Gillis index (a safety rating based on HIC, CD, and femur loads for both driver and passenger dummies), and the Consumers Union rating were each regressed against fatality rates for the total sample and then for restrained drivers only. The authors claimed there was no substantial relationship between fatality rate and HIC value or either of the crashworthiness ratings. However, their Table 1(4) shows that the fatality rate for cars with HIC's of less than 1,000 was 5 percent lower for unrestrained drivers and 17 percent lower for restrained drivers than for drivers of cars with HIC's greater than 1,000. The authors attempted to control for car size by analyzing small cars (<104in wheelbase) separately from large cars and to control for impact type by looking only at frontal collisions. Neither control was reported to substantially improve the strength of the relationship. However, this finding was not surprising because the effects of mass ratio and age distribution of driver, which are important and large effects, were not controlled.

In another study, Thomas et al.(5) reported no statistically significant association between various crashworthiness ratings based on results of NCAP tests for 14 French car models and the fatality rates among their occupants in frontal crashes. The fatality rates in this study were computed for crash-involved front-seat occupants aged 20 to 50 only, as the ratio of the number killed divided by the number present. The relationship between crashworthiness ratings and fatality rates was assessed using nonparametric statistical methods within groups of light, medium, and heavy model cars. The major weakness of this study was that these size groupings contained fewer than five models on average. With such small sample sizes, only a perfect correspondence of fatality rates and crashworthiness measures would have achieved statistical significance in most comparisons. It is worth noting that 12 of the 15 comparisons relating to fatality rates showed positive rank correlations between the index used and the fatality rates [(5) Table 1]. Failure to take into account explicitly the driver age and vehicle weight could have further blurred the results. Finally, no distinction was made between single- and multiple-vehicle crashes. The severity of the outcomes in collisions between two vehicles depends strongly on their relative weights, indicating a need to adjust the results for the weight of both cars in a multiple-vehicle collision.

A more comprehensive analysis of the North Carolina data, initially analyzed by Campbell(2), covering the years 1979 through 1982, was reported recently(7). Only data involving the specific make, model, and model-year

cars in the NCAP tests were included in the analyses. The effect of HIC test scores on the proportion of drivers involved in an accident who were killed or seriously injured was analyzed for belted and unbelted drivers in all types of crashes and for belted drivers in frontal crashes. The authors concluded that there was no association between the HIC parameter and injury risk. Because sample sizes for belted drivers were small, the data base was expanded to include vehicle model years other than the specific model year tested for those years where the base model had not changed. The Consumer Union Driver Protection Rating (CUDPR) was also added to the file. Statistically significant associations between CUDPR and the proportion of drivers killed or seriously injured were found for belted drivers in all types of crashes and in frontal crashes. In all other situations, the relationships were either not significant or negative. Multivariable linear and nonlinear models were used to investigate the effects of various predictor variables, including driver sex, crash type (single vehicle or multiple vehicle), car size (four categories), and crash speed (two categories). A significant effect was not found in any of the models for driver HIC; however, these models had serious limitations. Retaining nonfrontal crash configurations including side and rear impacts and rollover crashes made the models less likely to show significance for the NCAP test parameters. Modeling crash severity using two categories of crash speed (less than or greater than 50mph) may have been ineffective because the transition point was too high. Also, although four categories of car size were accommodated, no provision was made to model the mass ratio effect in multiple-vehicle crashes. Mass ratio and crash severity are two of the strongest factors in predicting injury risk; these variables were not adequately specified and their effects could mask relationships with crash test variables.

A recent study(6) used a sample of 695 crashes from FARS to determine the effect of the NCAP test results on the risk of fatality to drivers in frontal collisions between passenger cars. FARS data is outcome dependent because, for inclusion in the file, there must be a fatality in at least one vehicle. In this study, the analysis was limited to cases where there was a fatality in the other vehicle, thus the outcome of the collision in the case vehicle was not related to its inclusion in FARS. In addition, the sample was restricted to collisions involving two passenger cars of approximately equal weight, which eliminated the problem of mass differences between the vehicles.

Multiple logistic regression procedures were used to predict the odds of driver fatality. The independent or predictor variables included were the speed limit, the ratio of the two curb weights to indicate relative mass and their sum to differentiate vehicle size, driver age for the case vehicle driver and the other vehicle driver, and driver restraint use in both vehicles. The NCAP test results were modeled using the HIC and CD parameters, which were entered as rank variables to overcome problems of outlying values. The HIC and CD rankings were also summed to give a single figure of merit, SUM, to represent the overall crashworthiness of the vehicle.

The SUM parameter performed better than either HIC or CD, although all three parameters gave similar results. The combined HIC and CD parameter was significantly correlated such that vehicles with lower HIC and CD values in the NCAP crash tests had lower fatality rates than those with higher values. For all drivers, irrespective of restraint use, the risk of fatality was reduced 36 percent from 0.39 to 0.25 for cars with good crashworthiness ratings compared to those with poor ratings.

Because the number of restrained drivers in the sample was small, it was not possible to estimate a separate model for restrained drivers. Instead, the combined effects of the NCAP results and restraint use were modeled using an interaction term. In this data set, the risk of fatality for restrained drivers ranged from close to zero for cars with the lowest crashworthiness ratings to 0.58 for cars with the highest crashworthiness rating; the corresponding range for unrestrained drivers was 0.27 to 0.40.

Correlation of NCAP Test Results to Risk of Injury

For the current analysis, a sample of 6,405 single-car crashes was obtained from the Motor Vehicle Traffic Accident File of the Texas Department of Highways and Public Transportation and matched with the corresponding NCAP test results for each individual make and model of car. In addition to the HIC and CD parameters, femur load was included in this analysis. When a test result was not available for a particular model but an equivalent model had been tested, the results for the equivalent model were assigned. The data from the accident file and the dummy responses were used to estimate the odds of an incapacitating injury or death to a driver of a passenger car as a function of HIC, CD, and femur load of the tested car. The estimates were derived through multiple logistic regression(8) controlling for the simultaneous effects of driver age, vehicle mass, and crash severity. Results for restrained and unrestrained drivers were analyzed separately.

The Texas Motor Vehicle Traffic Accident File is a computerized file of all motor vehicle accidents that have been reported to the police. This analysis covers accidents occurring during the years 1980 to 1982. Only single-vehicle frontal collisions with fixed objects producing vehicle damage in the front center, front left, or front right were analyzed, so the study sample contained actual crashes with configurations comparable to the NCAP test crashes. Complete data were available for 314 restrained drivers and 6,091 unrestrained drivers. Drivers

were characterized as restrained if they were reported to be using the 3-point lapbelt and shoulder belt at the time of the accident. Drivers whose belt usage was unknown are not included in these analyses.

To fit the regression models, the logistic regression procedure from the SAS Users Group International (SUGI) Supplemental Library of the Statistical Analysis System was used(9). The dependent variable in each observation is the presence or absence of an incapacitating injury or death to the driver of a passenger car in an accident that has been reported to the police. In the Texas data, an incapacitating injury is defined as an injury that leaves the driver unable to walk or drive.

The regression equations were used to predict the log odds of an incapacitating driver injury or death. These odds are predicted as a function of driver age, vehicle mass, and crash severity as well as the HIC score, CD, and femur load derived from the NCAP tests for the particular make and model of car involved in the accident. Driver age was recoded as the years of age past age 35; for drivers 35 years of age or younger, age was recoded as zero. This function reflects the decreasing ability of older drivers to sustain a collision of a given severity without serious injury.

Vehicle mass was recoded as the difference between the mean mass of cars in the sample and the accident-involved car (2,960 lb for cars driven by restrained drivers and 3,119 lb for cars driven by unrestrained drivers). Similarly, the HIC, CD, and femur load values were transformed by subtracting the mean values found in the sample. These values for accidents involving restrained drivers were 1,000 for HIC, 50 for CD, and 912 for femur load; the corresponding figures for unrestrained drivers were 1,013 for HIC, 50 for CD, and 894 for femur load. These transformations have the effect of centering the estimates at zero for vehicles of average weight and crashworthiness. Crash severity was modeled using the TAD index, a variable in the Texas Motor Vehicle Accident File that denotes the severity of the damage sustained by each vehicle in an accident on an increasing scale of 1 to 7(10).

Regression equations were first derived with all three crash test parameters (HIC, CD, and femur load) included, while controlling for crash severity, driver age, and vehicle mass. For restrained drivers, the CD parameter proved to have a strong relationship with likelihood of injury, and neither HIC nor femur load added significantly to the model once the CD parameter was included. A similar pattern emerged for unrestrained drivers, although the femur load parameter was also significant.

Separate regression equations were derived for restrained and unrestrained drivers in which the only crash test parameter included was HIC. Using this model, the HIC parameter was statistically significant for unrestrained drivers, which suggests that it explains much the same variation as that explained by CD. However, it did not have as strong a relationship with crashworthiness in the sample as the CD parameter. The final regression coefficients were derived by dropping the nonsignificant variables: HIC and femur load in the case of restrained drivers and HIC for unrestrained drivers.

For restrained drivers, the parameter estimates given in Table 1 are based on 314 observations with 18 resulting in incapacitating injury or death. Crash severity had the strongest relationship with injury outcome followed by driver age and the CD parameter. Figure 1, which is based on these coefficients, shows the odds of an incapacitating injury or death to a hypothetical 35-year-old driver of a 3,420 lb car in crashes of differing severity at increasing levels of CD. The figure shows that for restrained drivers in very severe impacts (TADfs= 7) the risk of injury decreases substantially with decreasing CD; it drops from 0.55 for a high CD of 75g to 0.11 for the lowest CD value of 36g, which is an 80 percent reduction in risk. This reduction in injury risk is also present in the less severe impacts; for impacts of TAD severity 4, the risk drops from 0.15 to 0.02, a reduction of 87 percent.

The regression equation parameters for unrestrained drivers are shown in Table 2. In this much larger data set, there were 6,091 observations and 865 cases in which the driver was killed or sustained an incapacitating injury. Crash severity and driver age, followed by the CD

Table 1. Regression equation for injury odds for restrained drivers in a crash (chest deceleration only)

Independent Variable	Beta	Std. Error	Chi-square	p-value

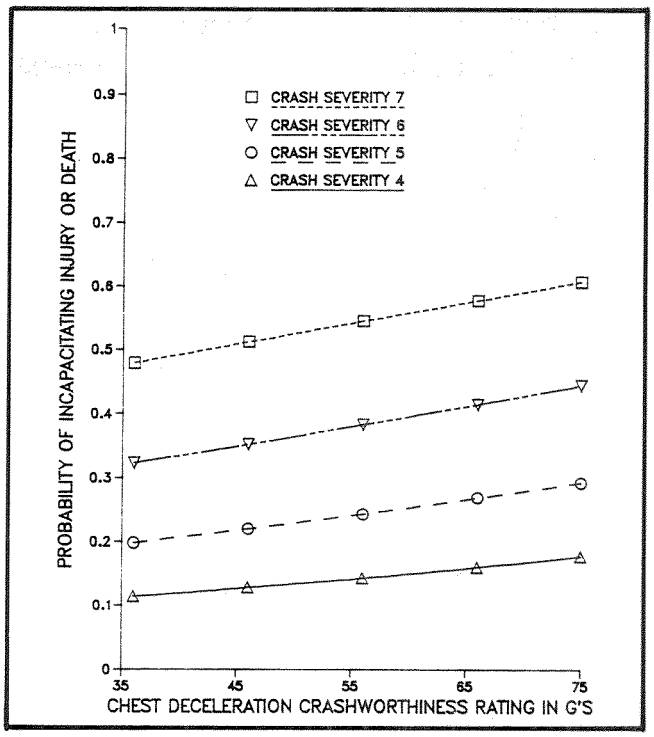

Figure 2. Probability of incapacitating injury or death for unrestrained drivers by NCAP chest deceleration at four levels of crash severity

parameter, had the strongest relationships with likelihood of injury. The parameter estimate for femur load has a negative sign, indicating that car models that had higher femur load in the NCAP tests tended to be associated with lower injury risks.

The influence of the CD measure on injury outcome is illustrated in Figure 2 using the regression coefficients from Table 2. For comparison purposes, the femur load for unrestrained drivers is set at the mean value for restrained drivers. Figure 2 shows a monotonically decreasing risk of injury with decreasing chest deceleration. For a crash of TAD severity 7, the risk of injury decreases from 0.61 for a CD of 75g to 0.48 for a CD of 36g—a reduction of 21 percent. This same trend is reflected in the lower crash severity levels; for impacts of TAD severity 4, the risk drops from 0.18 to 0.11—a reduction of 36 percent.

Table 2. Regression equation for injury odds for unrestrained drivers in a crash (chest deceleration and femur load only)

Independent Variable	Beta	Std. Error	Chi-square	p-value
Intercept	-4.5809	0.1336	1175.00	.001
CD	1.32×10^{-2}	4.11×10^{-3}	10.29	.001

Vehicle mass	-1.40×10^{-4}	6.67×10^{-5}	4.42	.036

Model chi-square = 684.05 with 5 d.f.
Fraction of concordant pairs of predicted probabilities and responses: 0.75.
Rank correlation between predicted probability and response: 0.52.
N = 6,091 (865 severely injured or killed).

Analysis of Driver Trajectories From NCAP Test Films

The analyses of the Texas data described above and the earlier FARS data(6) show that there are relationships between the NCAP test results and the risk of injury or death in frontal collisions. Both studies conclude that HIC, CD, or a combination thereof are related to the likelihood of injury in real-world crashes. To examine the possible biomechanical causes of these statistical results, the 16mm films from the NCAP tests were analyzed. The trajectories of drivers for cars with good test results (low HIC's and CD's) were compared to thise in cars with poor test results. By ranking the test results according to the driver HIC and CD values and comparing the characteristics of head and chest contact, it was possible to analyze the different trajectories that occurred from high to low HIC and CD values. Table 3 gives the NCAP crash tests for recent model years (1980-1984) ranked in descending order of a combined HIC and CD parameter (HIC' + CD'). This was computed giving equal weight to the head and chest parameters, by dividing each parameter

Table 3. Effect of driver trajectory on HIC and CD values for recent model year cars

Year/Make/Model	Driver HIC	Driver CD	Driver HIC'+CD' *	Driver Contact Points
1982 Renault Fuego	3768	50	4.77	Head hit steering wheel hub; chest hit lower rim
1984 Ford Tempo	2955	63	4.22	Head hit steering wheel hub

1984 Pontiac Fiero	309	31	0.93	Forehead grazed upper rim

*HIC/1000 + CD/50.

by an appropriate tolerance value, i.e., HIC/1000 and CD/50. The table gives the make, model, and model year of each car and the combined driver HIC and CD values together with a brief description of the contact points.

Figure 3 gives still frames from eight of the crash tests documenting the point at which driver contact with the vehicle interior surface occurred. The pattern of contact emerges quite clearly: For tests with high HIC and CD values [(HIC' + CD') $\geq$ 3.0; Figure 3-A], excessive forward movement of the driver occurs generally involving head and chest contact with the steering assembly. The head either strikes the steering wheel hub or travels over the steering wheel such that it hits the dashboard (either produces high HIC's). High values of CD are associated with this type of trajectory because there is significant chest contact with the steering assembly.

The next group of tests[2.5 $\leq$ (HIC' + CD') $<$ 3.0; Figures 3-B and 3-C] differ in that the chest load has been reduced by using the seatbelt to limit the forward movement of the dummy and prevent chest contact with the steering assembly, although this also modifies the head trajectory so that the head moves downward and strikes the steering wheel hub, producing high HIC values. For the tests with somewhat lower HIC's [2.0 $\leq$ (HIC' + CD') $<$ 2.5; Figures 3-D and 3-E], the forward movement of the driver is further controlled by allowing higher chest loads. This, in turn, modifies the head trajectory reducing downward movement so that facial contact occurs with the steering wheel rim rather than head contact with the hub.

In the tests with even lower HIC and CD values [1.5 $\leq$ (HIC' + CD') $<$ 2.0; Figures 3-F and 3-G], the forward movement of the dummy is optimized to minimize chest deceleration while preventing significant contact of the head with the steering wheel. Finally, in those tests with the lowest HIC and CD values [(HIC' + CD') $<$ 1.5; Figure 3-H], the driver trajectory is optimized to produce extremely low chest loads and to allow only minimal or no contact between the head and steering wheel.

Discussion

The analysis of the data from the Texas study shows significant relationships between the risk of serious injury

(3-A)

1980 Honda Civic
HIC = 2626; CD = 54g; Combined = 3.71

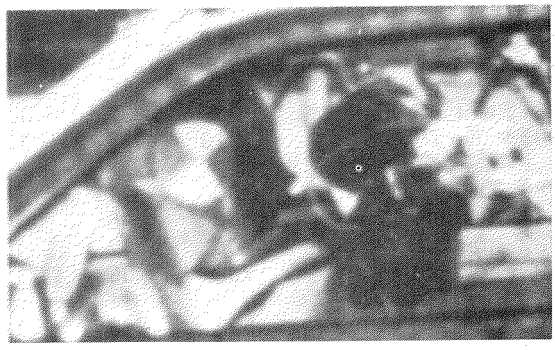
(3-E)

1983 Toyota Corolla
HIC = 767; CD = 67g; Combined = 2.10

(3-B)

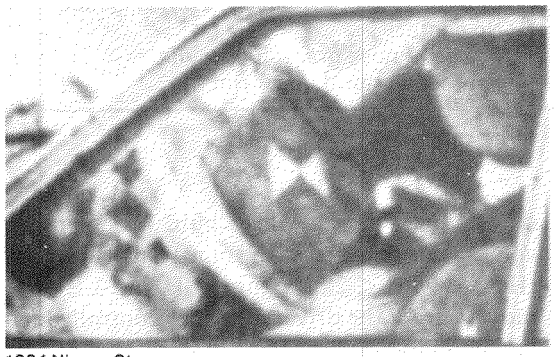
1984 Renault Sportswagon
HIC = 2053; CD = 43g; Combined = 2.91

(3-F)



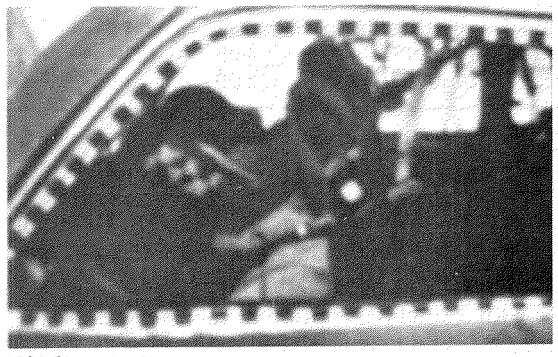
1984 Mercury Cougar
HIC = 652; CD = 55g; Combined = 1.75

(3-C)



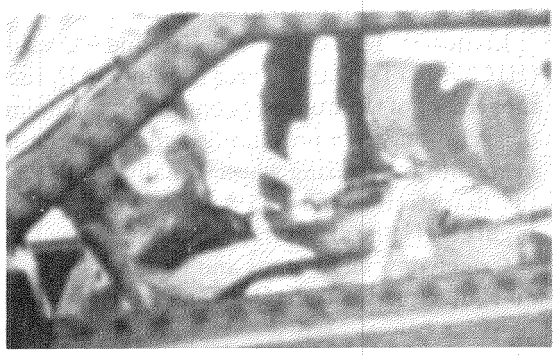
1984 Nissan Stanza
HIC = 1459; CD = 58g; Combined = 2.62

(3-G)



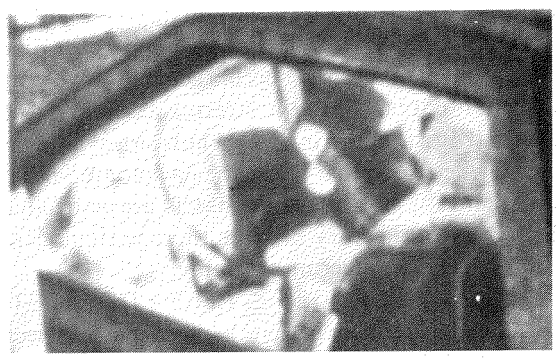
1980 Chevrolet Chevette
HIC = 668; CD = 45g; Combined = 1.57

(3-D)



1984 Plymouth Conquest
HIC = 1118; CD = 57g; Combined = 2.26

(3-H)



1984 Dodge Daytona
HIC = 507; CD = 37g; Combined = 1.25

Figure 3. Driver trajectory at most forward point in NCAP crash tests as a function of HIC and CD

or death for restrained drivers in frontal impacts and the results from the NCAP tests. The statistical results indicate that the CD parameter has a stronger relationship with injury risk than does HIC. The CD parameter can be expected to be the slightly better predictor of overall injury risk because it reflects both the way the front end of the car crushes and the performance characteristics of the seatbelt, whereas the HIC characterizes the head excursion. An earlier study based on FARS data showed similar trends, although the results were based on a very small sample of restrained occupants and cannot be considered as indicating a definitive result. The statistical results suggest that either the CD or HIC parameter measure driver injury risk in many frontal crash situations, but the film analysis shows that there are certain driver trajectories where a low HIC can be associated with a high CD and vice versa. Thus, for the closest relationships with overall injury risk, the anthropometric dummy parameters of HIC and CD should be used in some combination. Obviously, to relate injury to specific body regions, HIC would be the preferred parameter for head injury and CD for chest injury.

Although unrestrained drivers do not derive the same benefits from improved crashworthiness as restrained drivers, both the Texas and the earlier FARS analysis show the benefits are still considerable. It is also encouraging that both analyses show similar reductions in injury risk. The FARS analysis suggests a 32 percent reduction in risk of fatality for cars with good NCAP test results compared to those with poor results, and the Texas data suggest a corresponding reduction of 21 to 36 percent. Thus, differences in crashworthiness that produce superior performance for the restrained dummy in the 35mph NCAP tests also appear to provide improved protection (via efficient energy-absorbing steering assemblies and fascia panels) for unrestrained drivers. Although in the FARS analysis the combined HIC and CD parameter was marginally the stronger parameter for relationships with risk of fatality, the considerably larger Texas data set showed that CD was the better parameter for estimating the risk of serious injury or death and that femur load was negatively associated with risk of injury. The significance of the CD parameter suggests that the benefit for unrestrained drivers comes from the steering assembly performance. This is further indicated by the film analysis, which shows that the positioning of the dummy chest is relatively close to the steering wheel and interaction between the two often occurs in the NCAP tests.

The apparent significance of the femur load is less straightforward to explain, particularly as it suggests an increasing risk of serious injury with decreasing femur loads. However, the relative importance of the femur load parameter is considerably less than the CD parameter. One possible explanation for its apparent significance is that in a frontal impact an unrestrained occupant moves forward until the chest contacts the steering wheel and the knees strike the lower fascia panel. High femur loads could indicate early knee contact with the fascia panel, which would reduce the level of chest deceleration and hence the overall risk of serious injury or death. (This presupposes that the risk of serious injury or death due to high chest loads is greater than the risk due to high femur loads.)

The results presented here show a substantially stronger relationship between the NCAP results and occupant fatalities than has been reported previously(2,3,4,5,7). The main reasons for this are that in the present study only frontal collisions approximating the NCAP tests were used, and other confounding factors that could influence the risk of fatality or incapacitating injury in these collisions were controlled.

Conclusion

The results obtained from the New Car Assessment Program (NCAP) showed statistically significant relationships with the risk of serious injury or death in single-vehicle, fixed-object frontal impacts. Drivers of cars with better NCAP results had lower injury risk.

The NCAP tests measure crashworthiness performance with the three anthropometric dummy response parameters—HIC, CD, and femur load. Generally, CD had a stronger relationship with overall injury risk than HIC for both restrained and unrestrained drivers, although the film analysis of the driver trajectories suggests that a combination parameter of HIC and CD is desirable to avoid situations where low chest decelerations occur as a consequence of high head loads and vice versa. Femur load provided a significant negative contribution to predicting risk of injury for unrestrained drivers but not for restrained drivers.

For restrained drivers, the risk of injury decreased by between 80 and 87 percent, depending on crash severity, for cars with good NCAP test results compared to those with poor results. Unrestrained drivers did not derive as large a benefit from better crashworthiness measures as restrained drivers. For unrestrained drivers, there was a reduction in injury risk of between 21 and 36 percent, depending on crash severity, for cars with good test results compared to those with poor results.

A Review of the Effects of Belt Systems, Steering Assemblies, and Structural Design on the Safety Performance of Vehicles in the New Car Assessment Program

James Hackney
U.S. Department of Transportation, National Highway Traffic Safety Administration
Carlin Ellyson
Automated Sciences Group, Inc.

Introduction

Since 1979, the National Highway Traffic Safety Administration (NHTSA) has conducted crash tests of 159 different vehicle makes and models in the New Car Assessment Program (NCAP). Each of these vehicles was crashed into a rigid barrier at a test speed of 35mph. This is 5mph faster than the prescribed speed for compliance with Federal motor vehicle safety standards. The crash tests are designed to indicate, for vehicles within the same size class, the relative levels of occupant protection and vehicle safety performance. The data from the anthropomorphic devices (Part 572 dummies) contained in the driver and passenger positions in these vehicles are regularly released as part of NHTSA's Consumer Information Program(1). Trends in these data since 1979 indicate the manufacturers have responded by incorporation of changes in their vehicle designs to lower the measures recorded on the dummies. In this paper, different vehicle parameters, along with some of these specific vehicle design changes, will be tabulated and examined in an attempt to determine their effects on the dummy responses.

Three of the major vehicle attributes that affect the safety of restrained occupants in frontal crash events are the performances of the safety belts, steering assembly, and frontal structure. The following sections will explore these three elements.

Parameters of the safety belt systems are tabulated to allow examination of the effects of belt spoolout/stretch and belt loading on occupant performance.

The performance of the steering assembly appears to be a major factor to good or poor results of the dummy in these tests. The contribution of this component relative to driver HIC is reviewed.

The energy management capability of the frontal structure of the tested vehicles is examined. It has often been debated that to perform well in the 35mph barrier crash test, the frontal structure of the vehicle must be stiffer and will therefore provide an unduly harsh environment for the occupants in other real-world crash modes(2). This aspect is examined by using parameters of the crash pulse.

The analyses are performed exclusively with electronic data collected during each vehicle test. These data include the accelerations measured on the dummy's head, the accelerations measured in the occupant compartment

(the crash pulses), and the loads measured on the torso belts. The NHTSA Crash Test Data Base is the repository of all these data and provides the analyst an opportunity for extensive comparative studies of the vehicle parameters.

Update of Dummy Responses

To allow easy comparison of all test results, the Head Injury Criterion (HIC) and the resultant acceleration on the chest (chest g's) as recorded on the restrained driver and passenger dummies are grouped into six categories as shown in Tables 1 and 2(3).

In Figure 1, the six HIC levels are compared to the recommended life-threatening injury versus HIC relationship recently developed by the U.S. Delegation to the ISO(4). In the following sections, these six levels will be applied to individual vehicles to simplify comparative analyses.

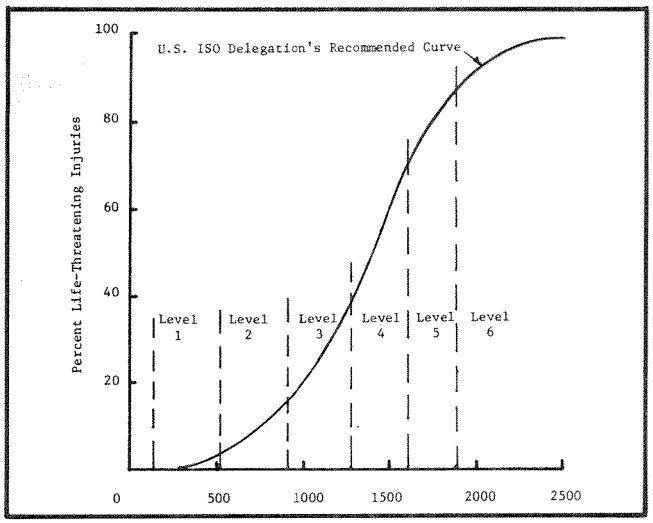

Figure 1. HIC levels shown with U.S. ISO delegation recommended curve

Table 1. HIC Levels

HIC	135 - 519	520 - 899	900 - 1254	1255 - 1574	1575 - 1859	>1860
Level	1	2	3	4	5	6

trends of increases in the percentages of lower level values (levels 1 and 2) with a concurrent decrease in the percentages of levels 4, 5, and 6. Figure 3, which is considered an even better graphic presentation of the vehicle performance trend since MY1979, shows the percentage of occupants, i.e., drivers and passengers, that received HIC's greater than 1,274 and/or chest g's greater than 68. A study of the data, which are used to develop this figure, provides safety engineers and manufacturers with information on outliers (poor-performing vehicles) tested during the 7-year period.

Table 10 contains the average and median values of the HIC's and chest g's of the driver and passenger dummies for the seven MY's. As seen in the level distributions and these averages and medians, most comparisons show that later MY vehicles have improved performance. It should be noted that the median (50th percentile) values of the HIC's are often significantly lower than the average values.

Vehicle Performance by Weight Class

In the above tables and figures, the NCAP data are grouped only by MY. No distinction is made for vehicle mass. It is well known that the lighter vehicles within the traffic mix in the United States are potentially less safe(6). This is, in part, due to the higher velocity changes that the lighter vehicles experience in collisions with heavier vehicles on the roadway.

The Passenger Car Classification Subcommittee of the Transportation Research Board has completed a final report on car size definitions(7). The weight classes as recommended from the report will be used to group the NCAP vehicles. The four weight classes are—

Small	Curb Weight below 2,450 lb
Compact	Curb Weight 2,451 to 2,950 lb
Intermediate	Curb Weight 2,951 to 3,450 lb
Large	Curb Weight above 3,451 lb

1984	1013	884	49	46	963	846	43	42
1985	1161	1014	50	51	1009	902	41	41

The vehicles in the NCAP are reported by test weight, which includes 328 lb for two dummies and a cargo weight of 100 lb for vehicles under 2,500 lb, 150 lb for vehicles between 2,500 and 3,500 lb, and 170 lb for vehicles over 3,500 lb.

The NCAP vehicles and the relevant dummy responses are grouped into these weight classifications in Tables 11 through 14. The dummy HIC's and chest g's are given for each vehicle. It should be noted that in these tables the vehicles within each weight class have been sorted. This sorting places all vehicles whose driver and passenger dummy received an HIC less than 1255 and a chest g less than 69 first in the tables. Conversely, the vehicles whose dummies recorded HIC's greater than 1254 and/or chest g's greater than 68 are last in the tables. These two groups will be referred to, relatively, as the low-risk group and the high-risk group. All subsequent tables of the four weight classes will be arranged in the same manner. Discussion will relate the safety parameters between the low- and high-risk groups.

Similar to Figures 2 and 3, the distributions for the four weight classes are shown in Figures 4 and 5. The average and median values of the HIC's and chest g's are given in Table 15.

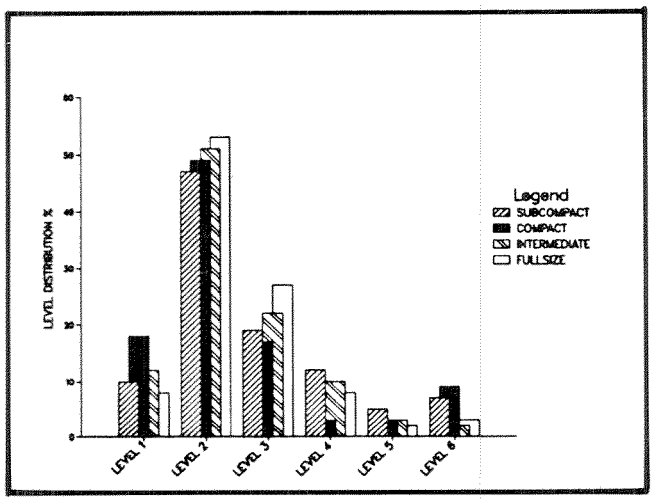

Figure 4. HIC and chest G level distribution by vehicle weight for NCAP vehicles

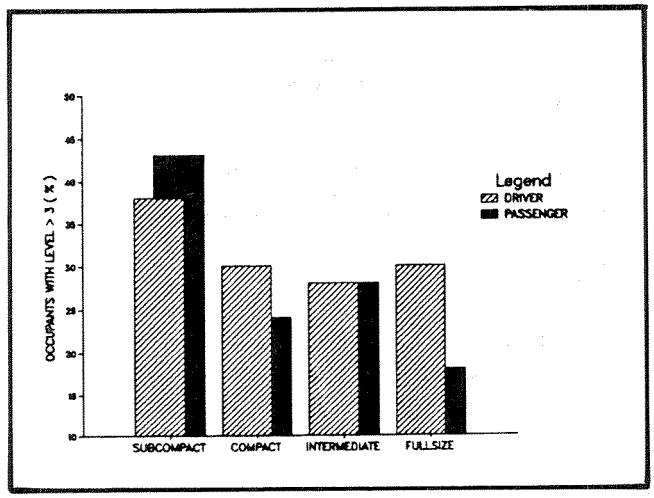

Figure 5. Percent of occupants with levels 3 by vehicle weight for NCAP vehicles

From Figures 4 and 5, the small vehicles that have been tested since 1979 show a tendency toward poorer performance than the other three weight classes. In Figure 5, the percentages of drivers and passengers for the small vehicles receiving HIC's greater than 1254 and/or chest g's greater than 68 are 38 percent and 43 percent. For the large vehicle weight class, these percentages are 30 percent and 18 percent. From Table 15, it is again noted that the median values are often significantly lower than the average values.

The remainder of this paper will present discussions of vehicle safety parameters within these selected weight groups and comparisons of the parameters between the different weight groups.

Belt Performance Parameters

The NCAP has provided the first large-scale dynamic evaluation of safety belts in today's vehicles. The experience in this program has been encouraging.

Complete failures of belt systems have occurred in only three vehicles. In each case, latching mechanisms or D-rings were the cause of the failures. Manufacturers' recalls were done on these vehicles to correct the problem.

Table 15. Average and median values of HIC and chest GS for four NCAP vehicle weight classes

Weight Class	Driver				Passenger			
	Average HIC	Median HIC	Average Chest GS	Median Chest GS	Average HIC	Median HIC	Average Chest GS	Median Chest GS
Small	1102	962	55	52	1185	1028	47	44
Compact	1152	867	49	47	1060	915	44	43
Intermediate	1059	860	51	51	1044	1050	44	43
Large	1121	976	51	47	959	894	44	42

Other design features contributing to high driver and passenger dummy measurements include excessive retractor spoolout, excessive belt stretch, and improper belt anchorage locations.

With continued emphasis on MUL's and with several States (and many foreign countries) having enacted such laws, it becomes increasingly important that the safety belt systems be designed to provide optimum protection for the vehicle occupants. The primary functions of the belt systems in providing this protection are to prevent or minimize occupant contact with interior surfaces and to maintain the occupant in the vehicle during a crash event. The belt system parameters in the crash involvement that are measures of these functions include the time-to-onset load on the occupant and the rate of belt loading. From the collected NCAP electronic data, these two parameters can be examined for the torso belts of the drivers and right front seat occupants. These parameters and the peak belt loads are given along with the occupant response in Tables 11 through 14 for the four selected weight classes. In these tables, the onset time is the time at which the torso belt load reaches 200 lb. The rate is the increase in load for each millisecond from 200 lb to nominally 1,000 lb. A typical illustration of these parameters is shown in Figure 6.

The average of the combined driver and passenger onset times and loading rates are given in Table 16 for the four weight classes. The ranges (minimum and maximum) of the values are also given. There appears to be a trend toward later onset times and lower load rates with increasing weight. The average values for the low- and high-risk groups are also given in this table. For all weight groups except the large, the onset times for the low-risk groups are slightly less than those of the high-risk groups.

The elements of the belt system that affect these two parameters include belt slack, belt length (the amount of belt contained on the retractor spool), how tightly the belt is wound on the spool, D-ring location (angle of belt relative to occupant torso), belt material (belt stretch), and belt web-locking mechanisms. In Table 17, the vehicles are listed that are known to have added belt web-locking mechanisms since the beginning of the NCAP (no locking mechanisms were known to have been installed in vehicles prior to the NCAP.) The web-locking

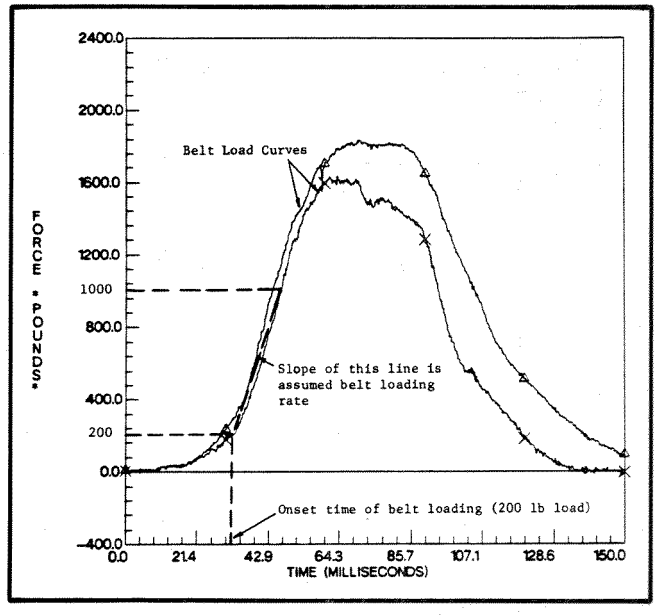

Figure 6. Illustration of belt system parameters

mechanisms should decrease the amount of spoolout and lead to an earlier belt load onset time. Comparisons of vehicle test results before and after the addition of web-locking mechanisms are given in Table 18. (Note: It is possible and probable that other design changes occurred to vehicles that may also affect the belt system and vehicle safety performance.) In this table, the belt load onset times, load rates, and peak forces for the drivers and passengers are given. Where the data are available, the addition of the web-locking mechanisms shows a decrease on the average of 20 to 30 percent in the onset time. The HIC's and chest g's are also compared in this table. Substantial decreases are noted in the driver and passenger responses. The effects of the web-locking mechanism decrease the potential for severe occupant contacts to interior vehicle compartment surfaces. All vehicles tested with web-locking mechanisms are in the low-risk group.

Steering Assembly Effects

The contact of the unrestrained driver with the steering assembly is a major contributor to injury(8). In high-

Table 16. Onset times and load rates of belt systems

		Weight Class

speed crash events, this will also be true of the restrained driver unless significant improvements are made to steering assembly performance. The NCAP data show significant contact will occur between the driver and the steering assembly. More than 29 percent (44 of 151) of the driver dummies in the NCAP tests had HIC measures that placed the vehicle performance in the high-risk group. In the small vehicle class, 18 of 56 (31 percent) were in the high-risk group, for the compacts 13 of 42 (32 percent), for the intermediates 6 of 30 (20 percent), and for the large vehicles 7 of 23 (30 percent).

The severity of these steering assembly impacts is dependent on several vehicle performance parameters including—

- The intrusion of the steering assembly into the occupant compartment
- The area of the head contact on the steering assembly and the force-deflection characteristics of the contact surface

*With web-locking mechanisms

- The amount that the belt system reduces the velocity of the occupant before contact occurs
- Effects of the structural performance that also may lead to differences in head contact velocities

The data used in this study are restricted to the electronic information available in the NHTSA Crash Test Data Base. These data do not contain steering assembly intrusion information or force-deflection characteristics of the impacted surfaces. Film analyses and component tests are planned to collect these important data. Until these data are available, a definitive assessment of the steering assembly performance cannot be completed. Therefore, in the following paragraphs, the review does not differentiate between the attributes of the steering assemblies, belt systems, and structural performance. However, other sections of this paper do present belt system and structural attributes on the vehicles that can be examined in conjunction with these steering assembly impact data.

In addition to the HIC values, a measure of the significance of the head-to-steering-assembly impact that can be examined from the electronic data of the NCAP is the change in velocity of the head during interaction with the steering wheel rim and/or hub. This change in velocity can be determined approximately by calculating the difference between the head acceleration resultants of the driver and front seat-passenger (see Figure 7). In this approach, it is assumed that the kinematics of the front-seat passenger are the same as those of the driver until the driver head contacts the steering assembly. It is also assumed that insignificant passenger head contacts occur during the time that the driver head is in contact with the steering assembly. The change in driver head velocity for each vehicle, as calculated by this method, is given in Tables 19 through 22. If the dummy head response data do not meet the above assumptions, the velocity change parameters are omitted from the tables. For comparison, the driver HIC's and chest g's are again shown in these tables. Also in the tables, the approximate time of contact, TS, and the assumed times of disengagement of head to steering assembly, TF, are given. Estimated average g levels of the head during contact with the steering assembly are calculated from these parameters and are given as DR HD GS.

In Table 23, the average values for these steering assembly parameters are given for the total fleet and for the low- and high-risk groups. For the total fleet, these data show a decreasing trend in the change in velocity of the head and in the magnitude of the g's with increasing vehicle weight. A 15 percent lower change in velocity and a 24 percent lower DR HD GS are seen for the large vehicle weight class as compared to the small vehicle class.

In comparing the low-risk group to the high-risk group, the expected results are found. An increase of almost 50 percent in the velocity parameter and a doubling in the value of the G parameter between the low- and high-risk groups are observed.

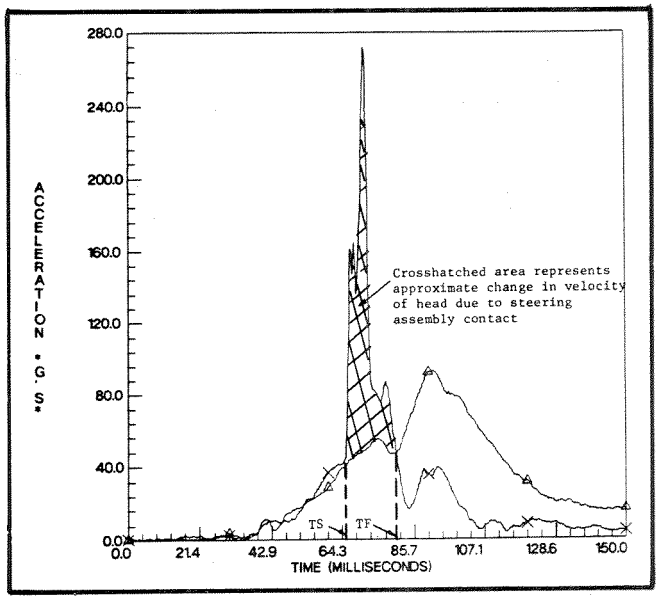

Figure 7. Overlayed resultant acceleration curves of driver passenger heads—showing parameters of steering assembly contact

Additional information of interest and possible importance is the location of the dummy driver in relation to the steering assembly. From Figure 8, the distances from the driver to the vehicle interior are defined. Values for these distances are given in Tables 19 through 22. The average values of these measurements are given in Table 24. It is interesting to note the very slight differences of the average values for the small vehicle weight class as compared to the large vehicle weight class.

Large	15.17	20.59	13.69	7.07

In addition, Tables 19 through 22 also provide data relative to the part of the steering assembly that the driver head contacted. If the contact is shown as steering wheel in the tables, the dummy head actually impacted both the rim and hub. In almost all tests, the steering wheel rim, hub, or both the rim and hub were struck. The severity of these head impacts is indicated by the resulting HIC and somewhat by the parameters as given in Tables 19 through 22.

Good performances of the restraint system and the steering assembly are both important in reducing or eliminating these impacts. The belt parameters discussed in the previous section need careful review to improve safety performance. The steering assembly must be designed to minimize intrusion and to provide a friendly environment when the head or other body part contacts occur for the restrained (and unrestrained) driver.

Structural Performance Parameters

A third vehicle attribute that can be examined from the NCAP data is the performance of the frontal structure during the crash. Safety elements that the frontal structure is expected to supply include a reasonable occupant compartment acceleration signature (crash pulse) and a collapse mode that does not cause excessive compartment intrusion. As in most safety design considerations, these elements require a compromise. The safety designer desires as much dynamic crush as possible, yet the crush must not lead to intrusion that violates the occupant space.

The crash pulse of the NCAP vehicles, as measured by accelerometers in the occupant compartment, can be analyzed to provide state-of-the-art information to the vehicle designer. Several methods can be used to examine these crash pulses. In the following paragraphs, two methods will be explored. The first method will use the simplified characteristics of the tipped equivalent square wave (TESW) as developed in (8). The second method uses the actual acceleration data highly filtered with an SAE J211B Class 30 filter.

An example of the TESW is shown in Figure 9. It is overlaid with the actual occupant compartment acceleration. The parameters from the automated process of the TESW that are preserved from the actual data are the maximum dynamic crush, the time to maximum dynamic crush (TMAX), and the time to centroid of the crash

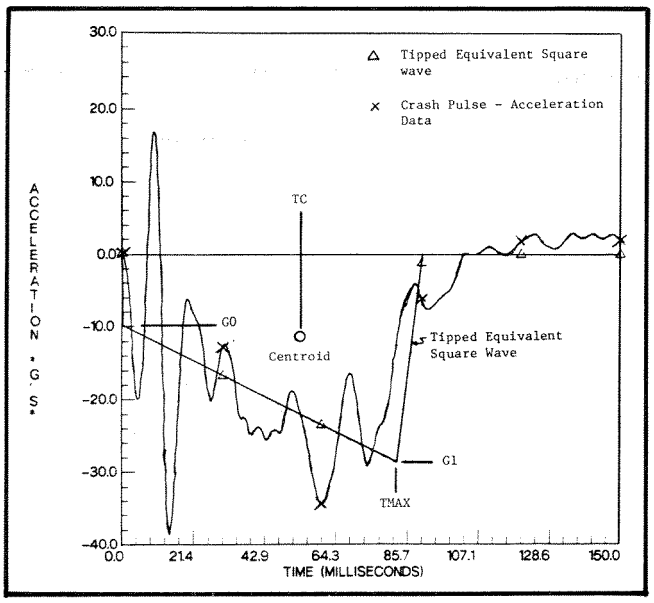

Figure 9. Tipped equivalent square wave overlayed with actual accleration data

pulse (TC). These values are given in Tables 25 through 28 for the four weight classes. In addition, g levels at the beginning of the pulse (G0) and at time of maximum crush (G1) are calculated and presented.

A further examination of the crash pulse utilizes high filtering of the actual accelerometer traces. The filtered trace is multiplied by the test weight of the vehicle and plotted against the vehicle's dynamic crush. This generates an approximate force-crush curve. From this curve, the peak force and an estimated linear stiffness of each vehicle are determined. The crush at the peak force is determined. The maximum dynamic crush is again obtained and can be compared to the equivalent value from the TESW. These parameters are also given in Tables 25 through 28 for the four weight classes.

The average values from the TESW and filtered force-crush curve for each weight class and for the low- and high-risk groups of each weight class are given in Table 29. From the average values of the crash pulse parameters for the total fleet, it is observed that, nominally, values are increasing with increasing weight (except for G0 and G1 of the TESW). In comparing the parameters of the low-risk group to the high-risk group within each weight class, it is seen that TMAX and maximum crush are the factors that show the most consistent trend. These values are larger for the low-risk groups. Except for the intermediate weight class, a similar trend of increasing peak force and increasing stiffness is also apparent from the low- to high-risk groups. From the average values of TC, G0, and G1 (which can be considered crash pulse shape functions) of the two risk groups, there appears to be a general trend toward a lower average g level and a slightly more square wave pulse shape.

Future Studies

The preceding discussions and analyses are considered preliminary and only a cursory examination of the data from NCAP. Much of these data have never been extracted from the NHTSA Crash Test Data Base and presented for review to automobile manufacturers and safety organizations in this consolidated format. It is hoped the manufacturers of the specific vehicles (along with others) will assist in a study of the tabulated information and provide comments to help validate, correct, and improve these data.

Future detailed studies of vehicle safety performance from the NCAP data planned by NHTSA Research and Development include—

1. Safety belt geometric assessments and webbing material (belt stretch) analysis. The present study was limited to data readily available in the NHTSA Crash Test Data Base. The belt anchorage locations and belt stretch information will be assembled for a large number of the NCAP vehicles. Analyses will be performed to determine the significance of these parameters.
2. Extensive film analyses of the steering assemblies. Digitized displacement-time histories of the steering assemblies are being generated from the high-speed films of the NCAP tests. These data will provide information on the relative importance of steering assembly motion and intrusion during the crash event. Tear-down studies will be performed on selected vehicles to determine the structural aspects that lead to excessive steering assembly intrusion into the occupant compartment. Component tests to measure the force-crush characteristics of rims, hubs, and columns will be conducted on a limited set of the NCAP vehicles. From these analyses and data, it is believed definitive information on the performance parameters of the steering assemblies that provide improved protection for the restrained occupant can be established.
3. Further evaluation of the crash energy management of the vehicle frontal structure. The present analysis used only the occupant compartment accelerations. Many of the NCAP tests have additional frontal structures data from multiple load cells mounted to the fixed rigid barrier. These load cell data provide a force-time distribution across the face of the vehicles. These data will be used along with some limited car-to-car and car-to-narrow-object test data to provide a better understanding of the structural performance/energy management systems of the vehicles. Again, limited tear-down studies will be conducted to identify vehicle design parameters that provide improved occupant protection.

Table 25. Structural performance parameters for the small vehicle weight class.

Conclusion

NCAP has provided the most comprehensive data on vehicle crash performance ever collected. These data are resident in the NHTSA Crash Test Data Base on a VAX 11/780 computer. In the preceding sections of this paper, a preliminary review and tabulation of these data have been conducted. The following conclusions can be drawn from this review.

1. For MY vehicles 1979 through 1984, a significant improvement in restrained dummy performance is noted for recent MY vehicles (see Figure 3). (Although data are presented for some of the MY1985 vehicles, tests on all vehicles were not completed in time to be included in this paper.)
2. When the tested vehicles are separated into four weight classes, the performance of the small vehicle weight class is significantly poorer than that of the large vehicle weight class (see Figure 5). It is well known that in the accident environment the probability of serious injury or fatality is higher for the small vehicle. These data indicate that this higher probability, which definitely is associated with the higher severity exposure of the small vehicles, may also be related to the small vehicle safety design features.
3. In studying the safety belt performance parameters, the addition of a web-locking mechanism is seen to decrease significantly the time-to-belt onset loading (see Table 18). For specific vehicles, this decrease contributes to a dramatic reduction in dummy responses. With the rapidly increasing number of States and countries mandating the use of safety belts, it is important that the most efficient belt systems be made available to consumers. The web-locking mechanism or similar design to decrease the belt load onset time appears to provide the vehicle driver and occupant with improved protection.
4. Examination of driver head impacts into the steering assembly show that almost 30 percent of the restrained driver dummies in the NCAP tests had HIC values that placed the vehicle performance in the high-risk group (HIC greater than 1,254). On average, the head-to-steering-assembly impacts in the small vehicle weight class appear to be more severe than those of the other weight classes. It should be noted the severity of these impacts are dependent not only on the steering assembly parameters but also on the belt systems and structural performance of the vehicles (see Table 23). Studies are ongoing to assess the design characteristics of steering assemblies (intrusion and force-crush properties) that contribute to the excessive danger.
5. From the review of the structural performance parameters, some not unexpected conclusions are that the length of time of the crash pulse and the total crush of the vehicle during the crash are important. Trends indicate that the possibility for good safety performance is improved with long crash pulse duration and large dynamic crush. In comparing a linear stiffness parameter, a slight trend of improved performance for lower stiffness is observed (see Table 29). The data as analyzed do not indicate a significantly stiffer vehicle is required to obtain good performance in the 35mph crash tests.
6. Belts, steering assemblies, and frontal structures must perform effectively as a system. A predominant outcome of this review is that the safety performance of the vehicle is dependent on the system. With the variety of vehicle makes and models, interior occupant compartments, and exterior structural designs, the configuration of this system presently spans very wide performance corridors. Several studies have been

outlined to better locate the elements in the corridors that will improve occupant protection.

Accident Research and Frontal Testing

Dr.-Ing. M. Danner
HUK-Verband, Munich

Frontal collisions are still the primary reason for fatal injuries of car occupants, although the relative importance of side collisions has increased because of the protective effect of the safety belt. In classifying accidents, more attention must be given to the different sequences in car-to-car and single-car accidents and to their damage and strain criteria. However, there are problems in classifying real accidents into collision types and assessing the share that can be reproduced by standardized crash tests.

1. Each categorization of real accidents into collision types has to summarize and generalize the typical influences of each case, such as relative car masses, structure rigidity, relative speeds, direction of impact, and the movement before and after the collision. Which types of strain criteria can be combined and which have to be absolutely separated has not yet been adequately analyzed.
2. The way of dividing the collision types into a few or more (according to offset and crash angle) influences the priorities of collision types and the role of a corresponding crash test. This question has not yet been adequately resolved.
3. The comparison of accidents with crash tests is additionally impeded by the fact that crash tests are usually driven with only one moving vehicle and with an idealized distribution of forces, quite different from a real accident.
4. The international available accident materials show substantial differences. Because of the rapid car-safety development, a comparison between real accidents and corresponding crash tests is sensible only on the basis of recent accident material no older than 5 years and of accidents with belted occupants only.

There are about 3,000 single-car accidents with 1,200 belted passengers and about 1,000 car-to-car accidents with safety belts recorded in the HUK-accident material, which can be used as a basis for the questions mentioned above. In car-to-car accidents, with passenger injuries from AIS 3 in spite of fastened belts, the two collision types, "crash in longitudinal direction, centered" and "angled collision, offset less than 50 percent," dominate each with a frequency of 40 percent, which can in principle be reproduced by the 0° and 30° frontal fixed barrier test. The remaining 20 percent are accidents with high offset (offset about two-thirds) and longitudinal or angled impact direction.

Seventy percent of the frontal collisions are below a comparable barrier test speed of 50km/h; the 80 percent point is at 60km/h. In former accident material with

passengers predominantly unbelted, 90 percent of the accidents with injuries were below 60km/h. Because of the protective effect of the belt, the injury borderline has been moved to higher speeds.

In single-car accidents, however, the offset frontal impact dominates with about 60 percent, followed by the two collision types, "centered frontal fixed barrier test in longitudinal direction" and "centered, limited object impact," with 15 percent each. The rest of the accidents (about 10 percent) can be characterized as angled, distributed fixed barrier impacts. The 90 percent point of the collision speeds in single-car accidents is about 60km/h.

If an overall statement is made for the accident scene in keeping with the real-life proportions of car-to-car and single-car accidents—

- Offset accidents with clearly less than than ½ direct contact area (angled and not angled) can be estimated to account for about 40 percent of the accidents with belted injured occupants from AIS 3, followed by
- Collisions corresponding to the centered 0° frontal fixed barrier test, with almost 30 percent frequency.
- Angled frontal collisions corresponding to the 30° crash, which account for about 25 percent of all serious injuries from AIS 3.
- The rest are other collisions.

From the accident researcher's point of view, the following recommendations for safety tests are made:

1. It is not sufficient to describe the real-life frontal accident by one standardized test only. Three tests should be taken as a basis.
2. The frontal fixed barrier test should still be used as the main reference test. It covers about one-third of the real accidents with serious or fatal injuries even with fastened belts. In addition, the test can very well be reproduced and compared. A crash speed of 50km/h corresponds to the majority of accidents, but it can be seen from studies with 100 percent belted occupants that it is not altogether unjustified to increase the collision speed because of higher injury borderlines caused by the protective effect of the safety belt.
3. In addition to this test, an angled crash or an offset test is necessary, which has to be carried out in such a way that it can simulate the large problem of one-sided intrusion of the passenger compartment. This can be achieved by a 30° barrier test, but at a higher speed than 50km/h. An offset test in car-longitudinal direction with frontal contact area about one-third and a speed of 50km/h seems even more frequent in real accidents.
4. In a third test configuration, it should be considered that to reduce the injury risk in both cars involved there has to be a balance between self- and partner protection. A supplementary car-to-movable-barrier test, for example, with 50 percent offset or fully distributed, would be desirable. The test should be carried out in such a way that a movable reference-weight barrier with a specific deformation structure would show satisfying safety criteria even when it crashes against the tested car with a reference speed—according to present knowledge, about 100km/h relative speed of the two moving vehicles. This test should give indications on partner protection. We know it is difficult to realize this suggestion and to define the corresponding reference vehicle, but it should be the aim of future research to develop supplementary tests for partner protection beyond the test procedures for self-protection.

Together with the two tests mentioned before, there would thus exist basic test procedures that correspond to the real-life accident scene to a greater extent than the frontal fixed barrier test does today.

Results of Crash Tests According to the ECE/GRCS Regulation Proposal Concerning 50km/h Frontal Impact Against the Rigid 30° Barrier

E.Faerber and
K.P. Glaeser
Federal Highway Research Institute (BASt)
Federal Republic of Germany

Abstract

The Federal Highway Research Institute (BASt) has advised the Federal Minister for Transport on drawing up a draft regulation for the protection of vehicle occupants in a frontal collision. This draft regulation provides for a collision between a vehicle and the rigid 30° barrier at 50km/h.

In determining the test criteria, a number of questions had to be answered: Which calculatory and influencing possibilities are there in the application of the head protection criterion? How can the head contact be clearly determined? What spreads do the measured values for the dummy demonstrate under the same test conditions, and must these be included in the draft regulation? How frequently does submarining occur and how can submarining be measured? What other regulations can be covered by the global test proposed by this draft regulation? Do small passenger cars currently on the market already fulfill these test conditions?

Results of the following studies by the BASt concerning these aspects are introduced in this paper:

- Theoretical studies in the "Application of the Head Protection Criterion"
- Practical applications (eight crash tests) on the topic "Variance of the Measured Values"
- Accident data analysis on the topic "Frequency of Submarining"
- Trolley tests on the topic "Determination of Submarining by Measurement"
- 10 crash tests using subcompact passenger cars
- Inclusion of other ECE regulations in the global test

The draft regulation is introduced and critically assessed.

Introduction

In Europe, a large number of ECE regulations have been approved for use in testing the passive vehicle safety of vehicle components. With the ECE regulation proposed by the Group of Experts on the Construction of Vehicles(1), a regulation is planned with which the interrelationship between all the components can be tested in a full-scale test. The initial drafts for this regulation have already been critically discussed in (2).

Summary of the Regulation Content

Test Conditions

- Head-on collision, 30° barrier, initial contact on steering wheel side
- Impact speed: 48 to 50km/h
- Vehicle weight = kerb weight
- Tank 90 percent filled with nonflammable liquid (density: 0.7 to 1g/cm^3)
- One dummy (Hybrid II) on each of the front seats, seatbelts fastened
- One dummy (Hybrid II) on the rear seat behind the driver's seat unless outer rear seats fitted with 3-point belts
- All seatbelts and belt anchorages in vehicle in accordance with ECE Regulations 16 and 14.
- Height-adjustable steering wheel in normal position or, if no normal position specified by manufacturers, in middle position
- Windows closed wherever possible; open only if required for measurement purposes; window winder or other devices in position as for closed window
- Doors closed but not locked
- Longitudinal seat position: H-point 50mm ahead of R-point
- Seat height adjustment: middle position
- Seat backrests in normal position or, if no normal position specified by manufacturers, inclined at 25° to the vertical
- Dummy position: dummy symmetry plane = seat symmetry plane
  - Driver:
    - Distance to the knee: 37cm (overall)
    - Distance from the left knee to dummy symmetry plane 15cm (overall)
    - Right foot on undepressed accelerator pedal or as near as possible in front of it, heel on the floor
    - Left foot on floor alongside clutch pedal, left leg as straight as possible
    - Hands on steering wheel in "quarter to three" position
  - Passenger:
    - Legs stretched out as straight and parallel as possible

— Feet on floor or at right angles to thighs, heels on the floor
— Elbows against backrest, hands on thighs

Measured Values

- HPC (Head Performance Criterion); criterion:
  — No head-vehicle contact or
  — <1000 (calculation as for HIC, from start of head-vehicle contact to end of recording time, tolerance +250)
- Resulting acceleration of the chest; criterion: a_{3ms} 60g
- Upper thigh longitudinal forces; criterion: $F_{max} < 10kN$ and $F_{20ms} < 8kN$
- Behavior of the lapbelt (if fitted); criterion: no submarining

Further Requirements

- Door opening (as ECE-R32 and ECE-R33)
- Fuel leakage (as ECE-R34)

Special Problems in the Application of the Draft Regulation

During the discussions into the drawing up of the draft regulation, attention was paid to the following problem areas: determination of a Head Protection Criterion (HPC), the spread of the test results in full-scale tests, and detection of submarining. Results of the tests performed by the BASt will be discussed.

Head Protection Criterion

Various head protection criteria are based on the Wayne State Cerebral Concussion Tolerance Curve, which represents a borderline between translatory head loads that are dangerous to life and those not dangerous to life.

In recent studies(3), serious head and brain injuries resulting in death are divided into subdural haematoma (SDH) and diffuse axonal injuries (DAI). According to (3), both types of injury occur under the same mechanical loads, namely rotatory accelerations that differ only in their severity.

If one considers the results of this study, then the translatory acceleration of the head is, at least for severe head injuries, of minor significance. In contrast to this, however, is the fact that in vehicle safety crash tests with dummies, translatory accelerations are now almost exclusively measured and taken as the basis for protection criteria. Translatory head accelerations will also be evaluated in the ECE/GRCS draft regulation, since the uniform measurement and evaluation of rotatory accelerations does not at present appear to be sufficiently reliable.

Since the load limit for the head according to the WSU curve was evaluated using skull crash tests against steel plates, an HPC derived from the WSU curve should be applied only in the event of head contact. Head contact can, for example, be determined by measurement if electrically conducting contact zones on the head of the dummy and on the vehicle close a circuit during contact. Electrically conducting paints or foils applied to the head of the dummy have only an insignificant effect on the calibration values specified in U.S. Part 572. Despite the often noncontinuous contact circuiting, it is nevertheless normally possible to determine the start of contact with sufficient accuracy. Due to the frequent damage to the contact surfaces, however, the end of contact can usually not be determined satisfactorily. In comparative tests, it was discovered that the required contact times could not be determined with a sufficient degree of accuracy using high-speed film recordings.

The requirements for measured data recording are specified in ISO and SAE standards. The level of the requirements sets a limit to the increase in the number of channels. During the tests carried out by the BASt into this subject(4), it was discovered that large reductions in the requirements had only an insignificant influence on the HIC value. For example, the limit frequency of the low-pass filters for the head accelerations could be reduced from 1,000Hz to 300Hz, and, for certain filter types, even down to 100Hz. A reduction in the scanning rate during digitization of the measured data from the standard 8,000Hz to approximately 1,000Hz also had only a slight effect on the HIC value.

On the one hand, the HIC can be calculated from all the possible pairs of times of the measurement interval. The maximum value is then the desired HIC value. However, this method requires high computation times, even from powerful computers. For this reason, it is necessary to find suitable iterative approximation methods. When comparing the various methods, it was discovered that all the methods produced results with the required accuracy. The various methods for performing the integration required by the HIC formula affected the HIC value only insignificantly.

Because the cutoff frequency of analog and digital filters, digitization rate, and iterative calculation procedures have only minor effects on the HIC/HPC values, the cutoff frequency proposed in the ECE/GRCS draft regulation was reduced from 1,000Hz to 600Hz, and a defined calculation procedure was not demanded.

Spread of the Measured Values in Full-Scale Tests

Varied statements are made from various quarters regarding the reproducibility of the measured data from standardized crash tests.

The collision between vehicle and a rigid wall represents a more simplified type of crash than the vehicle-vehicle collision.

To be in a position to make statistically significant statements from the expected spread of the test results, it appeared necessary to perform at least eight crash tests. The vehicle used for the tests was the Opel Kadett D, built between 1979 and 1984. Used vehicles between 1 and 2 years were used. A comprehensive summary of the results has been published in (5).

In technical spheres, the normal distribution is generally used to describe the frequency distributions. A test of the measured results for normal distribution, e.g., using the chi-squared fit test, could not be carried out due to the small number of experiments. In Tables 1 and 2, spreads have been drawn up for selected parameters. The following dimensions are used in the tables for describing the distribution of the individual parameters:

- Arithmetic mean (x)
- Standard deviation (s_v)
- Coefficient of variation (cv)
- Minimum and maximum values (min., max.)

Vehicle-Related Measurements

The deformation of the front of the vehicle was measured using a measuring frame according to the displacement of 13 measuring points. The coefficients of variation of the vehicle deformation on the driver's side lay between 2 and 10 percent and, for the points with the greatest displacement, between 2 and 4 percent. The vehicle accelerations also varied by the same magnitude (see Table 1).

Table 1. Dispersion of car measurement values

	Maximum Car Deformation, Driver Side mm	Maximum Car Acceleration g	Mean Car Acceleration g	Car Velocity Change Δv km/h

cv %	13	22	10	13	29	4	94	63	74	28

Dummy-Measured Values

Selected spreads are listed in Table 2. In two tests, slight head/steering wheel contacts—in one test also a chest/steering wheel contact—were suspected but could not be proved definitely. For this reason, the HPC was not calculated according to the ECE/GRCS draft regulation (i.e., only for the duration of the contact) but was specified as an HIC as proposed in the FMVSS 208 for the entire duration of the resulting acceleration. The mean head accelerations, the HIC values, and their spreads are higher for the driver than for the front-seat passenger. This may, on the one hand, be due to the fact that in certain cases slight head/steering wheel contacts may be suspected, and, on the other hand, the movements of the two front-seat dummies differ due to the vehicle rotation.

The same effects can be observed for the chest loads.

Due to the movement of the vehicle, the two dummies moved to the left relative to the movement of the vehicle, so they moved forward in the vehicle with the right knee leading. A knee contact with higher longitudinal femur forces was therefore observed primarily for the right leg.

Regarding the forces in the left femur of the driver and front-seat passenger, the wide spread of 94 and 74 percent, respectively, can be explained by the fact that a knee contact occurred in only one and two tests, respectively. In cases where such knee contacts occurred in every test, the variances (28 percent) are considerably smaller. Due to the large forward displacement of the front-seat passenger dummy, the femur forces in this dummy were higher than in the driver dummy.

Methods for the Detection of Submarining

Submarining is defined as the sliding of the pelvis under the lapbelt loop or the riding up of the lapbelt over the crest of the ilium of vehicle occupants wearing seatbelts under frontal collision conditions. Submarining is promoted by soft seat upholstery and/or an unfavorable seatbelt geometry (small lapbelt angle) as well as misuse of the seatbelt system (belt too loose or relaxed seat position)(6).

The importance of submarining as a result of direct effects of the belt in an accident is due less to the frequency of the injury than to the seriousness of the abdominal injuries. For example, the number of cases of submarining relative to the number of injured front-seat occupants wearing seatbelts in head-on collisions in the accident material collected by the Accident Research Department in Hanover (259 cases) represented 4.6 percent; in the accident research material of Peugeot-Renault (1,073 cases), 5.8 percent. It is estimated that approximately 2 percent of all injuries with AIS $>$ 3 are abdominal injuries caused by submarining(7). For this reason, an abdominal protection criterion has been integrated into the draft ECE/GRCS guidelines for the 30° head-on collision.

Since the draft regulation proposes only a measuring method for detecting the submarining effect, although other methods are also accepted in principle, a comparative study of the measuring methods described in the draft regulation with another method used until now was carried out.

Six trolley tests were performed at 50km/h under simulated head-on collision conditions on the crash test facility of the BASt. The standard seatbelt systems of a Ford Capri II and a Citroen GS Club were fitted to the frame of a trolley so that in each case, two different measuring methods could be tested in parallel to provide a total of 12 individual results at the end of the series of tests. Steering wheel and instrument panel were not installed.

The position of the seatbelt anchorages in both vehicles lay within the limits specified in ECE Regulation 14. Film recordings were made, in which the bones of the crest of the ilium of the dummy were marked with target points, so that the sliding of the pelvis under the seatbelt during submarining could be clearly detected.

Each dummy was fitted with one of the special submarining measuring devices described below.

The one measuring method is based on a development by the Association-Peugeot-Renault (APR), in which two hook-shaped force transducers fitted with strain gauges are screwed onto the crest of the ilium of a Hybrid II dummy pelvis (Figure 1). If the lapbelt rides up over the iliac crest under submarining conditions, the transducers are subjected to a bending force, i.e., indicating abdominal loading, provided the lapbelt loads are applied vertically to the APR transducers. This measuring method conforms to that described in the ECE/GRCS draft regulation, which specifies a load limit of 800N.

The second method of detecting submarining is based on the use of a submarining indicator pelvis (SIP). Three force transducers are fitted, one above the other, into the

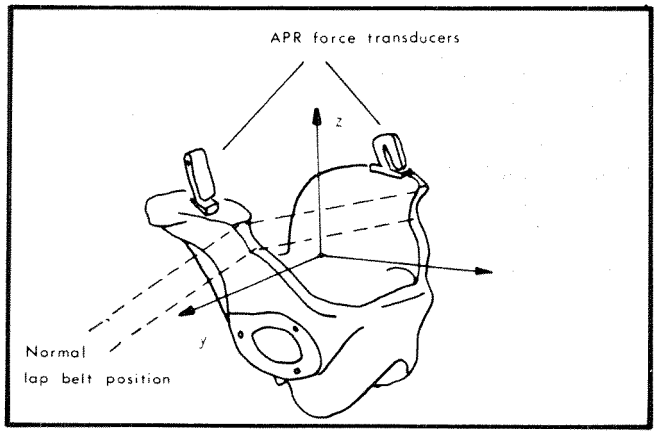

Figure 1. Dummy pelvis APR transducers

left- and right-hand ala of the ilium of the dummy pelvis, over which the lapbelt slips on collision, allowing the relative movement between pelvis and lapbelt to be deduced from the temporal relationship between the force transducer signals. This test method is only able, however, to prove whether or not submarining has taken place (Figure 2). In the event of submarining, it does not allow any statement to be made as to the size of the abdominal load.

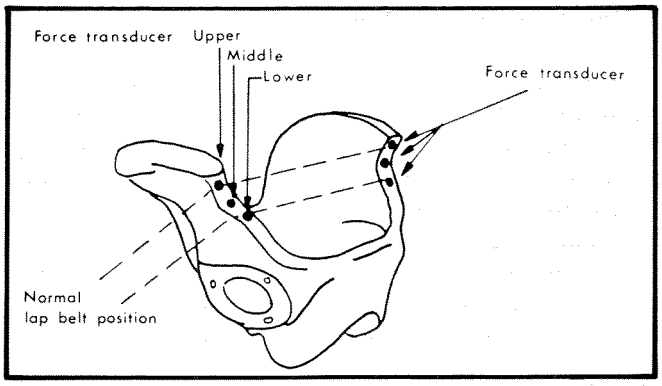

Figure 2. Submarining indicator pelvis (SIP)

As mentioned above, the decision as to wheter submarining had taken place during the test or not was based on films of the dummy movements.

This film analysis represents a suitable method of detecting submarining but is unsuitable for use in vehicle approval tests, since the test regulations make high demands on the integrity of the normal condition of the vehicle, thus forbidding the removal of the doors for filming the movement of the dummy pelvis.

Analysis of the test data has shown that the SIP method permits uncertainties in determining the sequences of movement during submarining, since the only factor for evaluation after a critical upward movement of the belt loop along the ala of the ilium is the sudden drop in the signal of the upper force transducer. From the test results, the question must certainly be posed whether, on the basis of a numerical evaluation of the signal drop, a submarining criterion such as "drop in signal in Δt" can be defined, from which submarining can be proved where the criterion is exceeded and excluded where the criterion is not exceeded. It appeared that an analysis of the temporal pattern of the lapbelt forces, which can be characterized under submarining conditions by two clear maxima with a minimum at the point when the lapbelt passes the upper force transducer of the iliac wing, in conjunction with the analysis of the temporal pattern of the upper pelvis force transducer can considerably increase the detection probability of whether or not submarining has taken place.

The APR measuring method also appears suitable for determining critical lapbelt movements. An assessment of the abdominal loads on the basis of the measured pressure forces presupposes, however, that the lapbelt forces are applied vertically to the surface of the APR transducer. Since such conditions cannot always be fulfilled, an incorrect indication of uncritical abdominal loads can be produced, although the belt forces acting on the abdomen exceed the biomechanical tolerance limits. The measuring curves of the lapbelt forces with two clear maxima under submarining conditions can also be used here, as already described above, as an additional criterion for determining submarining.

The results can be summarized as follows. The known measuring methods are not conclusive when applied alone. With the introduction of the 30° global tests by the ECE, the installation of belt force transducers should be permitted, if not even demanded, for reliable proof of the submarining-free restraint of the dummy by the safety belt. A method of interpreting a combination of measuring values from the force transducers and the belt force transducers must be worked out. The ECE Regulation 14 (Position of the Seat Belt Anchorage Points) is insufficient to prove that submarining is prevented.

Results of 10 Standardized Tests With Subcompact Cars

To investigate the applicability of the test methodology of the ECE/GRCS draft regulation and to determine to what extent subcompact cars already on the road satisfy the proposed safety requirements, a series of 10 crash tests was carried out. On the basis of the test results, an attempt should also be made to determine which existing ECE regulations are covered by the new draft regulation.

In the first three tests, no head contact measurement could be carried out, since an earlier version of the draft proposal did not permit the use of electrically conducting materials. In addition to the contact measurements, it was also possible to use the SIP from the fourth test onward. For the VW Golf, the results from one 30° and two 0° collisions were available for comparison with the results of the 0° and 30° barrier tests.

Vehicle-Measured Values

The vehicle types and certain of their technical data are shown in Table 3. The vehicles were bought second-hand and were between 1 and 1.5 years old at the time of the test. Table 4 shows the maximum vehicle deformations.

In each of the tests, the front of the vehicle on the passenger side was only slightly deformed. The deformation in the longitudinal direction of the vehicle was 10 to 30mm. Due to the one-sided loading with the 30° configuration, it is reasonable to assume that the maximum deformation would be slighter with the 0° barrier.

Table 5 shows selected parameters to describe the deceleration of the vehicle. As already stated, comparisons between the 0° and the 30° positions of the barrier can be made only for the VW Golf. Surprisingly, however, as shown in Table 6, there are no major differences between the two configurations. Contrary to this, however, a major research project carried out by the CCMC(9) with 71 tests and 20 different types of vehicles shows that if all models are taken into consideration, the vehicle accelerations and the velocity changes are on average noticeably higher in the 0° tests than in the 30° tests.

Δv m/s	14.8	14.6	14.6
Average Accel. a g	12.1	12.2	11.9

Dummy-Measured Values

The measured values are summarized in Table 7. In tests 2 and 9, the limit for the chest protection criterion was slightly exceeded as the driver collided with the steering wheel. In test 10, an excessive longitudinal force was measured in the right femur of the driver due to a collision with the steering column and the instrument panel (see also, section "Detection of Submarining"). As far as the other criteria were concerned, the subcompact cars available on the market in 198G4 satisfied the safety requirements.

The results for one test with the 0° barrier position and one test with the 30° barrier position were available for comparison of the dummy loads. The measured values for the dummy are shown in Table 8. In the 0° collision, the head accelerations are noticeably higher than in the 30° collision. This difference is considerably greater for all dummy-measured values in the CCMC study already mentioned(9).

The values for the HPC and abdomen protection criterion are discussed in greater detail below.

Head Protection Criterion (HPC)

As already mentioned several times, the HPC must be calculated only in the event of a head collision, and then from the beginning of the contact. For the head protection criteria HIC most widely used to date, this temporal restriction does not apply. The passenger dummies suffered no head contact during the 10 standardized tests, so the HPC was satisfied for all the tests. The HIC values calculated for the entire period of measurement are listed in Table 9. If one compares the HPC and HIC values for the driver dummies summarized in Table 10, it becomes apparent that certain HPC values are considerably lower than the HIC values. This effect occurs whenever the head contact takes place in the period t_1 to t_2 for which the HIC is calculated.

Due to its major effect on the HPC value, the measurement of head contact must be carried out with great care and accuracy. The reason for the considerable differences between HIC and HPC in test 10, for example, is that in these standardized tests, the head of the driver dummies moved between the A-pillar on the barrier side (here the left-hand A-pillar) and the rim of the steering wheel due to the angled position of the barrier. These movements generally result in simply glancing contacts and thus to contacts that are barely noticeable in the head acceleration sequence.

By analyzing acceleration traces from crash tests carried out previously in this respect, it can be stated that the difference between HIC and HPC is not as marked if a clearer and harder head collision against vehicle components occurs.

Abdomen Protection Criterion

From test 4 on, a dummy fitted with an SIP was used to record any occurrence of submarining. With the exception of one test that was performed twice, the dummy was positioned in each case on the driver's seat.

For test 3, Ford Fiesta, the occurrence of submarining was indicated by the final position of the dummy.

The recording of submarining using measurements performed in the subsequent tests, taking into consideration the seatbelt force patterns and femur forces, produced an indication of submarining in only one case (test 10, Renault R5). The reason for the slipping of the dummy under the lapbelt included the tearing of the seat out of the seat rail and thus the change, i.e., reduction, in the lapbelt angle.

The belt slipped over the right-hand ala of the ilium. This is an indication that even in the event of a 30°

collision, ECE Regulation 14 (Position of the Seat Belt Anchorages) alone does not guarantee that submarining will not occur.

Inclusion of Other ECE Regulations in the Global Test

It is planned that the 30° global test will also cover a number of other ECE regulations. Annex 8 lists those regulations that will be regarded as having been satisfied if the global test is satisfactorily completed:

- ECE 11, "Door latches and hinges," complete
- ECE 12, "Steering mechanism," complete
- ECE 14, "Safety belt anchorages" for front seats
- ECE 17, "Seats and headrests" for front seats and head-on collisions
- ECE 21, "Interior fittings" for front seats and vehicle interior
- ECE 33, "Head-on collisions," complete
- ECE 34, "Fire risks" during head-on collisions

The fulfillment of these regulations is somewhat controversial. Comments on this subject have been forwarded from Great Britain and West Germany(10,11).

In tests with subcompact cars, no problems were encountered regarding the strength of the safety belts and the belt anchorage points. All the seatbelts could be opened without the use of tools, and the dummies could be removed undamaged.

During the crash tests, the doors of all the test vehicles remained closed. After the crash, at least one door, normally the passenger door, could be opened. One exception to this was the Toyota Starlet on which the locking mechanism locked the passenger door during the crash. The driver's door was also so severely damaged that it could not be opened without the use of tools.

With the exception of one vehicle, the Citroen 2 CV, the fuel tank and fuel pipes remained undamaged during and after the crash. A quasi-static rollover test on the vehicle after the crash could not be performed. On the vehicle mentioned above, a fuel pipe was damaged during the crash. The leak rate was greater than 30g/min.

In tests carried out on subcompact cars, the seat mountings frequently left something to be desired. We chose a criterion of a permanent seat forward displacement of 1cm. In 5 of the 10 vehicles tested, this forward displacement of the driver's seat was exceeded, in some cases by up to 11cm. The same applies to the passenger seat. In one case (Peugeot 104), both dummy and seat were held by the safety belt. If the seat is torn out of its mountings, the seatbelt geometry (lapbelt angle) is altered and the tendency to submarining increased. Submarining for this reason occurred in the Renault R5 test.

In standardized tests with subcompact cars, the survival area in accordance with ECE Regulation 33 was determined for the driver's side, i.e., the more severely deformed side. Since the required minimum distances were always measured relative to a fixed seat plane in the vehicle (R-point plane) and the distances quoted are really minimum distances, the permitted deformation of the foot well was exceeded on only one vehicle, a Peugeot 104. The majority of vehicles, however, exhibited severe deformations of the foot well bulkhead and instrument panel (up to 20cm). Due to the displacement of the seat caused by the collision (which was not, however, taken into consideration in the required method of measurement), the space for the vehicle occupants was in some cases considerably restricted. If, however, one considers the distances—contrary to ECE Regulation 33, but in the sense of survival area—not relative to the vehicle-related R-point plane but relative to the seat-related H-point plane, the vehicles Renault R5, Toyota Starlet, and Peugeot 104 would not have satisfied the requirements.

In the crash tests against the 30° barrier—the vehicles were fitted with dummies—the intrusion of the steering wheel into the passenger compartment could not be measured. Either the dummy collided with the steering wheel, thus preventing further intrusion of the steering

column, or, as was normally the case, the head of the dummy struck the rim of the steering wheel to the left of the steering column, thus obstructing the view to the center of the steering wheel. In some cases, however, it was nevertheless possible to deduce considerable intrusions from the film recordings. On several vehicles, the steering column was forced up sharply (e.g., on the Citroen 2 CV by 7° to the vertical). This produced a greater hazard to the occupants by the then horizontal rim of the steering wheel.

Conclusion and Discussion of the Results

The content, limitation, and application of the ECE draft regulation for the 30° head-on collision were investigated in a range of studies. The tested subcompact cars from model years 1982/83 satisfied, with few exceptions, the requirements of the proposed ECE global test for head-on collisions. It is therefore not possible to differentiate between safe and less safe vehicles using this test configuration alone. Proof of satisfaction of the requirements of the proposed global test would not automatically increase the safety of the tested vehicles. Furthermore, it is difficult to assess the safety of a vehicle with a single test.

Compared with the 0° collision, the average vehicle deceleration is less in the 30° collision(9); on the other hand, the 30° collision makes greater demands on the vehicle as far as survival area and steering column intrusion are concerned. Due to the angled collision, the dummy moves forward at an angle corresponding to the position of the barrier. As a result, no central collision with the steering wheel occurs. The dummy normally only glances the rim of the steering wheel, and the measured values for the head remain low. The more demanding test condition is presented in the 0° collision in which the possibility of a central collision with the steering wheel and steering column and correspondingly higher head and chest accelerations of the dummy exists.

In the 0° collision specified in ECE Regulations 12 and 33, no dummy is used, although the loads for the occupants will be higher than in the 30° test. In the proposed 30° collision, on the other hand, neither the intrusion of the steering wheel nor the survival area are taken into consideration, although it is to be expected that these would be higher than in the 0° test.

The following conclusions can therefore be drawn on the practical application of the draft regulation:

- The accurate determination of the start of head contact is of great importance. This is possible with a sufficient degree of accuracy. The HPC determination of the duration of head contact produces, in some cases, considera
- The accurate determination of the start of head contact is of great importance. This is possible with a sufficient degree of accuracy. The HPC determination of the duration of head contact produces, in some cases, considerably lower values than the HIC determination of the complete head acceleration pattern. The spread of the HPC values is known and has been incorporated into the draft regulation (tolerance +250).
- The measurement of chest loads and femur loads creates no problems.
- The occurrence of submarining can be detected using several methods. The two methods most frequently used to date are suitable only in combination with the interpretation of belt and, in some cases, femur forces.

The inclusion of certain other existing ECE regulations or parts thereof in the global test must be considered very carefully. Although it is correct to say that the interrelationships of the safety systems in the vehicle should be tested in full-scale tests, it should nevertheless not be forgotten that in real collisions, a wide range of collision situations occur that can and should be tested more simply and at lesser expense in component tests. The inclusion of existing regulations in the proposed global test must not cause the safety of the vehicles to deteriorate.

The requirements made on the survival area, which must be regarded as not very high in ECE Regulation 33, can be satisfied even if the seat is torn out of its mountings. The seat attachment, anchorages of the seatbelts, the strength of the safety belts and door locks, and the energy-absorption capability of the instrument panel and the steering wheel should continue to be tested in component tests, independently of the measured dummy values.

The inclusion of minimum requirements for the door-opening behaviour and leak resistance of the fuel tank in the draft regulation is planned and considered to be correct.

Abstract

From a file of real-world accidents analyzed by the Peugeot SA/Renault accident investigation team, 572 frontal impacts with a ΔV of more than 35km/h were extracted. These were described and classified on the basis of a large number of criteria that make it possible to compare the degree of representativeness of an oblique test and of a perpendicular test.

This exhaustive descriptive method makes it possible to provide an objective basis for discussions concerned with the procedures of a homologation test.

The Characteristics of Frontal Impacts in Real-World Accidents

In the field of secondary safety, car manufacturers and governments aim at a common objective—that of achieving a set of solutions from among the various technical options and rulemaking procedures that can be envisaged, which will make it possible to guarantee car passengers a level of protection that covers the largest possible range of accident impact types.

Such solutions are, in principle, extremely numerous. But the energy-reducing constraints that weigh down on car manufacture have become so stringent that great attention must be given to the ultimate cost-benefit balance that can be predicted for each of the possible options.

As a means of evaluating the safety of a vehicle, the frontal impact global test is the only one that enables manufacturers to combine intelligently the whole range of factors that govern occupant protection: structure, linking features, restraint systems, seats, etc. In this respect, the global test procedure militates in favor of an optimum use of the materials consumed in the process of vehicle manufacture. With this objective in view, two types of problem remain to be solved, the biomechanical and the accidentological—

- Biomechanical Problems—That of replicating, by using a dummy on board, the kinematics of a

living occupant, and that of the interpretation of the measurements taken from this dummy, which must provide a reliable prognosis of the injury consequences the same impact would have produced upon a real accident victim.

- Accidentological Problems—That of the representativeness of the test procedure. To what type of frontal impact should the vehicle be subjected, bearing in mind that the solutions adopted by the manufacturer to guarantee protection in the test configuration used must also be effective in the maximum of other frontal configurations to which car passengers are exposed when out on the road?

Dummies are improved constantly, and the injury predictions, based on parameters that can be measured in tests, are increasingly reliable. Biomechanical problems today constitute, therefore, themes for research to comprehend more deeply, and no longer are they obstacles to the integrated test option. This is due to the fact that biomechanics is making advances through a rigorous methodology; this is an essential factor that enables exchanges between laboratories and data collected to be accumulated. The same cannot be said of accidentological work. But the representativeness of a test procedure cannot, by definition, be judged other than by reference to real-world accident data.

It is necessary that the knowledge gathered on the subject of accidents be expressed in a language common to all teams gathering and analyzing accidentological data, and that no important parameter be neglected among those that differentiate between various types of impact and that are correlated with injury severity.

In the absence of a strict standardization of the method descriptive of real impacts, accident data collected in various countries that are intensely motorized will always show up divergent patterns, which will make it easy to reach a wide range of interpretations so far as the practical meaning of a particular test procedure is concerned.

These divergent patterns appear not only because of the specificity of the methods of classification used but to a considerable extent because of the different sampling criteria of the cases studied to the peculiarities of the vehicle mix, the road network, and its environment.

The international VDI (Vehicle Deformation Index) code is a useful methodological tool for standardizing descriptions, but it is far from satisfactory for differentiating impacts in all the ways that must be considered when what is involved is the problem of matching them to a particular test mode. The accidentological justification for the latter must be based on a description of the maximum number of parameters that determine exactly the kinematics of occupants and the seriousness of their injuries. It is important to attribute to the impact categories distinguished with the help of these criteria a certain number of indications that make it possible to compare aspects of the sample described and of struck, accident location, collision type, etc.

The accidentological justifications of such a test are rooted in a detailed description such as that proposed below and cannot be based on the usual short-cut, which consists of describing accident data by indicating solely how real-world impacts are broken down into some categories of equivalent test procedures. This direct relating of one thing to another is likely to be strongly influenced by preferences for a particular procedure due to criteria that are not linked to real occupant safety considerations. It has thus been recently suggested(1) that a perpendicular test was preferable to an oblique impact as a type of test procedure since the latter represents an obstacle to the production of airbags. This kind of argument is of the same nature as those that would have us forget that a global test should be preferred to another not because it shows up better a particular means of occupant protection but because it reveals more clearly the level of safety that the model being tested will make available to those traveling in it in the real world of accidents.

Description of Frontal Impacts in the Survey Organized by Peugeot SA/Renault

Selection Criteria

Starting in 1970, 3,580 frontal impacts have been analyzed by the Peugeot SA/Renault accident investigation team. The following description concerns a subsample of cases selected on the basis of these criteria:

1. Cars equipped with 3-point seatbelts
2. Vertical location of damage of types E in the VDI (see above) system; that is, the whole of the lower part of the belt line
3. Direction of the principal force: 11, 12, 01
4. Impact violence estimated by the parameters $\frac{\Delta V}{I}$ and
5. ΔV equal to or lower than 35km/h

Criterion 2, eliminates all cases of running-under into heavy trucks—an impact type that results in most instances in deformations based upon which any estimate of the violence involved is very imprecise. It is considered that the protection of car passengers in collisions with heavy trucks raises the issue of modifications to the heavy trucks and not to the cars themselves.

Criterion 5, ΔV equal to or greater than 35km/h, enables us to use a sample of accidents in which the probability of injury is not inconsiderable. In this way,

one avoids the skew that the presence of impacts without risk for occupants can introduce into the description of impacts, which the test procedure must represent as well as possible. Such impacts without risk are the harmless ones that can, indeed, skew the description in cases where they show peculiarities of impact angle, of the degree of overlap, etc. We show in Table 1 the breakdown of cases of impact in which ΔV was equal to or lower than 35km/h, shown by direction of impact and the horizontal extent of deformation.

Category B2 includes overlap of between one-third and one-half with oblique deformation. The side member on the side opposite the impact is not solicited. This is a frequent configuration in frontal-frontal collisions. The average decelerations for values of ΔV between 45 and 55km/h are of the order of 10g.

Category C includes deformation of the entire width of the front face—an asymmetrical characteristic of head-on collisions with little degree of offset between the two vehicles. The two side members are solicited.

Table 1. Direction of principal force and horizontal location of damage for frontal impacts with $\Delta V < 35$km/h.

The classification in this table concerns 1,057 cases.

Definition of the Five Categories of Frontal Impact

The directions of impact, the geometry of deformations, and the kinematics of the vehicle and of occupants between the beginning and the end of the period of contact between the vehicle and the struck obstacle are of such wide variety in frontal impacts that any attempt at categorizing them necessarily involves an element of the arbitrary. What is important is to reduce this as much as possible by the use of technical criteria.

The five categories proposed here take account of the front-end configurations of European cars. The differences essentially have to do with the way in which the side members and the engine transmission units are solicited—a solicitation that depends on the degree of overlap at the interface with the front end of the other vehicle and on the impact violence.

Category A (Figure 1) includes impacts with overlap of between one-quarter and one-third of the front end. A single side member is solicited in one-third overlaps. This type of rectangular deformation is characteristic of collisions that are offset against another vehicle or against a fixed obstacle. The car body side is often solicited to a considerable extent.

Category B1 includes rectangular deformation that can be reproduced by impact against a barrier at 0° with overlap of between one-third and one-half. The relative rarity of this type of deformation justifies its allocation to category B2 now described.

Category D includes deformation observed in less than 20 percent of frontal impacts. Deformations of the passenger compartment are rare for ΔV values of less than 60km/h. Impacts of this category are fairly well reproduced by using the barrier at 0°.

The graphical representation of illustrating these categories is a less than ideal manner of doing so. Other variants exist for each category. In particular, the depth of penetration is arbitrarily shown since it can be less than appears or, on the contrary, greater. But constants remain and they are very precise:

1. The general appearance of deformation, which is rather rectangular or rather triangular (B2, etc.)
2. Overlap of one-quarter to one-third of the front end, overlap of one-half to two-thirds of the front end, or overlap that is total, the above applying whatever is the depth of crush
3. Angle of deformation less than 15° in categories B1 and D; between 15° and 45° in categories B2 and C

Principal Characteristics of the Categories of Frontal Impacts

Impacts by Type of Collision

Deformations that are evenly spread across the front end (category D) are relatively rare in head-on collisions (Figure 2). In 85 percent of cases, deformations are

only a fraction (about 75 percent) of all the impacts with overlap of between one-quarter and one-third of front ends. Bearing in mind that this distribution of impacts by type of collision is observed, one cannot say that the perpendicular test is representative of head-on collisions.

The high level of representation of impacts of the 0° type in collisions against the side of another vehicle (front-to-side) should also be noted. Such collisions, however, are rarely severe for the occupants of the asymmetrical; even this proportion is under estimated. In point of fact, our analysis has concerned only those cases in the sample where it has been possible to calculate the value of ΔV. In a large proportion of the collisions that resulted in category A deformation, with much offset contact, impact was followed by immediate separation of the two vehicles. In such cases, it is impossible to calculate ΔV, or it is at least rash to do so. In all of the 164 cases, the value of ΔV is known. These cases represent striking vehicle; the average level of deceleration is relatively low due to the considerable penetration into the side of the struck car.

The Average Value of Deceleration

This value increases logically with the horizontal extent of deformations. It reaches 14g between 46 and 55km/h for impacts akin to those against the barrier at 0° (Figure 3). The overestimation of average levels of deceleration by perpendicular impact has been pointed out in earlier publications(2,3,4), which have brought out the fact that the oblique impact produces decelerations of the same order of magnitude as in the majority of frontal impacts occurring in real-world accidents. But this difference in severity is not a relevant justification of the oblique impact. It could even, on the contrary, justify the choice of a 0° test for the very reason that this gives higher values to the parameters used as head and thorax injury criteria. This is, by the way, the reason given by a certain number of manufacturers for abandoning their oblique impact test.

The defect in this manner of reasoning is that of neglecting the fact that the major cause of serious injuries for restrained occupants is intrusion and that the structure's resistance to intrusion cannot be verified by means of a perpendicular impact—unless, that is, the operation is undertaken at very high speed—and obliges manufacturers to adopt solutions of which the cost-benefit analysis would be catastrophic. As witness, the first ESV models.

The intrusion measured at the level of the A-pillar exceeds 150mm in 71 percent of cases of the very offset impacts (category A, Figure 4) in which ΔV lies between 45 and 55km/h. On the other hand, in this same spread of speeds, intrusion is only observed in 4 percent of impacts with deformations spread across the whole of the front end (category D). The consequences of intrusion for restrained occupants are extremely serious (Table 2).

Intrusion provides the main explanation of the distribution of drivers who are killed or seriously injured in the various categories of frontal impact. These are as numerous in the impact categories with very little overlap (category A) as in those related to the 0° test (Figure 5)—the impacts related to the impact test contributing 55 percent of the total of the serious or fatal cases (restrained drivers).

Table 2. Severe injury and fatality rate for restrained drivers

Intrusion	ΔV (km/h)		
	46 - 55	56 - 65	66 - 75
< 150mm	.13	.31	.50
≥ 150mm	.37	.83	.94

The Breakdown of Serious Injury by Body Segment

This breakdown, being the subject of measures in tests, shows the importance of injuries of the bony pelvis, fractures of the acetabulum in general, and of the lower limbs (Figure 7).

If one takes the figure of 100 to represent the serious injuries recorded in impacts that relate to the oblique test (categories B1, B2, etc.) and if one proceeds in the same manner for the serious category D injuries (impacts related to the 0° test), one observes that an oblique test replicates more faithfully the exposure to risk of the various body segments considered (including the abdomen) than would a perpendicular test (Table 3).

The same calculation made with respect to drivers that were not restrained gives a different breakdown (Figure 8 and Table 4).

Because the seatbelt limits occupant displacement, the head/steering wheel contact is by far the most frequent among restrained drivers (Figure 9).

The above data seen as a whole do justify one of the criticisms leveled at the oblique test: this does not verify the effectiveness of head protection in an entirely satisfactory fashion.

It would only be necessary to improve it in an appropriate way for this test to become undeniably useful as a procedure.

Table 3. Breakdown of serious injuries by body segment in impacts related to the oblique test, to the 0° test, and in all impacts. Drivers restrained (retractor belts)

Impact	Body Segment				
	Head	Thorax	Abdomen	Pelvis & Lower Limbs	Total
Impacts related:

- to 0° test	25.0	12.5	25.0	37.5	100.0
All impacts	25.9	7.4	14.8	51.9	100.0

Table 4. Breakdown of serious injuries by body segment. Drivers unrestrained.

Impact	Body Segment				
	Head	Thorax	Abdomen	Pelvis & Lower Limbs	Total
Impacts related:					
- to 30° test	14.5	20.4	14.7	50.7	100.0
- to 0° test	21.0	21.0	18.4	39.5	100.0
All impacts	16.9	19.6	15.3	48.1	100.0

Conclusion

The integrated test is the optimum procedure for verifying the level of safety of a vehicle to the extent that this procedure brings in the greatest number of potential risk factors for the occupant.

For a given procedure, the fact that it produces high values for the parameters used as injury criteria is not an adequate proof of relevance. The procedure must also oblige vehicle manufacturers to adopt effective counter-measures in the greatest number of real-world accident configurations: this is the function of a "representative" test.

A description of 572 frontal impacts with a ΔV greater than 35km/h shows that the oblique test is the most representative of the sample.

It is highly desirable that accident data available to a large number of accident analysis teams should be described in the same way with a view to providing an objective basis for the decisions that must be taken by the appropriate governmental and intergovernmental bodies concerning homologation procedures.

Testhouse Experiences With the Draft ECE Regulation for Head-On Collisions

C.G. Huijskens,
J. Maltha, and
A. Dyche
Research Institute for Road Vehicles, TNO, Delft, The Netherlands

Abstract

TNO performed a series of well-controlled full-scale 30° angled barrier tests with Volvo 343 vehicles. In addition, a series of simplified sled tests with a Volvo 343 body mounted at angles of 15° and 19° (i.e., the angle between the longitudinal axes of the car body and sled) were conducted. The sled tests were carried out with a ΔV-time history obtained from the full-scale barrier tests. Test conditions and evaluation of the dummy results for driver and passenger were based on the new draft ECE regulation for head-on collisions and on the proposed ISO DIS 7862E for the simplified sled simulations of barrier crashes.

It was found that the ECE sled test procedure in itself is well defined and feasible with minor modifications. It should be noted that all the dummy results were low in comparison with the performance criteria in the regulation, and so, considering the dummy as a measuring instrument, the results are at the lower end of its operating range. For vehicles with different ΔV-time histories for the left and right sides during the full-scale test, it is not possible to reproduce dummy kinematics and at the same time all major injury parameters with a single mounting angle of the body on the sled and one ΔV-time history. The paper presents more details about the mounting angle and ΔV-time history problems.

Introduction

The new draft ECE regulation for occupant protection in head-on collisions specifies a 50km/h full-scale crash test against a 30° angled flat rigid barrier(1). If a vehicle type meets the requirements of this new draft regulation, it will be considered to satisfy ECE Regulations 11, 12, 14, 17, 21, 33, and 34. In case of modifications of a standard vehicle type with respect to interior fittings, a simplified equivalent impact test with a car body on a sled can be carried out (see Figure 1).

The regulation refers for the simplified sled test to an annex "test procedure with trolley," which is based on the ISO Draft International Standard 7862E(2). This standard is currently under modification by the experts of Working Group 1 of ISO/TC22/SC12 and now specifies a standard angle of 15° for mounting the vehicle body on the sled as the best representation of the 30° angled barrier test. However, this group recognizes that this standard 15° angle is not sufficiently representative for all types of vehicles and hopes to define in the future a method of calculating an equivalent angle of body mounting based on results of the 30° barrier test and more specific for the type of vehicle.

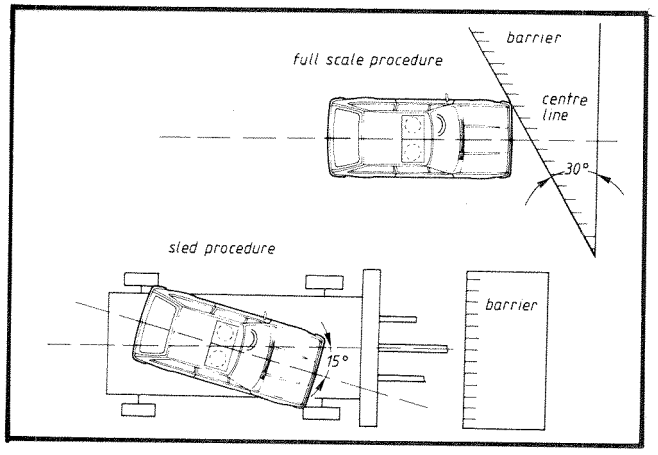

Figure 1. Test procedures of draft ECE regulation on head-on collisions

At the TNO crash facility, two full-scale 30° barrier tests, two 15° simplified sled tests, and two 19° simplified sled tests were conducted.

The vehicles and bodies in the tests were all Volvo 343, which is considered to be a good representative of a standard mid-sized European car. All tests were carried out with two Part 572 dummies and standard 3-point retractor restraint systems. The impact velocity of the full-scale tests was 50km/h, and for the sled tests the impact velocity was calculated to be 45km/h to obtain the same final ΔV-time history as measured in the full-scale tests.

The objectives of the test program were—

- To investigate the practicalities of the full-scale and sled test procedures
- To find out how closely the full-scale tests could be reproduced by the simplified sled tests at the standard angle of 15°
- To find a calculation technique for a car-specific angle in the sled test and check if this resulted in a better representation of the full-scale test
- To investigate the repeatability of the test results

Test Procedures

Barrier Tests

The full-scale 30° angled barrier tests are the baseline tests for the simplified sled test procedure. The sled tests were to be carried out with a velocity change-time history reproducing the ΔV-time curve from the barrier tests. The ΔV-time history that was to be used for the simplified sled test was established from the integration of the longitudinal accelerations of the sills. The regulation states that the impact (driver) side integrated acceleration should be reproduced within ±0.5m/s, but, due to a large difference between the left and right side ΔV-time histories (e.g., 2.2m/s at 140ms) in these full-scale tests, an average ΔV-time history of both sides was used for the velocity-time history of the sled test (see Figure 2). The accelerations were filtered at CFC 180 before integration.

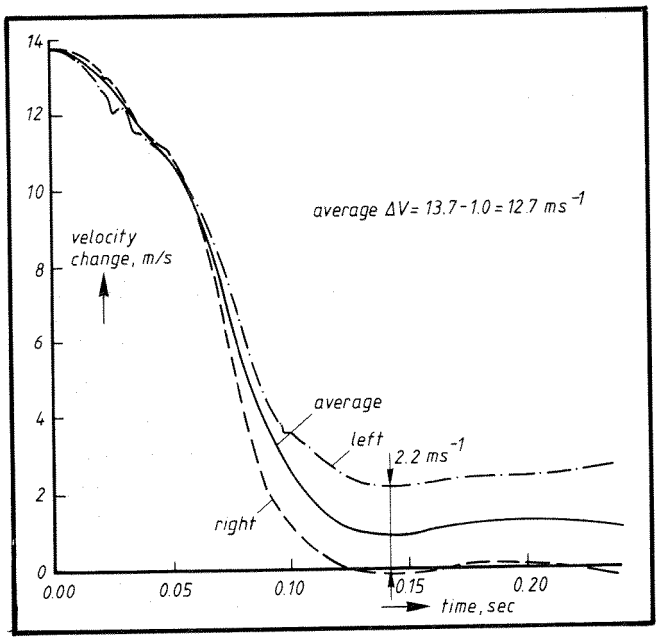

Figure 2. V-time curves of the full-scale 30°angled barrier test

Calculation of Equivalent Angle of Mounting for the Simplified Sled Test

It is recognized that the standardized 15° angle of the vehicle body mounting for the simplified sled test might not give the best possible reproduction of the full-scale barrier tests for all types of vehicles. Current discussion in the ISO Working Group led to a resolution that asked for calculation methods of a so-called Equivalent Angle, which is specific for a certain type of vehicle.

The translation angle resulting from a combined forward and sideward translation of the vehicle is defined here as a fixed angle that is the result of the ratio of the average (left and right sides) longitudinal and lateral ΔV-time histories. However, the ratio between ΔV longitudinal and ΔV lateral is a function of time. The method used to obtain the Equivalent Angle was to define the times of the most important dummy-related criteria and calculate the instantaneous translation angle at these times and then simply average it (see Table 1).

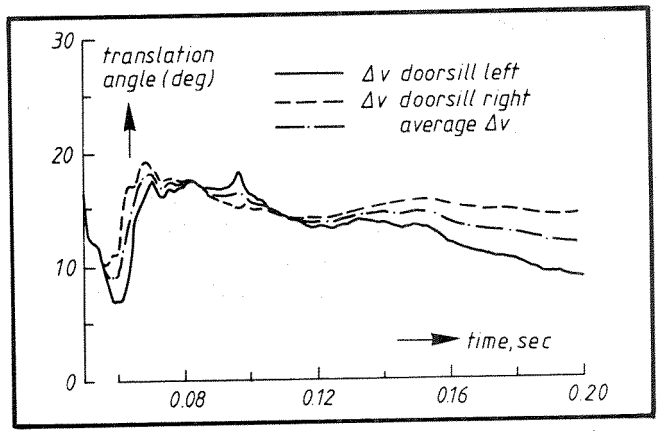

Figure 3. Calculated translation angle as function of time

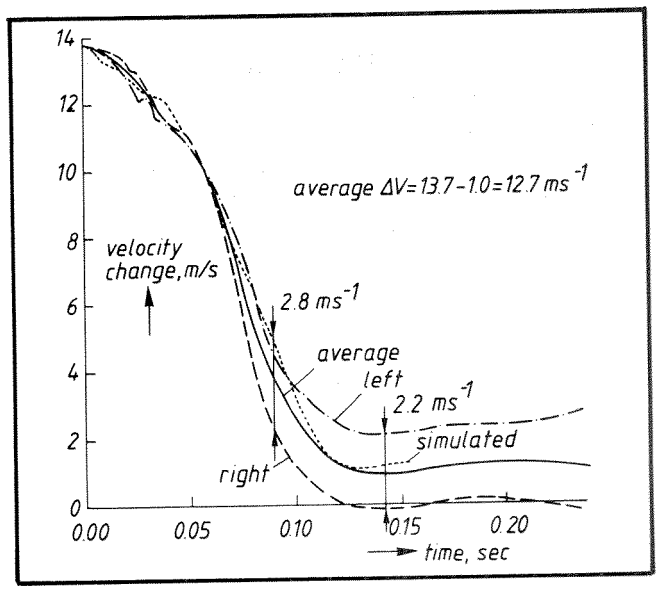

Figure 4. Simulated and full-scale V-time histories

Table 1. Optimal car body to sled mounting angles for the different criteria

Criteria	Time (ms)	Translation Angle (degrees)
max. belt loads	97	16.3
max. res. chest accn.	105	14.9
max. res. pelvis accn.	107	14.6
max. res. head accn.	135	14.3
max. head excursion	140	14.5
Average		14.9

For the Volvo 343 vehicle, this resulted in an Equivalent Angle of 14.9°.

The criteria chosen were based on the final objective of the test procedure, which is to obtain identical injury-related measurements as in the barrier test (a problem is that the injury-related measurements are dependent on the type of the vehicle and restraint used). The criteria selected were the time that maximum head, chest, and pelvis accelerations, the maximum belt loads, and the maximum head excursion occurred.

The translation angle is calculated from:

Translation Angle (t) = arctan (ΔV lateral (t)/ΔV longitudinal (t)) (1)

It was also observed that in the full-scale test, the vehicle rotated clockwise (viewed from above) during the selected time-interval (97 to 140ms) and this rotation was also a function of time (see Figure 5). The effect of the vehicle rotation on the kinematics of the dummy relative to the vehicle compartment combines with the lateral movement of the vehicle. This complicated kinematics can obviously not be exactly duplicated by one fixed angle, but a mean angle of 4° was selected to be added to the 15° Equivalent Angle. The total angle of 19° is similar to the angle of movement of the dummy relative to the vehicle, measured from high-speed film.

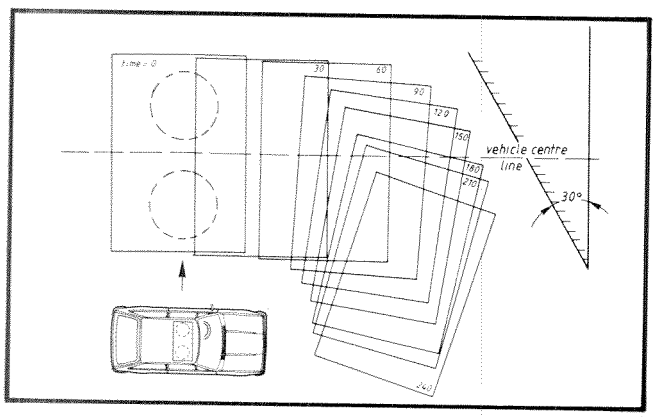

Figure 5. Top view of vehicle movement in the full-scale 30° angled barrier impact test

Simplified Sled Tests

For the simplified sled tests, a Volvo 343 body was mounted on a subframe attached to the suspension mounts and chassis. Then the body was reinforced in these critical areas by welding additional supports from these areas to the subframe. The subframe with body was bolted on the rigid sled at an angle of 15° or 19°. The center of gravity of the car body was on the longitudinal centerline of the sled. The sled was decelerated by a programmed array of steel-crumpling tubes, resulting in a ΔV-curve similar to the average ΔV-time history of the left and right sills in the full-scale tests (see Figure 4).

Results of 30° Angled Barrier Impact Test

The two tests carried out on a concrete laboratory floor covering had similar vehicle movements and dummy results. For the first part of the impact phase, the vehicle continued to move in the same direction as its initial velocity. After 60ms, the vehicle rotated clockwise (viewed from above) with a rotational velocity (yaw velocity) of 1.5rad/s at 140ms, and it also continued to move forward with a velocity of 1.0m/s at 140ms (see Figure 5).

In this 30° collision, the occupant trajectory with relation to the laboratory reference frame was in the direction of the initial movement of the car before impact for most of the time during the impact phase. The lateral displacement of the occupant relative to the vehicle was due mainly to the lateral movement of the vehicle. No contact occurred between the dummies and the vehicle, except the knees (but the femur load cells indicated no significant loads acted to the knees) and the driver's left arm.

Comparison of Sled and Full-Scale Results

General

In general, when the peak values and corresponding times of the dummy results are considered, the variation between the three different test modes (30° barrier, 15° and 19° sled tests) is within the variation between the two tests in the same test mode. This implies that both the 15° and 19° tests were reasonable representations of the 30° barrier tests as far as the overall injury parameters are concerned. It should be noted, however, that only two tests were carried out for each test mode. It should also be noted that the dummy results were low in comparison with the injury levels of the regulation, and no contact occurred between the dummies and the vehicle structure except for the knees and the driver's left arm. When the individual time histories of the dummy results and the dummy kinematics are studied in detail, differences between the test modes can be seen, which are discussed in the following sections.

Driver

The 15° sled test results were generally more like the full-scale results than the 19° sled test results. The chest acceleration and belt loads in the full-scale and 15° sled tests had slightly longer duration signals. The head accelerations in the 15° sled tests were slightly higher than in the full-scale tests, and they had more peaks and troughs in the vertical and longitudinal directions during

the arm-to-door contact period. The arm contacted the door earlier and further rearward than in the full-scale tests and 15° sled tests. Generally, the 15° sled test results, apart from the differences during the arm and knees contact times, were similar to the full-scale results except that they indicated that the sled ΔV was slightly higher by having longer signals.

Passenger

The lateral movement of the dummy during the full-scale tests and the sled tests appeared to be critical as to the way the dummy rotated out of the shoulder seatbelt. It could be analyzed from the high-speed film of the 15° sled tests that the dummy did not move as far laterally as in the full-scale tests and the rotation of the shoulders was different. The dummy tended to move in the direction of its initial velocity.

The 19° sled tests, although closer to the full-scale than the 15° tests, still did not duplicate the full-scale results exactly. The dummy accelerations and the shoulder belt loads were both lower and longer in duration in the 19° tests compared with the full-scale results. These results suggest that the overall sled velocity change was too low and also rotation of the vehicle compartment in the full-scale tests may have caused the dummy to rotate differently out of the shoulder belt.

Discussion of the Results

It can be seen from previous sections that due to the different ΔV-time histories for both vehicle sides, one ΔV reference curve (obtained by integration of the longitudinal acceleration of the vehicle) cannot be used to exactly duplicate both the driver and passenger side dummy results in the simplified sled test.

The vehicle rotation may also affect the position of the dummy relative to the seatbelt anchorages and hence the reaction of the restraint system on the dummy. The increased angle of 19° did not appear to improve the results or the seatbelt performance dummy passenger. The 19° mounting angle also produced different contact areas between the driver dummy and the vehicle, which were better at 15°. A better solution would be to carry out two separate tests for the driver and passenger with different ΔV-time histories and mounting angles.

In the sled tests, there was no attempt to simulate the movement of the vehicle other than laterally. It is known that for a perpendicular full-scale frontal impact, such effects as vehicle pitch and body distortions affect the dummy kinematics and produce different results when compared with a sled test with the same ΔV(3). These effects will combine with differences caused by the "inexact" simulation of the lateral vehicle movement in the sled test simulation. All of the dummy results were low compared with the injury criteria according to the regulation, and no head or chest contact occurred. When the dummy is considered as a measuring instrument, the variation between tests, as a percentage of the measuring range of the dummy, is low, so differences between tests are masked by random errors. The differences in dummy results in terms of mean accelerations were low but could be expected to be much higher if head and chest contact had occurred due to difference in contact areas and times, which could not be duplicated exactly.

Conclusion

1. The test procedures for testing to the draft ECE regulation are well defined and were feasible from the practical point of view.
2. The standard body mounting angle of 15° for the simplified sled tests gives overall peak and average dummy results similar to the 30° barrier tests. This may be specific for the test vehicle chosen.
3. A method used to calculate an Equivalent Angle for the Volvo 343 results in an angle of 14.9° for the relationship between the lateral and longitudinal ΔV.
4. It would appear that one fixed mounting angle and velocity time history cannot exactly reproduce both the passenger and driver results where a large difference in ΔV-time histories between the left and right sides occurs. A better method would be to define a velocity time history and calculate a mounting angle for each dummy position, then carry out a separate test for each dummy.

Comparison of 0° and Oblique Tests

J. Hackney
U.S. Department of Transportation, National Highway Traffic Safety Administration

The accident experience in the United States as taken from the national crash severity study indicates that more than 60 percent of AIS 3 and greater injuries occur in frontal collisions that have a principal direction of force of 12 o'clock. Almost 60 percent of all frontal crash occurrences are in this clock direction. Additionally, the NCSS data show that the most prominent frontal crash mode has distributed frontal damage—more than 30 percent of AIS 3 and greater injuries occur in this crash mode. The risks associated with these 12 o'clock DOF and distributed damage crashes are higher than any other frontal collision.

Also, a predominant amount of societal harm, AIS 2 and greater (using Dr. Malliaris' definition of harm), in frontal events has a 12 o'clock PDOF. Again, the largest single contributor to harm is the distributed damage crash mode. Offset crash modes with 12 o'clock PDOF are the next largest contributors to harm. The first oblique PDOF (11 o'clock) is ranked sixth in contributing to harm. These U.S. accident data all indicate the appropriateness and support the use of the 0° barrier test.

From controlled crash tests, we can compare the relative dummy responses of 30° and 0° barrier tests. Figure 1 shows the average response for six vehicles (12 dummies) in the two test conditions. The test speed was 35mph. These responses are in terms of percent of FMVSS 208 requirements. From these data, it is quite obvious that a 30° test is essentially no requirement. For the National Highway Traffic Safety Administration or the vehicle manufacturer to use this oblique test to evaluate safety performance of present production vehicles would represent a very significant step toward reducing safety levels that exist in today's vehicle fleet.

Applying Computer Techniques in the Design and Development of an Occupant Restraint System

N. D. Grew
Austin Rover Group Limited, BL Cars PLC, Cowley, Oxford, United Kingdom

Abstract

Computer techniques are applied in all areas of vehicle design having an influence over the speed of the design process and the efficiency and coherence of the design itself. The deployment of analytical methods removes the need for some test work and changes the role of much of the rest.

A restraint system design has implications for several vehicle areas:

- Body design
- Seat design
- Interior trim and hardware
- Steering System

and must be considered against all these as well as the structural crashworthiness of the vehicle.

At the concept stage, computer methods outline the implications of the functional specification so it can be modified if found to be unreasonable or inconsistent. As the vehicle design progresses, the requirements of the restraint system are broadly defined using programs to assess comfort and dynamic performance.

Initial sled test work is based on the realistic possibilities as determined from the dynamic simulations, and the results of these tests serve to refine the model and improve background data. These tests are deliberately

kept simple, and the computer model is used to study the effects of different impact conditions and component designs. This information is fed to design areas. This sequence of test and simulation is repeated in conjunction with prototype vehicle tests. The process means that sled tests have been effectively used and their combination with computer simulations gives a better understanding of, and confidence level in, the restraint system performance in the full vehicle test.

Introduction

The design of an occupant restraint system involves the integration of vehicle components from a variety of design areas. Each area considers the safety of the occupant as a part of its design brief, and the nature of each component affects the time required from design to tooling to manufacture.

Computer-aided design techniques can be applied in the design process, both to the specific areas of component design and to the overall restraint concept. Thus, simulation techniques can define the performance required of each component, and computer analysis can be used in the design of each component to meet the specification.

Practical testing of components and restraint system is both necessary and a legal requirement. The integration of this testing with the computer techniques is important if the strengths of the analysis methods are to be used efficiently.

The following discussion centres on the design and development of a system to protect the occupant in a frontal collision, but the principles and approach can be applied to other crash conditions.

The Concept

Once the decision has been taken to design a new model, the nature of the vehicle is defined in terms of its dimensions, levels of specification, and intended markets. The laws governing sales into those markets, competitor vehicles, and in-house policies will determine the safety performance the vehicle must meet. At this stage, therefore, it is important to insure that the nature of the vehicle concept in terms of its dimensions, etc., is compatible with the necessary safety performance and to provide some idea, to the various design areas, of the specific responsibilities that implies for them.

Once this feasibility study is completed, these responsibilities can be defined more precisely, taking into account their interaction as components of the occupant restraint system (see Figure 1).

Two types of computer simulation model will be developed: one of the structure in which the occupant is merely another constrained mass; the other of the occupant and basic interior in which the structural collapse is seen only in its effect on overall vehicle kinetics and intrusions into the passenger compartment. The first gives important data that enables the second to be

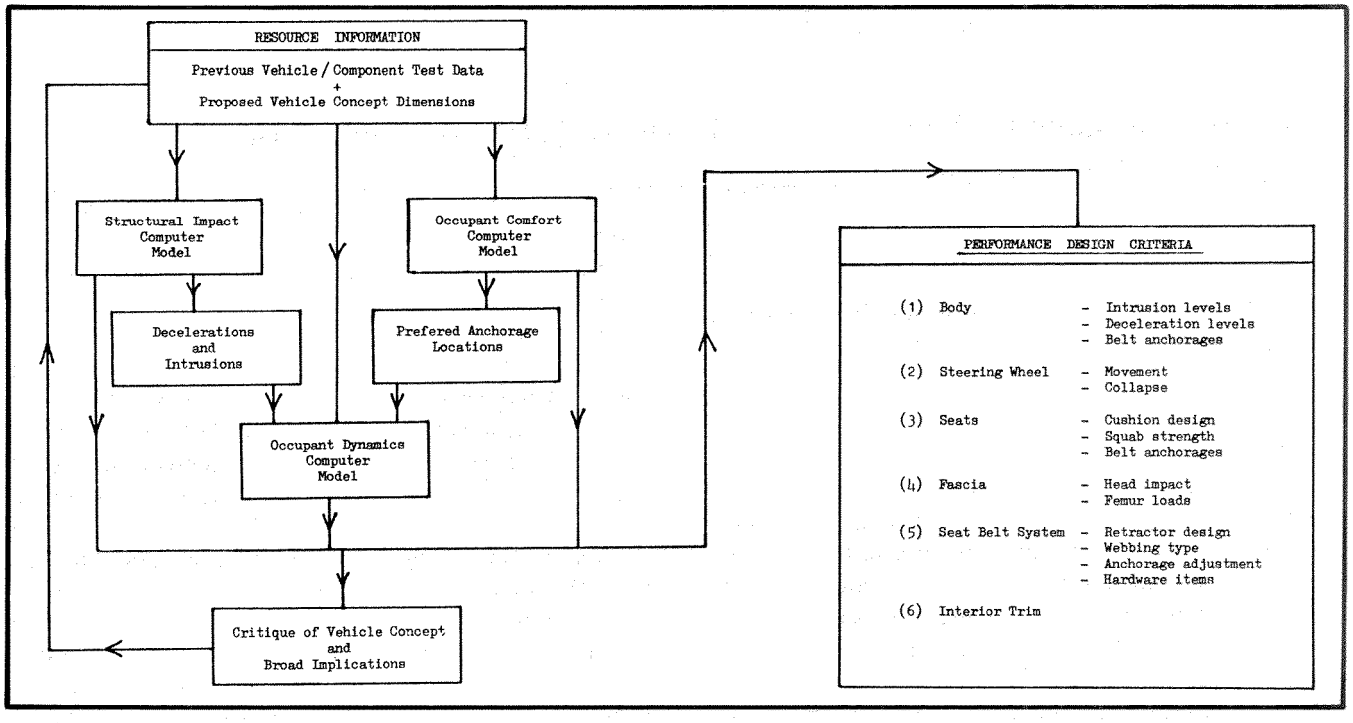

Figure 1. Application of computer simulation techniques at the vehicle concept stage

configured in a realistic manner. The results of the occupant simulations will throw light on the consequences of the structural performance and may force some changes to be made.

The structural modelling techniques involve discrete masses with appropriate constraints and stiffness elements and use CSMP (Continous System Modelling Program) and ADAMS computer programs(1).

The occupant modelling uses a version of the CALSPAN CVS program, which has been significantly modified by Austin Rover over a period of several years(2). Figure 2 shows a schematic combination of these two techniques.

Seatbelt Comfort

At this stage, the packaging hardpoints will become clear, and it is important to establish the seatbelt anchorage locations with these. For this purpose, a computer program BELTFIT is applied(3).

This program was written by MIRA (Motor Industry Research Association) to enable a user to create a seatbelt system that meets the geometric constraints of legal comfort zones and the comfort requirements of the expected range of vehicle users. The anchorages can be appraised against the selected requirements of the appropriate markets and positioned accordingly. Likewise, any necessary features such as anchorage attachment to the seat or height adjustment can be decided on by considering the variety of potential occupant sizes and postures. The program warns of certain sources of discomfort, and the pictorial representation gives the user the option to add his own experience and judgement (see Figure 3). Thus, anchorage locations, the part of the vehicle to which they are attached, and any ranges of motion can be specified and available for the design areas concerned to begin working with.

Such an anchorage arrangement gives a good basis for a seatbelt system that will perform well under accident conditions. However, other design areas need to know the parameters within which they should be operating. At the earliest stages, the simulation techniques can help to define these.

Occupant Dynamics

Figure 4 shows a simple simulation carried out at the early stages of a design concept. A restraint system from a current vehicle has been appropriately modified with a series of planes included to represent potential positions for the steering wheel during a barrier impact of the proposed vehicle. These planes are given no stiffness, but they each register the time, point, and speed of impact of the head. By carrying out a series of simulations with different webbing stiffnesses, impact trajectories are determined. These can then be used to give guidelines as to the limitations that should be set upon steering wheel movement so that the head should not strike the wheel hub.

Also, some indication of kinetic energy to be absorbed by the steering system can be gained from the impact speeds of chest and head. Typically, a trajectory using a medium webbing rate will be used as the basis of the decision so there is flexibility to alter the trajectory, if required, as the details of the restraint system become clearer and the computer model more accurate.

A similar method can be used to determine facia impact requirements for the passenger side although, generally, the headform pendulum test upon the component will be more stringent than the needs of an occupant wearing his seatbelt.

From the computer simulations carried out up to this point, the viability of the vehicle concept will have been established and critical areas identified. Some design areas will be evolving analytical component models and applying the basic guidelines from the occupant simulations in appraising their designs; for example, the facia is usually a large plastic moulding requiring a complex forming tool for which the design lead time is long. The application of finite element techniques is crucial at this stage to establish the impact, beam strength, and vibration properties (Figure 5).

From the point of view of the whole vehicle and restraint simulation models, this is the stage to carry out practical benchmark tests using modified existing components and parts that might be needed to improve the crash performance.

Sled Testing

A representation of the restraint system is set up on a sled mounted on a Hyge test rig. The deceleration pulses are taken from current structural simulation models, and appropriate controlling pin profiles are chosen or constructed to give approximations to these. In the first series of tests, the hardware will be composed of current vehicle components set in the most likely positions. This corresponds to the initial computer simulation model and will help to verify or improve it.

Using information from the computer model, some tests will differ from the standard to explore changes that the model has indicated would lead to improved performance.

The computer model can present data from areas in which it is impractical to measure, and, to help in its development, the data collected from the sled tests will be much more comprehensive than would be needed to verify standard injury criteria. Figure 6 summarises the sort of records that are made and the types of data construed from them.

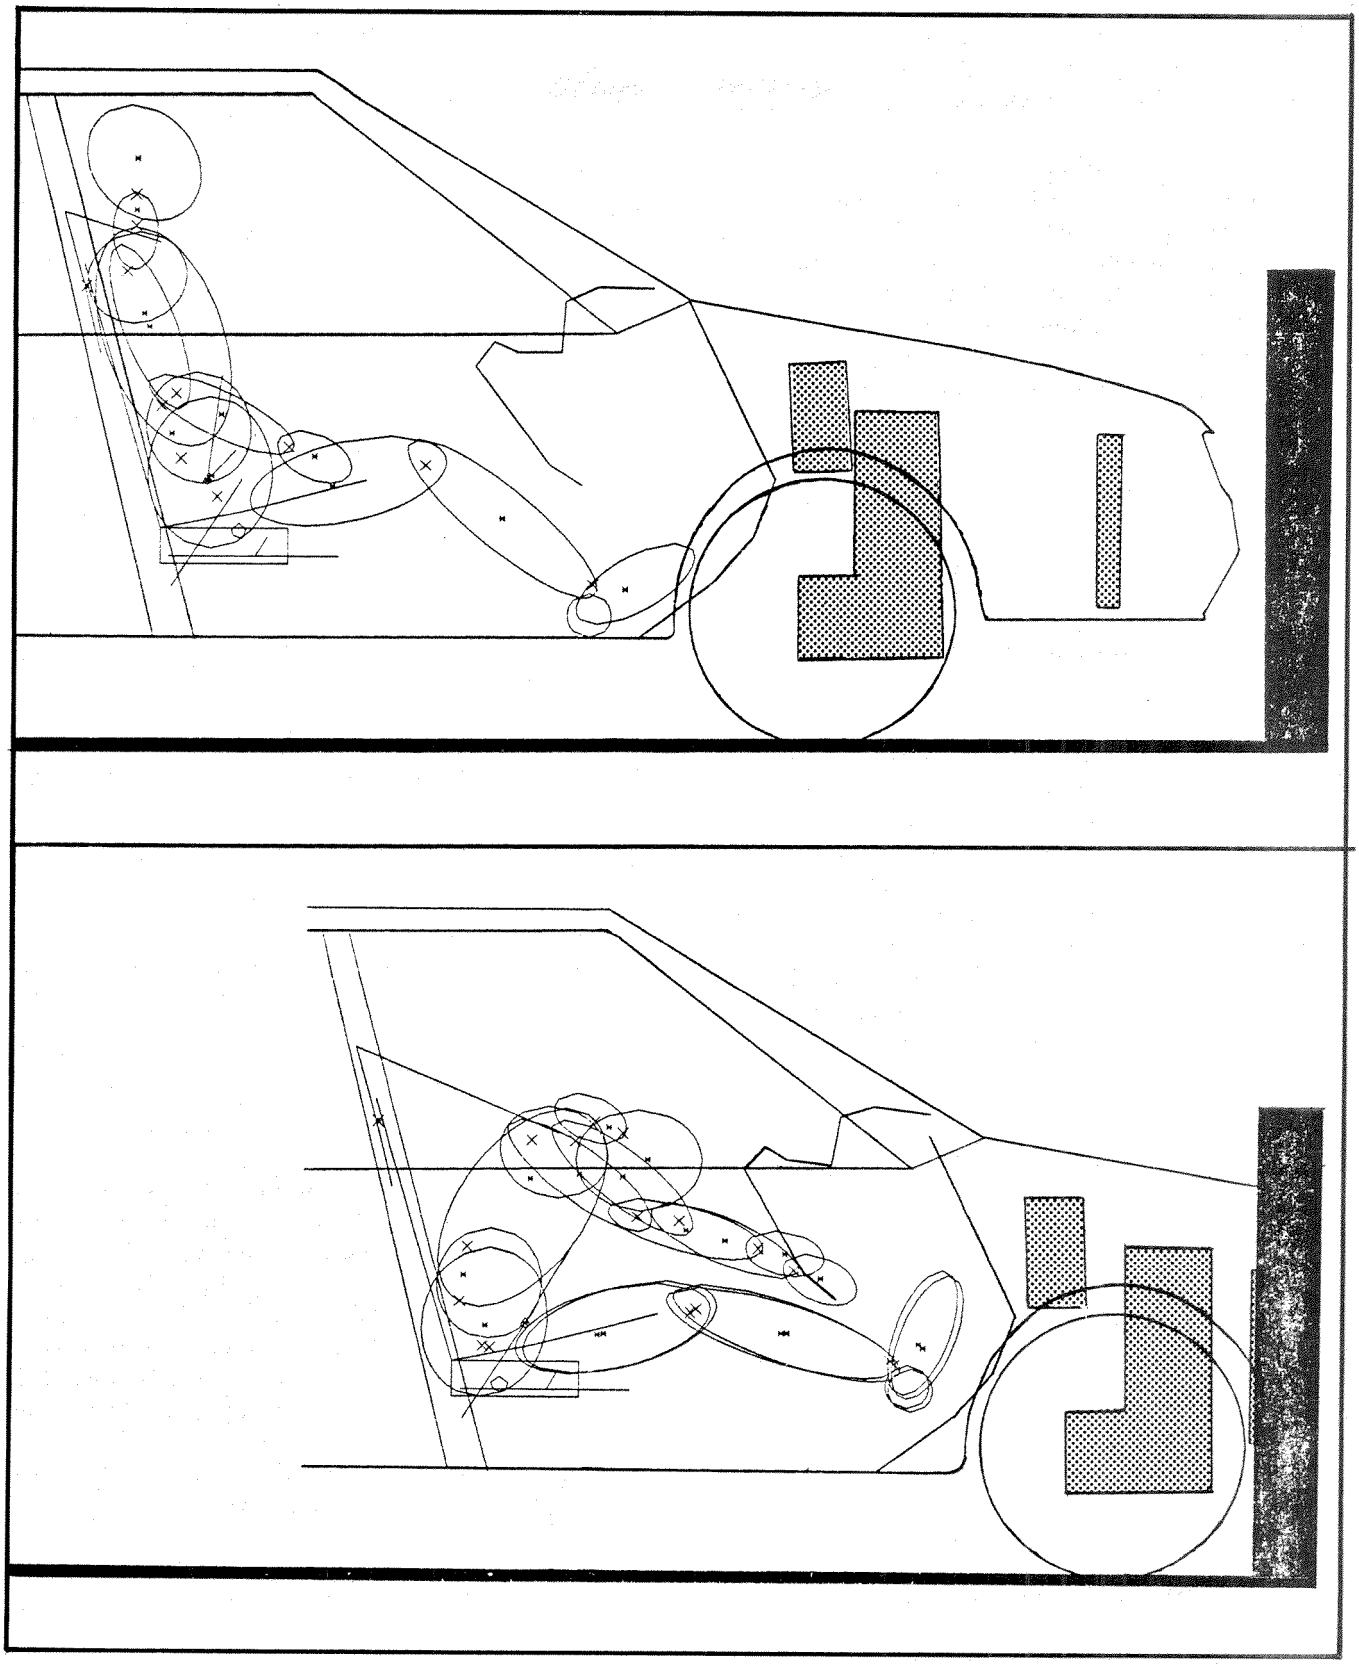

Figure 2. Schematic combination of occupant and structural simulation models

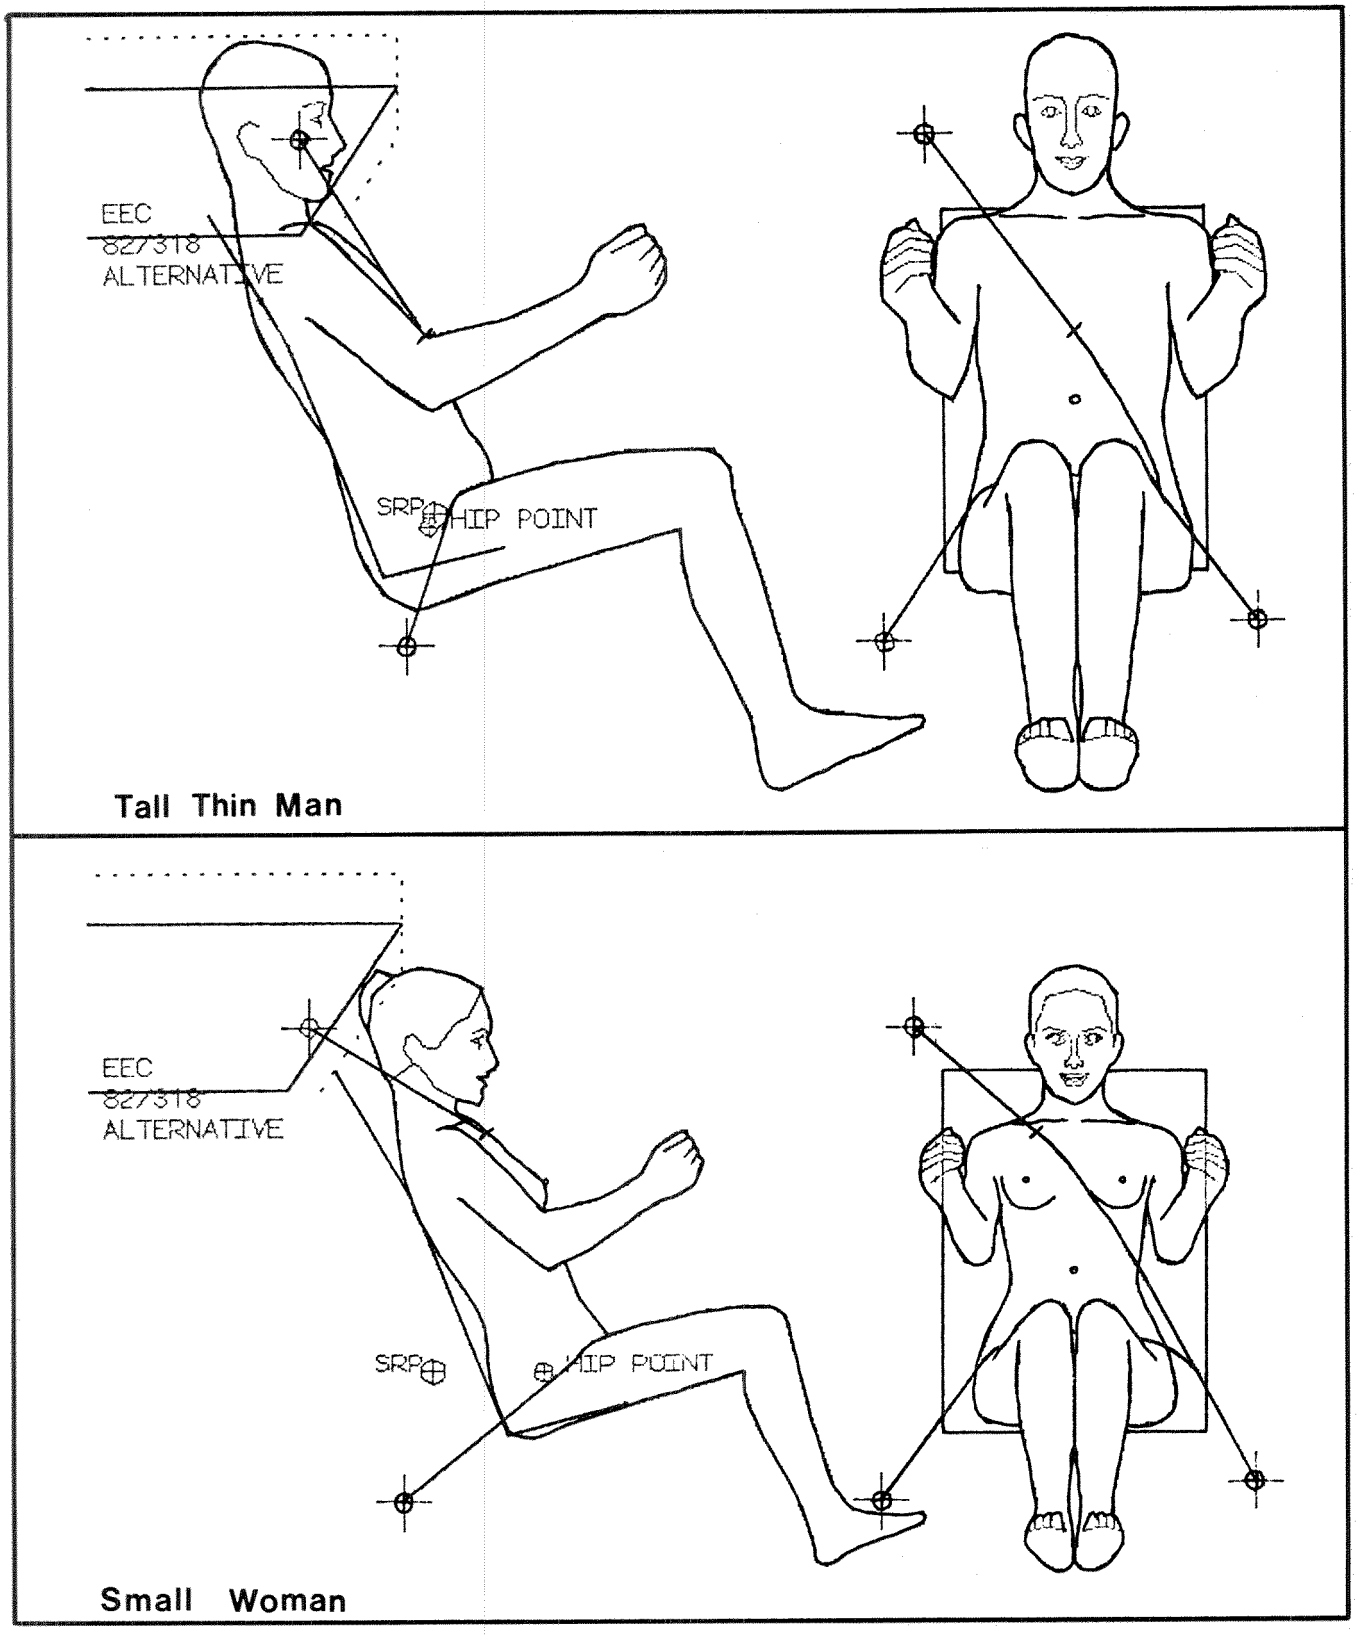

Figure 3. BELTFIT displays for assessments of seatbelt comfort

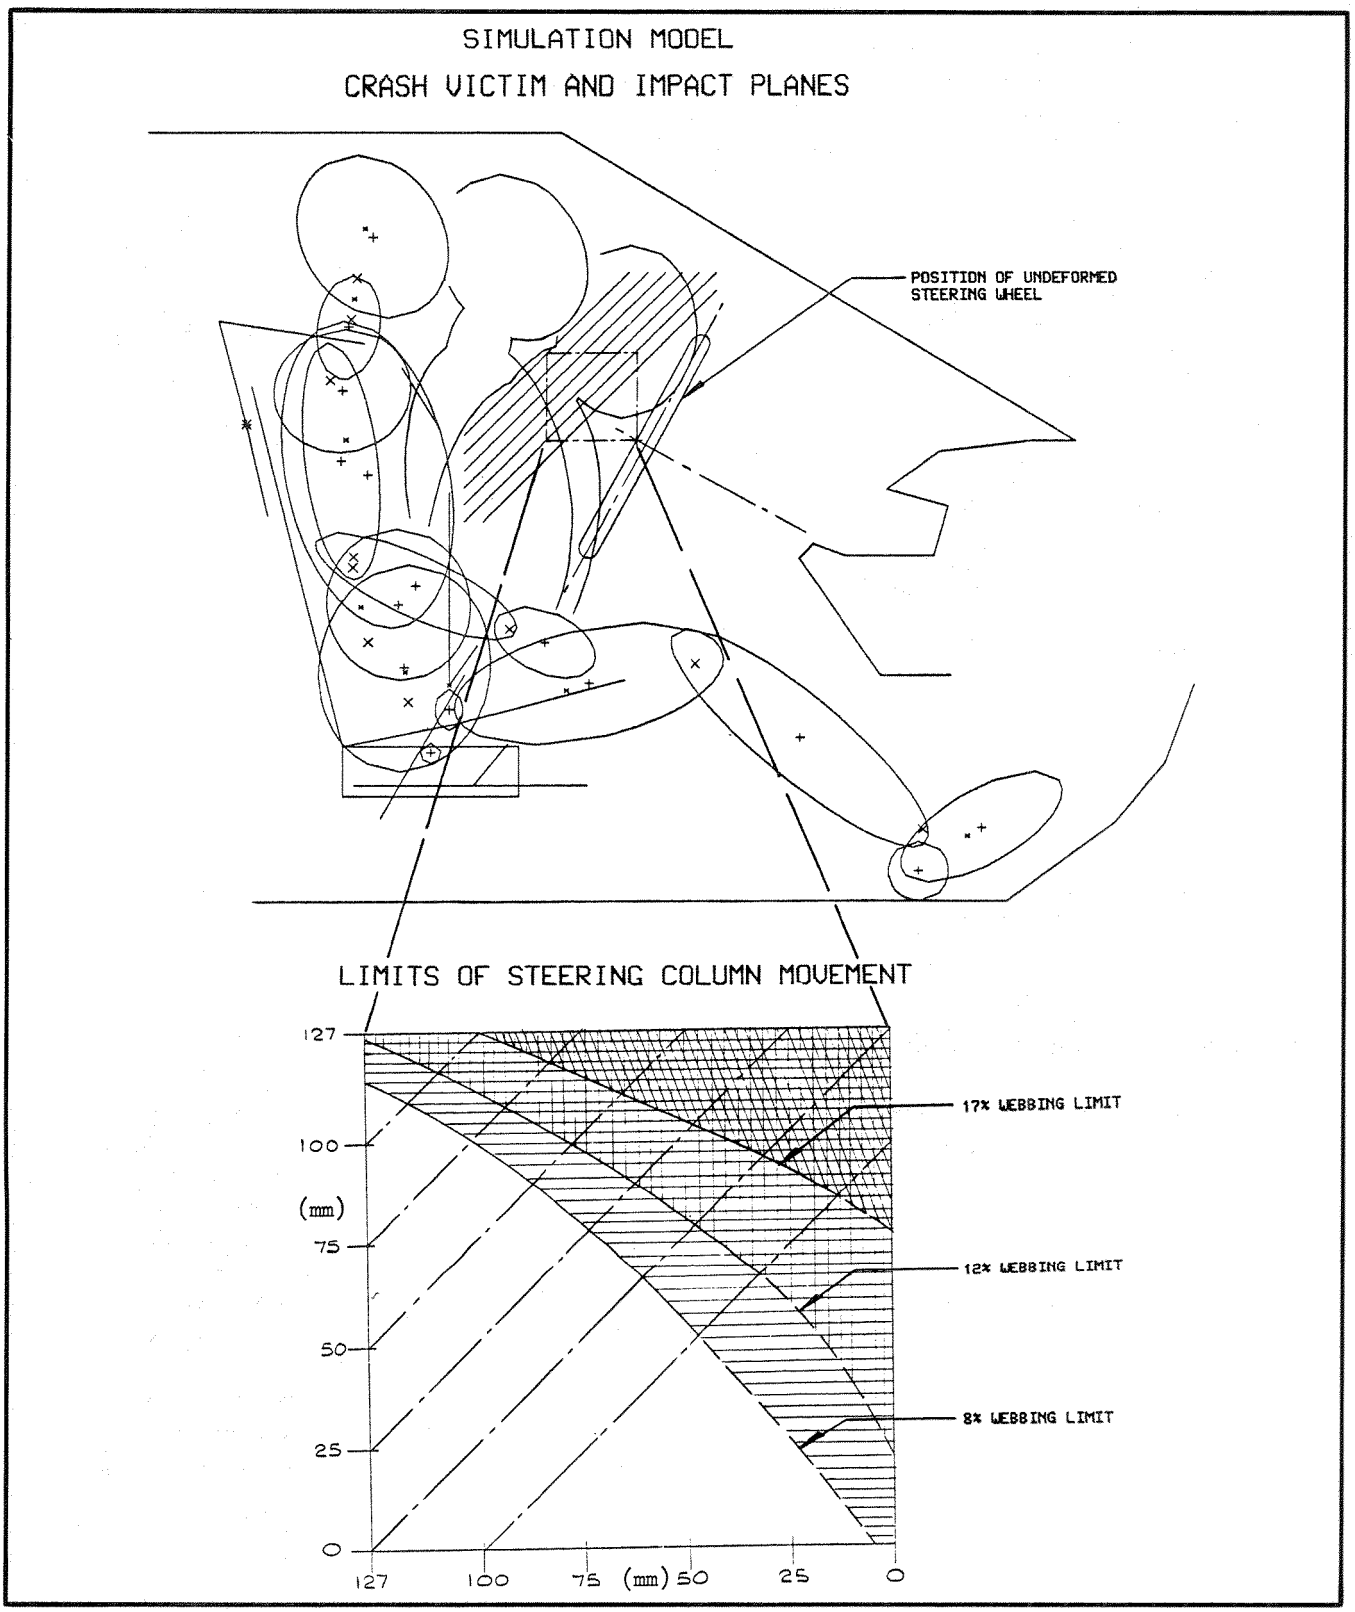

Figure 4. Simulation model of crash victim and impact planes

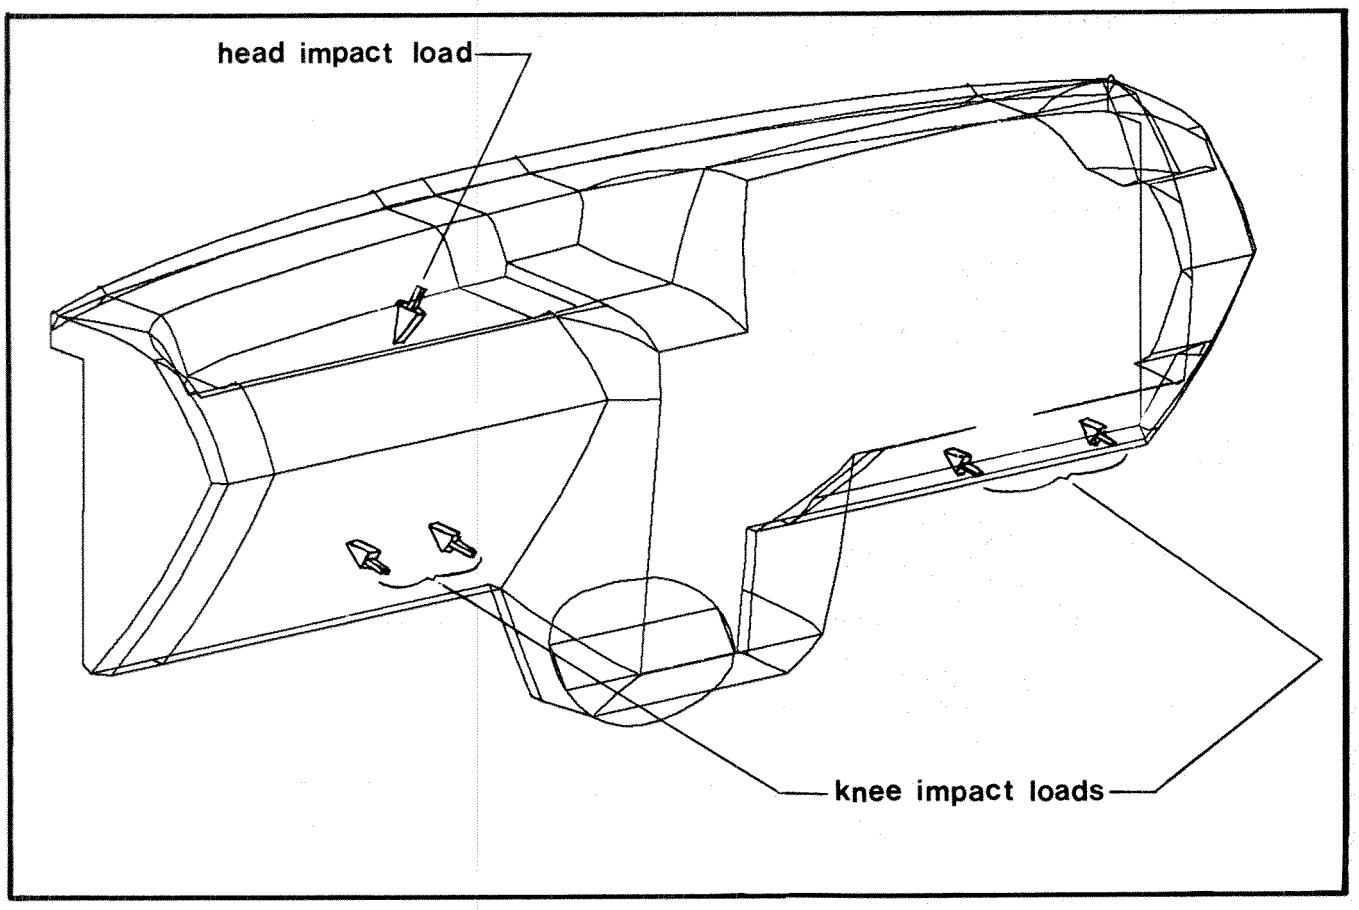

Figure 5. Fascia model for structural analysis with typical loading conditions

Developing the Computer Model

The computer model of the restraint system is modified in the light of the practical test data and by the same token helps to interpret the tests. The validated model and the enhanced understanding of the restraint system are now put to good use. Any undesirable features of the system can be ironed out in principle by changes to the model and component design areas kept informed of the results. By working in conjunction with these areas, the principles, verified on the simulation model, can be turned into features of the design. Specific loading conditions are passed from the simulation data for application on computer models of the component structure.

In parallel with this, the computer simulations of the structure will be continuing, and more definitive information will be forthcoming about the deceleration pulses and intrusion levels. These are built into the computer simulation of the occupant.

The computer model will now have changed considerably from the one that existed prior to the first sled test. To verify the model and check prototype hardware, a further series of tests is embarked upon.

A Development Example

This sequence of events is best illustrated by an example. A concept restraint system was tested as previously described, the components consisting of an inertia reel seatbelt, floor and toeboard, and current seat. In a simulated 35mph impact, a dominant and undesirable feature of the results was very high head accelerations. These were even excessive at lower speeds. The computer model had not predicted these accelerations to be as high as was found. It became evident that the lie of the lapbelt differed sufficiently from the vehicle for which the seat model had been developed to render the seat model inadequate. Alterations to the seat model brought about significant changes to the simulation results until they were similar to the test results. From this, it became evident that the dominant feature of the restraint system was a problem with the pelvis submarining. Figure 7A illustrates this and shows the test and computer simulation results. It was argued that the lack of any facia in either model was the cause of the submarining, and so a facia was built into the computer model. This caused some improvement, but submarining was still evident. Some form of pelvic restraint was then built into the simulation

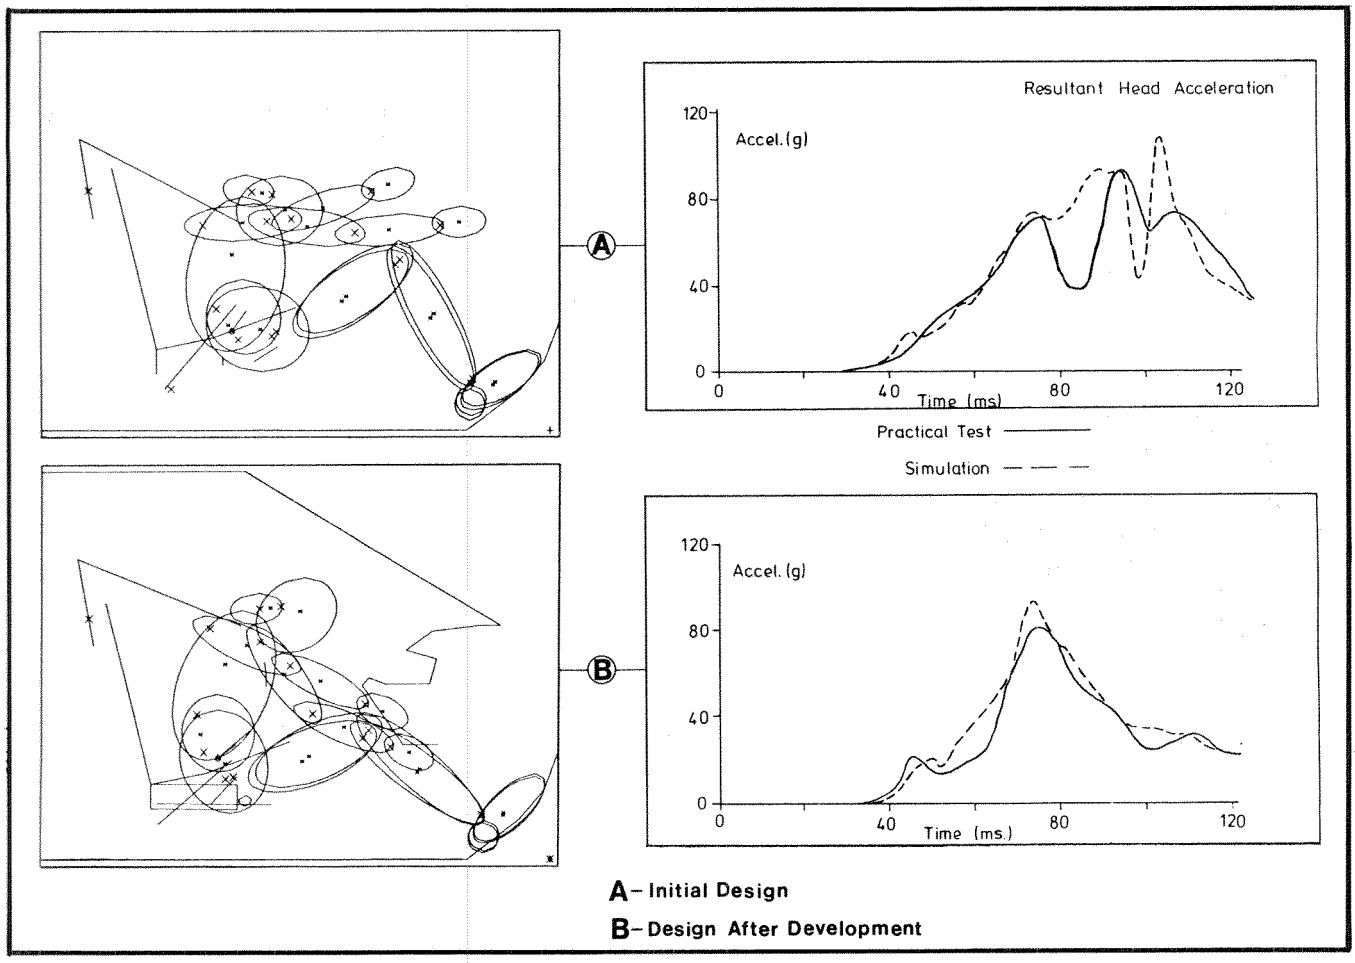

Figure 7. Example of restraint system development

seat model. The submarining was controlled (see Figure 7B). By working with the seat design area a prototype seat was evolved that would be expected to perform in practice as the computer simulation showed was needed.

A second practical sled test was carried out with this seat, other prototype hardware, and a simple foam-covered buffer representing the facia. The practical test bore out the computer simulation. The restraint system was by no means satisfactory yet, but the computer model was shown to be accurate and other changes, such as a revised deceleration pulse, could be introduced with confidence. Loading data was also passed to the seat design area so they could use it on their finite element model of the seat structure (see Figure 8).

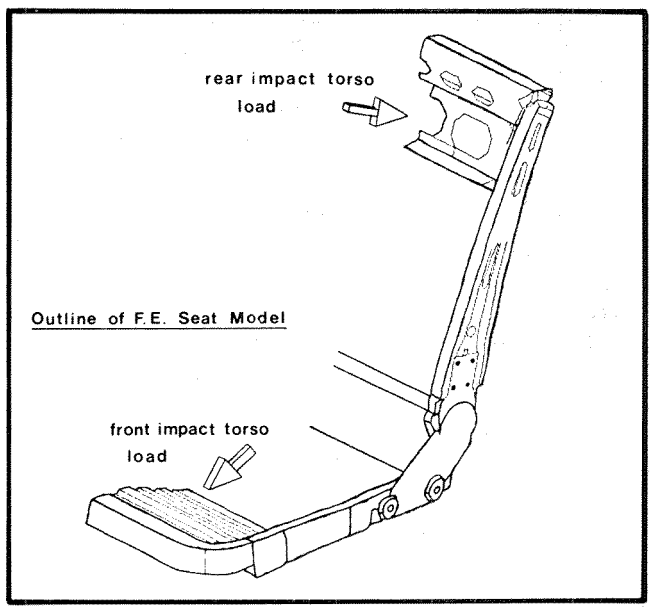

Figure 8. Seat model for structural analysis with typical loading conditions

The Interior

As has already been indicated, component areas will be using analytical methods in their designs and adopting criteria that includes data from early computer simulations and updated as the simulation model is refined.

The structural simulation of the vehicle body provides basic deceleration data to the occupant simulation, but the movements of interior features are determined by the collapse of the structure. The combination of these movements and those of the dummy and the design of these interior features are very important. Early concept simulations have given some design criteria, but the tuning of trajectories and the stiffness characteristics of the components are crucial.

Passenger Side

For simplicity, the sled tests and corresponding computer simulations represent a passenger in an undeformed interior. The consequences of intrusions can be indicated by changes to the computer model. This may mean, also, changes to the stiffness of the seatbelt webbing or even retractor to give an acceptable head trajectory for the facia movement. The computer technique is capable of including web-lock and pretensioner devices (see Figure 9).

At the same time, leg-to-facia contacts are considered, and the design requirements of peak load and absorbed energy are transmitted to facia design.

Driver Side

In a similar way, the interaction of driver and steering wheel can be modelled as an extension of the passenger model. The steering system model must include the

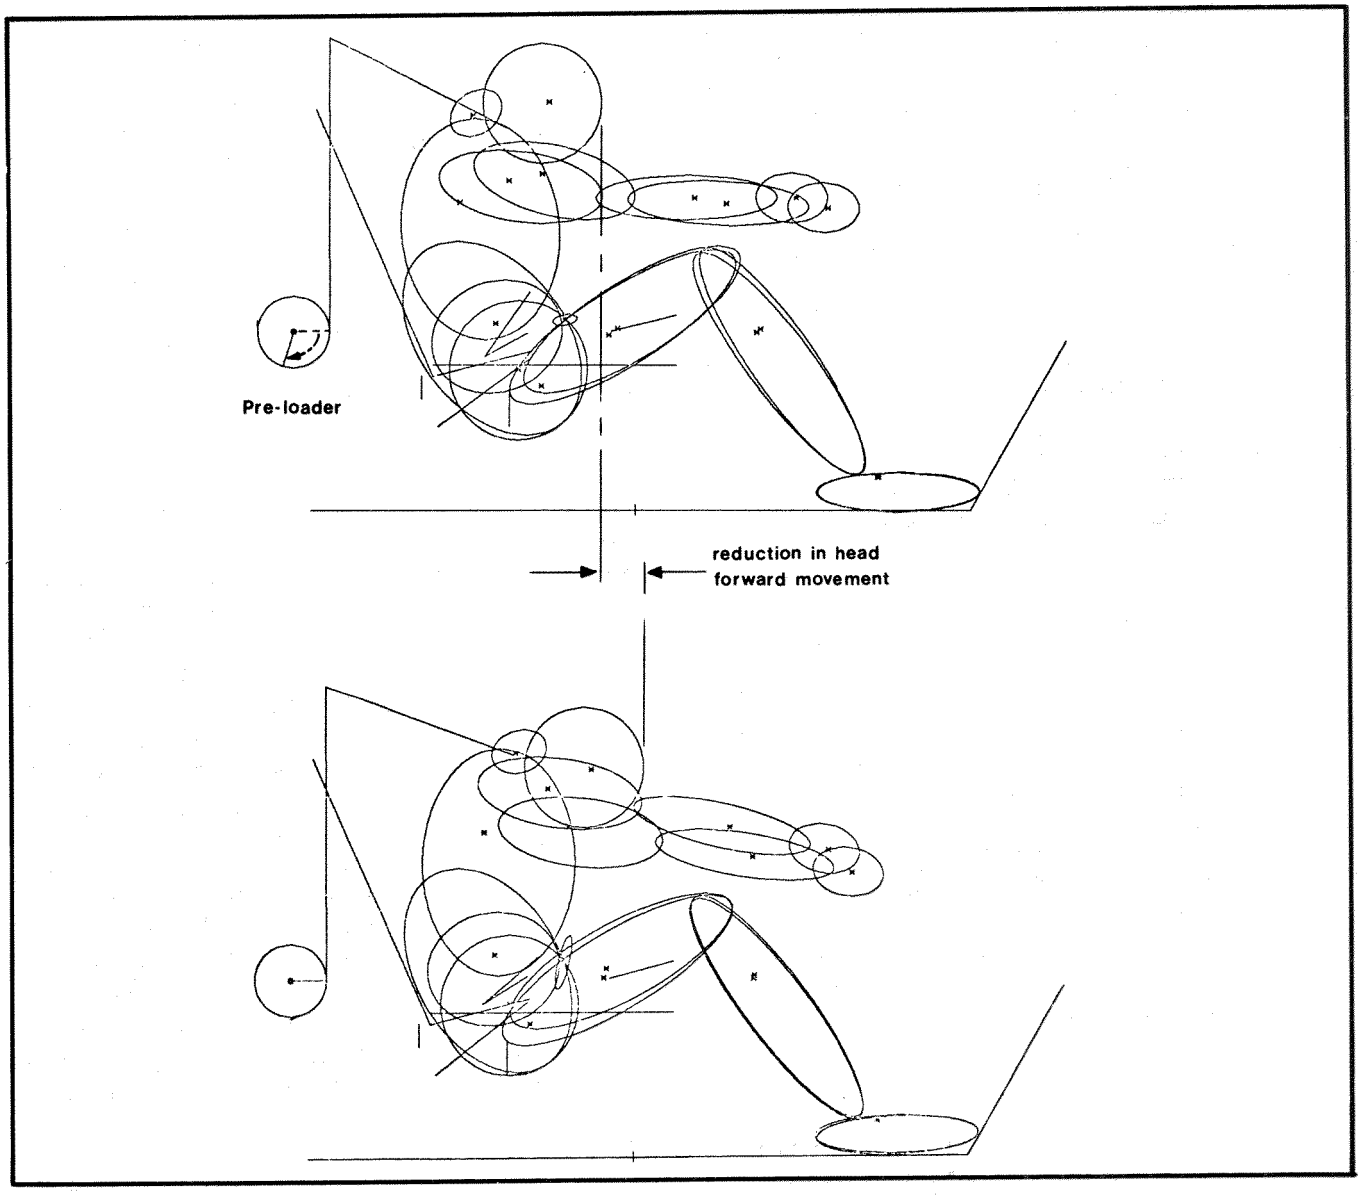

Figure 9. Simulation including Web-lock and pretensioner devices

facilities for the upper and lower rims to deform, the wheel to flex on the column, and the column to collapse (see Figure 10).

Usually the movement of the steering wheel has come to an end before the possibility of any chest or head contact and is, therefore, modelled in its final position prior to driver impact. However, the computer technique includes the facility to allow the trajectory of the wheel to be introduced if necessary.

At this stage, it is usually a case of tuning the restraint system to give a dummy movement compatible with the trajectory of the wheel. However, should the design of steering system or its movement prove difficult to match, then the need for and magnitude of any changes can be assessed using the computer model and the information fed back into the design process.

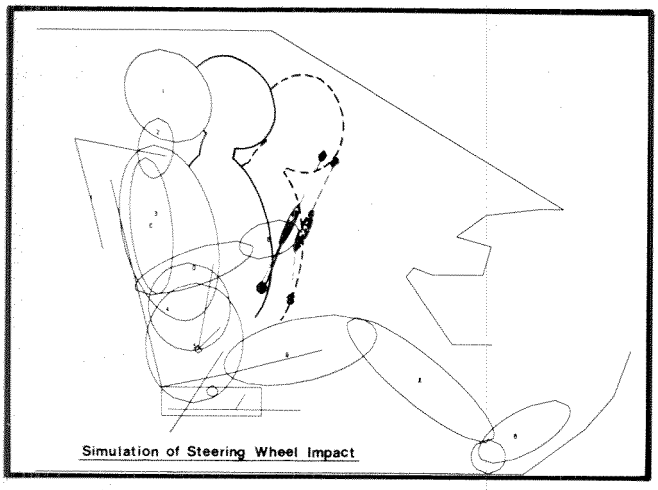

Figure 10. Simulation of steering wheel impact

Vehicle Testing

The first full prototype vehicle crash tests will take place with a reasonable confidence in the qualities of the restraint system and an awareness of the critical areas. Thus, measuring devices will be set up to give data that can be correlated with sled test and computer simulation with particular attention to the identified critical areas. In particular, the movements of parts of the interior and the interaction of the dummies with them are the subject of instrumentation as these are the least predictable features.

The results from the vehicle crash tests will be used to validate and modify the computer model with particular attention to the interior impacts and vehicle deceleration pulse. It may well be necessary to introduce vehicle pitch into the computer model input.

The computer simulation model is important, also, as an interpretive tool. The camera views of the occupants in a vehicle are limited and rarely such that data from any two can be successfully combined to give movement in orthogonal planes. The computer model can be verified against those views that are available and the direct measurements of contact, force, and acceleration. The effects and significance of events during impact can be appraised to give a more complete picture of the test.

The full vehicle crash test helps in the validation and improvement of all the analytical models applied to the vehicle and its components. Obviously the sequence of computer simulation, sled test, component analysis, and crash test will be repeated during the design process to the mutual benefit of each.

The computer simulation models can be used to assess the likely vehicle performance in impact environments either beyond the current specification or ahead of the completion of all prototype testing. For example, the angled barrier impact is less severe for the occupant in terms of vehicle deceleration levels but more severe in terms of impacted side intrusion levels and more uncertain in terms of head trajectories. The passenger (normally the nonimpacted side) will tend to move toward the centre of the vehicle with the risk of his head contacting the switchgear binnacle in front of the driver (see Figure 11). The driver will experience greater loading from the lower facia and the possibility of glancing off the wheel toward side glass or A-pillar. These features can be investigated using the occupant simulation model validated from initial vehicle 90° barrier impacts with modifications derived from similarly validated structural models.

Conclusion

Computer simulation techniques are an important part of the vehicle design process—at the outset, helping in the formulation of the concept and then assisting the actual design by analysis of systems and components. As with all analytical approaches, the need for good problem definition and specific data helps highlight design requirements and draw design areas together.

Computer simulations of the occupants in an impact situation yield data with sufficient accuracy to satisfy the analytical methods used in component design.

It is essential to integrate the test programme with the computer simulations. The practical tests establish and validate the models, and the models help interpret the tests and insure that unnecessary testing is avoided. The design process is not a simple logical progression—a motor car is more than just a machine, and marketing, styling, etc., are rarely constant points of reference. However, computer techniques are flexible, and such analytical models can adapt to changes as well as giving information on the implications of modifications. As such, these techniques help the length of the design process to be shortened or at least maintained in the face of more stringent design requirements.

The Use of the DRACR Airbag Simulation Model as a Design Tool

Lars-Gunnar Skötte,
Hugo Mellander, and
David J. Biss
Volvo Car Corporation

Abstract

The airbag simulation program DRACR has been revised to include belt routines. The amended program is used to indicate optimal choice of parameters for a driver supplementary airbag system. As a validation, results from sled tests are given and compared with the computer runs. A good agreement is found for the values of the most essential protection criteria such as chest g's and HIC's. The model has proven to be useful in the engineering process of an airbag restraint system. The interrelationship between important input variables is easily studied. Further validation of the model by other teams is encouraged.

Introduction

The use of computers as design tools in high-tech companies is today a matter of course. Mathematical simulations of complex systems give many possibilities to study important parameters at early design stages and avoid extensive development tests, which in many cases take the form of a trial-and-error testing.

The engineering of an airbag system is a good example of where such an approach is suitable. Such a system consists of a large number of parameters, and an efficient way to handle these variables is to use a mathematical model. An early system analysis of bags, inflators, and steering system will shorten the time of development and make the process more efficient.

With this in mind, Volvo decided to start a project directed at the development and installation of a new computer model for the simulation of a driver airbag system. The model should be able to simulate the airbag inflation phase, different bag parameters, belts, different occupant sizes, etc. The DRACR model was chosen among available models to form a platform for the work. This report describes briefly the model and, more deeply, the parameter sensitivity studies and validations that have been made.

History

Volvo has been using computerized mathematical simulation models for airbag systems since 1975. The first model used a preinflated bag and in 1979 was improved to describe the inflator mass flow characteristics. In 1983, Volvo and Fitzpatrick Engineering developed a seatbelt routine and updated the DRACR model, which was then to become the Volvo DRACR model (VDRACR) described in this paper.

The VDRACR Project

The project included—

- Updating the DRACR model
- Installation, input data preparation, and debugging
- Parameter sensitivity analysis
- Design of different airbag systems for testing

Updating the DRACR Model

As the existing DRACR model did not include all capabilities required by Volvo, the model had to be improved. For example, a belt routine was added for simulation of an airbag in combination with belts. The H-point was allowed to move also in the vertical plane, and the model was changed to allow chest contact with the steering wheel through the airbag.

VDRACR Model Description

To understand the nature of the model and the results from the computer simulations, a short description of the model and its capability is presented below.

VDRACR is an acronym for Volvo DRiver Air Cushion Rotation. The model is a two-dimensional, lumped-mass computer model of a vehicle driver interacting with an airbag with or without a belt restraint system. The airbag is mounted in the steering wheel. The rotation suffix in the title means that the model simulates the rotation of the steering wheel with respect to the steering column as well as the rotation of the steering column with respect to the compartment. Different compartment geometries and occupant sizes and positions can be modeled easily. A schematic of the VDRACR model is depicted in Figure 1.

The driver is modeled by four masses: the head, the main torso, the sternal, and the lower body (pelvis and legs). The H-point is free to move in the vertical plane as well as the horizontal plane. The model simulates the pelvic girdle and torso compliance for belt interaction and sternal and chest compliance for airbag interaction. The abdomen compliance for steering wheel rim interaction is computed.

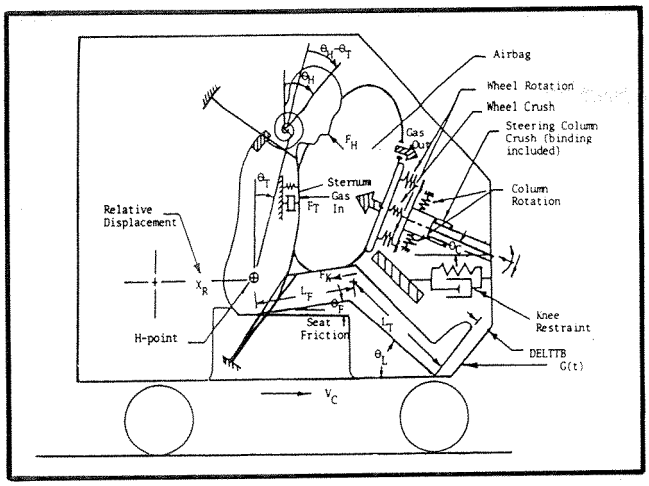

Figure 1. Schematic of VDRACR model

The airbag is modeled as an ellipsoid (actually an oblate spheroid), which is the most realistic shape of the driver airbag. The bag transmits forces from the driver head/chest to the steering wheel/column. The program uses a tabular input for the inflator gas mass flow-time properties.

The belt system in VDRACR can be used in combination with an airbag or as a stand-alone restraint system. A 2-point or 3-point belt can be simulated.

The system is described by the force-deflection properties of the webbing, the coefficient of friction between belt and latch plate, initial slack, and the amount of webbing that may stretch in each of the torso and lapbelts.

VDRACR models the steering wheel/column crush and rotation. An accurate simulation of this is important to achieve an overall simulation realism. The program calculates in each time integration interval the airbag forces and pressure before it proceeds with the steering wheel/column calculations, and in each time step the program uses a minimum energy method to determine which crush mode (steering wheel/column-rotation/crush) will occur. VDRACR models the column in a way that can be representative of most current car designs.

The model also has the capability to—

- Simulate the out-of-position driver
- Compute all the conventional protection criteria such as HIC's, chest g's, head g's, femur load, peak chest g's with 3ms clip

As a design tool, the program is oriented toward the hardware actually encountered in most design situations.

In addition, the program modules describing the performance of the various hardware components are designed to be complementary to one another. VDRACR is structured to provide balanced treatment of all the various restraint components that make up the total model.

Installation

The installation of the VDRACR model required—

- Changing the Fortran code to fit the mainframe computer at Volvo
- Creating an input file consisting of over 150 different parameters
- Building up knowledge inside Volvo of how the model was structured and how the program parameter interaction adds up to an overall system performance. It is the interaction of the major parameters affecting the driver airbag, as they vary over the range of interest, that many times has a greater effect on the results than the variation of any single parameter.

Parameter Sensitivity Analysis

The program input file consists of many different parameters. Some of these are more suitable for parameter studies and are used to optimize the airbag system, e.g., bag parameters as volume, ratio of axis, and ventilation area. Other parameters are more or less fixed because they depend on what can be delivered or developed by suppliers—for example, inflators—or are related to the vehicle. To form a basis for the sensitivity analysis, the vehicle-dependent parameters were decided and plugged into the model. The parameter sensitivity analysis was made for the overall system, and interesting parameters were varied.

For example, the interaction between chest g's, steering wheel plus steering column stroke, bag geometry and ventilation, occupant size, and inflators were varied. This is shown in Figures 2 to 4.

Figure 2 shows a plot of chest g's along with total stroke (steering wheel plus column) versus vent area for a

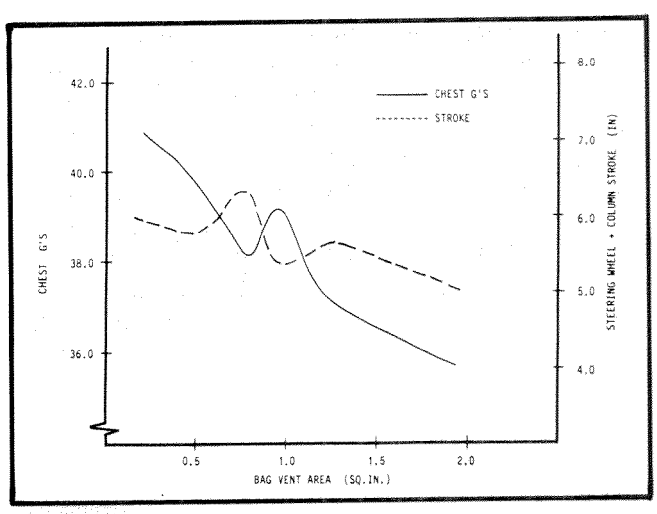

Figure 2. Chest g's and steering wheel plus column stroke versus bag vent area

67 liter bag with 280mm straps (internal straps to maintain the shape of the airbag) restraining a 50th percentile man in a 30mph barrier crash. Of interest is that chest g's and the total stroke are good mirror images of each other. Dips in the chest g's curve are matched with maxima in the total stroke and vice versa.

This appears to be the result of the program using a minimum energy approach to determine the collapse load during the program iterations. The chest g's and total stroke decrease for larger vent areas, which means that the bag dissipates energy. If the vent area is increased more than is shown in the plot, a point is reached where the chest g's raise again because there is not enough gas in the bag to prevent the occupant from bottoming out against the steering wheel.

This is actually shown in Figure 3: A 95th percentile male restrained by a 64 liter bag with 270mm straps, in a 30mph barrier test.

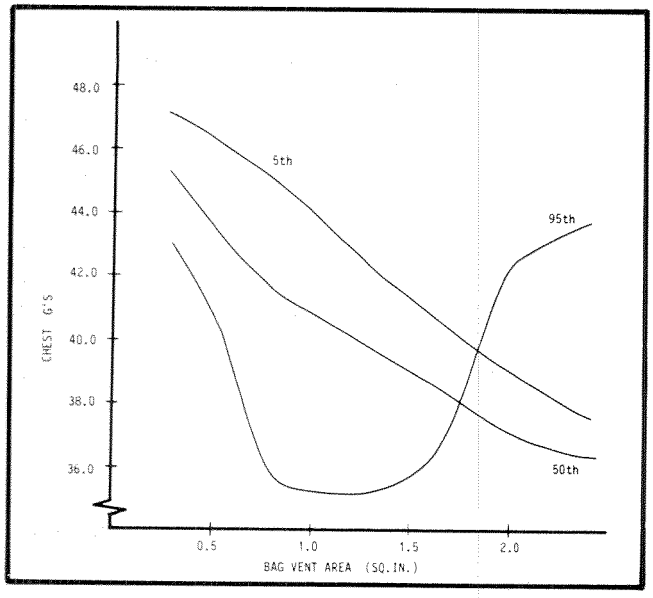

Figure 3. Chest g's versus bag vent area for a 95th, 50th, and 5th percentile driver restrained by a 64-liter airbag in a 30mph barrier crash

If the vent size is less than $0.8in^2$, the bag is too stiff for the 95th percentile which results in high chest g's. Around $1in^2$ the vent area is an optimum to get low chest g's, and above $1.5in^2$ the driver bottoms out against the steering wheel and the chest g's raise again. The 50th percentile male and the 5th percentile female are also shown in Figure 3. In these cases, the smaller driver does not bottom out as the 95th, because there is a sufficient amount of gas in the bag to protect the driver.

Figure 4 shows the chest g's versus bag vent area for a 35mph barrier crash with the driver, a 50th percentile male, restrained by a 67 liter bag with 280mm straps and a 3-point belt. Two sizes of inflator are used, 75 and 80g.

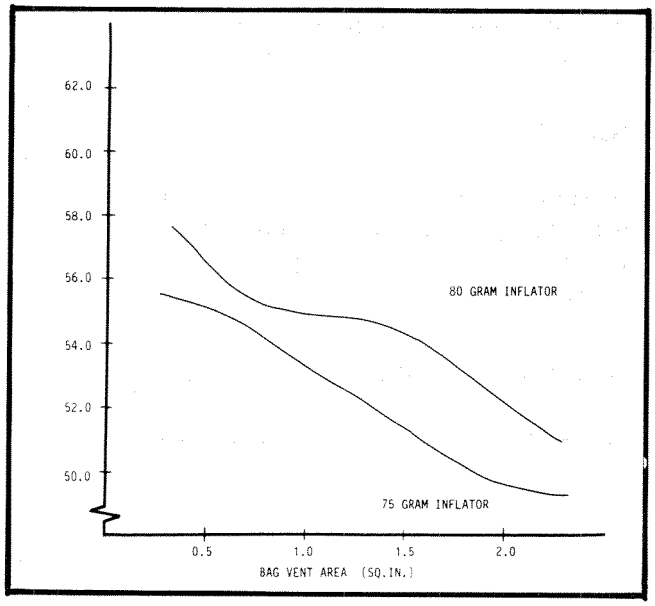

Figure 4. Chest g's versus bag vent area for a 50th percentile driver restrained by a 67-liter bag and 3-point belt in a 35mph barrier crash

In this configuration the driver receives higher chest g's with the 80g inflator as he will be more restrained. The simulations show that when a belt and an airbag are used together, the total forces on the chest are higher than if a separate system, either airbag or belt, was used. However, HIC values are decreased in tests with airbags combined with belts compared to belt-only systems due to the favorable ride down of the head.

Figures 2 to 4 demonstrate how the model gives the user the opportunity to optimize the sytem for best restraint performance.

Design of Different Airbag Systems for Testing

A number of candidate airbag systems were investigated using the optimizing procedure described above. It is important to have in mind that the objective of this work was to develop an airbag that would give protection for a 5th as well as a 95th percentile occupant and at the same time perform satisfactorily for the 50th percentile with and without a belt.

It will sometimes be easy to optimize the chest g's and HIC's for the belted 50th percentile male driver, but an unbelted 95th percentile driver may bottom out against the steering wheel with such a configuration. Also the 5th percentile female driver with belt can be overrestrained with high chest g's as a consequence. A suitable combination that meets all desirable requirements has to be found.

Over 1,000 computer analysis runs have been done, and some of the most promising combinations, depending on the availability of components and materials, were

chosen for testing and served as a basis for validation of the model.

Validation

A series of HYGE sled tests with driver airbag systems was conducted to validate the VDRACR model against experimental data. Four different test series were conducted.

General Test Conditions

50th percentile dummy, 75g inflator, bag vent area 2.65in^2.

Test Matrix

A: 35mph, 64 liter bag/280mm straps, 3-point belt
B: 35mph, 52 liter bag/220mm straps, 3-point belt
C: 30mph, 64 liter bag/280mm straps, no belt
D: 30mph, 52 liter bag/220mm straps, no belt

Results

HIC's, chest g's, head g's belt forces, chest displacements, and femur forces resulting from simulation and sled tests are compared below. Table 1 shows an overview of the results.

Figure 5 compares chest g's and HIC's from sled tests and simulations.

Examples of plots of other parameters from the tests are shown in Appendix 1.

The results show a good overall correlation. Important parameters such as chest g's, HIC's, and belt forces correlate satisfactorily.

There is a difference between simulated and experimental knee forces. This may be a result of a too stiff knee pad characteristics in the program data input.

It is important to point out that it is difficult to have an exact correlation between model input parameters and testing conditions. Some of the input parameters are results from static component tests. Dummy-related parameters such as neck and chest parameters are also

Table 1. Representative characteristics of structural components

hard to describe precisely. In the film, the bag shows a tendency to move up toward the windshield, which is not possible to describe in the model.

Conclusion

The VDRACR model has shown itself to be a good tool for design and development of a driver restraint airbag system. The model makes it easy to study several different airbag system parameters and their interrelationships.

Further validations should be done with different occupant sizes. Our validation is carried out against results from sled tests, and, of course, a validation against a barrier test is desirable. It is important to continue work with the model, refine the input parameters, and find methods to get improved input data for different systems guiding the event such as steering column bracket characteristics, seat cushion friction, etc.

Even if the results from sled tests and mathematical simulations are not always comparable in absolute figures, the trends suggested by the model are confirmed with the sled experiments.

The model seems capable of detecting changes in restraint system parameters and predicting trends in HIC's and chest g's, both in airbag-only exposure as well as in airbag and belt exposure.

Recommendations

A refinement of the description of the occupant is recommended. An improvement of the force balance between bag and chest is needed for simulation of a bag moving up toward the windshield, which occurred in the sled tests.

Sometimes minor algorithmical errors appear when the value of a parameter is changed. A more extensive error interrupt routine is needed. The model appears to be sensitive to changes of the integration time step, which perhaps is not relevant. The user of the model must have a good understanding of the function and capability of the model to be able to make full use of its possibilities.

Acknowledgments

The authors would like to thank the U.S. Department of Transportation, National Highway Traffic Safety Administration, for making the DRACR model available and also Fitzpatrick Engineering for their excellent work in improving the model.

An Analytical Management of Frontal Crash Impact Response

Koji Kurimoto,
Shigemiki Takeda, and
Hisanori Uehara
Mazda Motor Corporation, Japan

Abstract

The rotational behavior of the vehicle in the vertical plane at frontal collision against a flat barrier often plays an important role with respect to an evaluation of passenger compartment integrity and occupant protection.

An analytical method to examine the degree of influence of vehicle front end parameters, both on the behavior of the vehicle and its occupant, is presented, employing a two-dimensional finite element vehicle model and a two-dimensional lumped-mass occupant model.

The feasibility of the method is discussed by comparing the calculated results with the experimented ones, in relation to the behavior of passenger compartment and its occupant injury measure.

Preface

In high-speed frontal collisions, a rotation of passenger compartment in a vertical plane, often referred to as nose dive, is often observed. The effect of this rotation, especially on an occupant behavior restrained by a seatbelt, is not very well understood. This rotation may give rise to a substantial increase of crash space, or it may degrade restraint capability of a seatbelt system, due to an additional forward movement of the seatbelt anchorage points.

This paper describes the application of a computer model to simulate both the vehicle dynamics and its interaction with the occupant in the frontal barrier crash. The vehicle is assumed to be a small passenger car, and its occupant is assumed to be restrained by a conventional 3-point seatbelt system. Each behavior at collision is treated in the vertical, two-dimensional plane.

The object of this study is to assess a method of examining the effect of changes in vehicle front end parameters on the rotation of passenger compartment and, further, on its occupant injury measure in terms of the deceleration and displacement of the occupant head.

Mathematical Modeling

General Description

Mathematical representation of an ordinary passenger car, and its occupant restrained by the conventional 3-point seatbelt, is formed on a vertical plane, assuming their kinematics in the horizontal plane have little effect on the respective performance.

In this study, the direct kinematic interaction between the vehicle and its occupant is neglected due to the relatively small influence of the occupant dynamics on that of the vehicle. Thus, the deceleration, the rotation, and the vertical displacement of the passenger compartment during collision obtained in the mathematical simulation of the vehicle model are to be fed into that of the occupant model to obtain its response.

The vehicle is represented by a combination of two-dimensional finite element beams and springs of nonlinear characteristics. A distinctive feature of this model is characterized by the consideration of bending momentum, compared to a lumped-mass and spring model.

The conventional anthropomorphic dummy is treated as an occupant, represented by a two-dimensional lumped-mass model. Here the front-seat passenger is dealt with for simplicity. The mathematical model is provided with seat and both shoulder and lapbelt anchorages. These points on the vehicle where the dummy receives respective reaction force are assumed to change their locations according to the rotation of the passenger compartment, resulting in the variation of restraining forces on the dummy during the vehicle collision.

Vehicle Model Formation

The deformation of a structural component is generally dominated either by bending deformation or by axial compression.

The bending deformation is treated by a two-dimensional finite element beam model, where each material point within a plane is identified by a curvilinear coordinate system. The cross-sectional buckling accompanying a beam bending is treated, based on the empirical relationship between a curvature change of the reference axis and the amount of buckling.

The axial deformation is treated, based on empirical equations. In cases where both the bending and axial deformation are possibly exhibited in a structural component, the condition for occurrence of axial deformation is determined by comparison of the maximum values of bending force and the maximum axial collapse force.

When any element within a structural component is connected to other components, the influence on the element is taken into consideration by including it in an internal force vector of the discrete equilibrium equation. This equation is solved by a step-by-step explicit finite difference method(1,3).

The vehicle model selected here is a certain front-engine and front-wheel-drive passenger vehicle whose mathematical model is shown in Figure 1.

The front side frame of this model consists of a curved box beam in a vertical plane, constituting local plastic hinges, and tends to undergo bending deformation during crash.

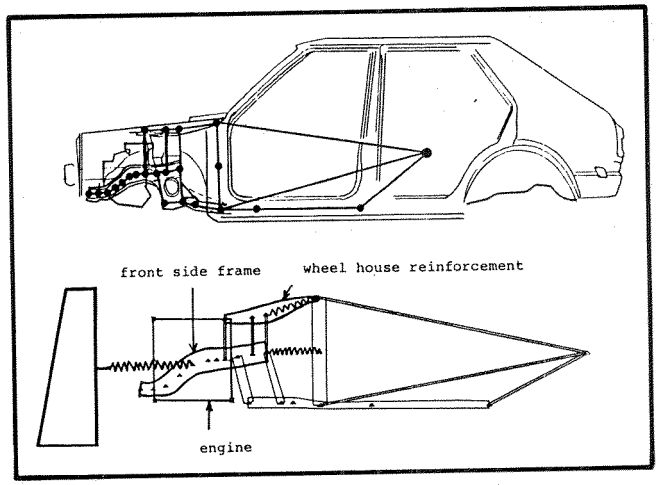

Figure 1. Schematic of vehicle model

Occupant Model Formation

A two-dimensional, five-mass, and multi-degree of freedom dynamic occupant model is employed, whose geometric, inertial, and joint characteristics are determined based on the specifications of the Part 572 hybrid dummy and on some measurements(4).

This mathematical model is provided with a seat and a conventional 3-point seatbelt system. The surface of the seat is assumed to make interaction with parts of the dummy, generating the reaction force, depending on the load versus deformation of the seat cushion in the vertical direction. Both the shoulder belt and the lapbelt are to make contact with the occupant model at two points respectively, again generating the reaction force at each point depending on the load versus relative displacement between the dummy and the respective seatbelt anchorage point on the vehicle.

This mathematical occupant model, the schematic of which is shown in Figure 2, is assumed to be stimulated by the vehicle deceleration in the longitudinal direction.

To simulate the effect of passenger compartment behavior on its occupant, the magnitudes of the deceleration, the rotation, and vertical movement of its reference point as a function of time are used as input to the occupant model. Knowing these values, the position of the bottom of the seat cushion and of the seatbelt

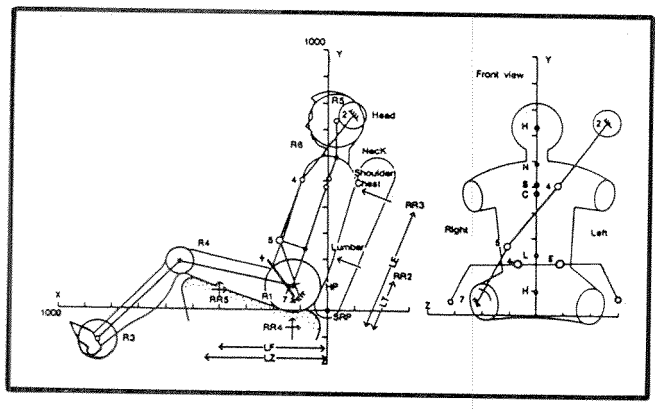

Figure 2. Schematic of occupant model

anchorage points are calculated at successive time intervals, resulting in the determination of the respective reaction force acting on the occupant based on the predetermined load versus deformation characteristics.

Simulation Fidelities

Vehicle Kinematics

Two full-scale frontal barrier crash tests at 35mph were performed with vehicles of different specifications with respect to the deformation characteristics of structural components, as shown in Table 1, obtaining different rotational behaviors of the passenger compartment.

Taking these test results into account, several computer simulations were executed on the vehicle simulation model in Figure 1. The deformation characteristics of structural components listed in Table 1 are calculated in the model based on the dimensional specification and the material property. Those of other components are estimated and adjusted by empirical methods(5).

Case	Specification	
Small Passenger Compartment Rotation	1. Wheelhouse Reinforcement	SPC 1.2t
	2. Front Side Frame (Inner)	HPC 1.0t
Large Passenger Compartment Rotation	1. Wheelhouse Reinforcement	SPC 1.0t
	2. Front Side Frame (Inner)	HPC 1.2t

Table 1. Results from sled tests and simulations

The comparison of tested and calculated results with respect to the vehicle deceleration, the rotation, and vertical movement of the passenger compartment is shown in Figures 3, 4, and 5. The results of the simulation compare reasonably to the test results.

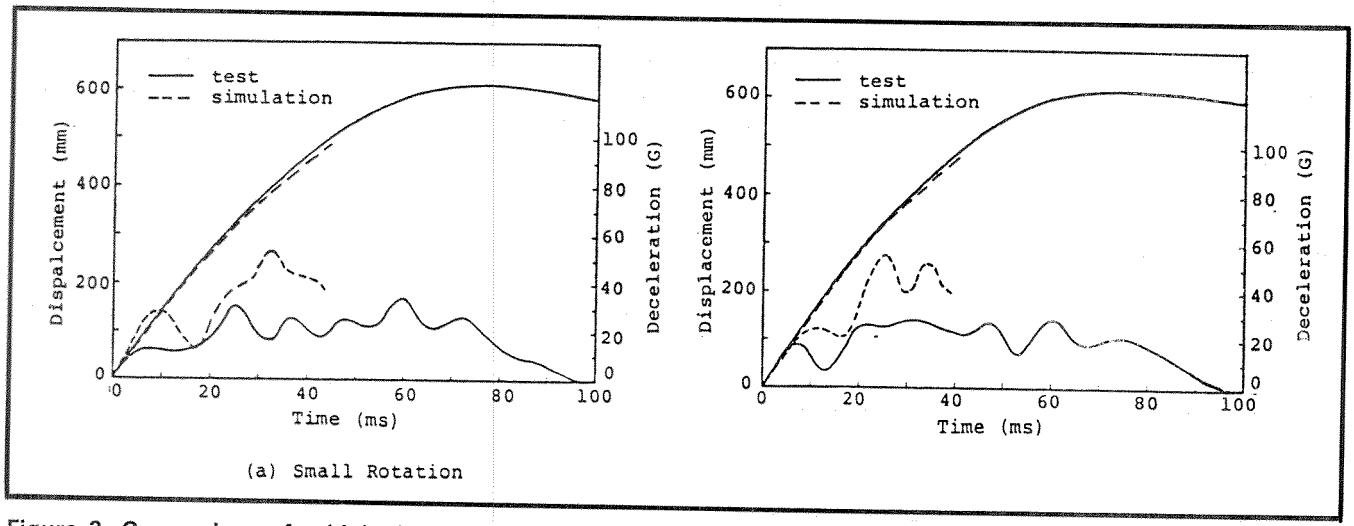
Occupant Kinematics

The occupant behaviors at the passenger side during two full-scale barrier crash tests described above were referenced to improve the simulation fidelity of the mathematical occupant model.

To this end, several computer runs were made, where the occupant models are stimulated by the vehicle deceleration, the rotation, and the vertical movement of the passenger compartment, which were actually measured during the previously mentioned crash test.

The computed results in terms of the resultant deceleration of head and the displacement of head relative to reference point of passenger compartment on the horizontal plane are compared with those by the full-scale crash tests.

With some adjustment of restraint characteristics for the occupant, including the force versus deformation



(a) Small Rotation

Figure 3. Comparison of vehicle decelerations and deformations

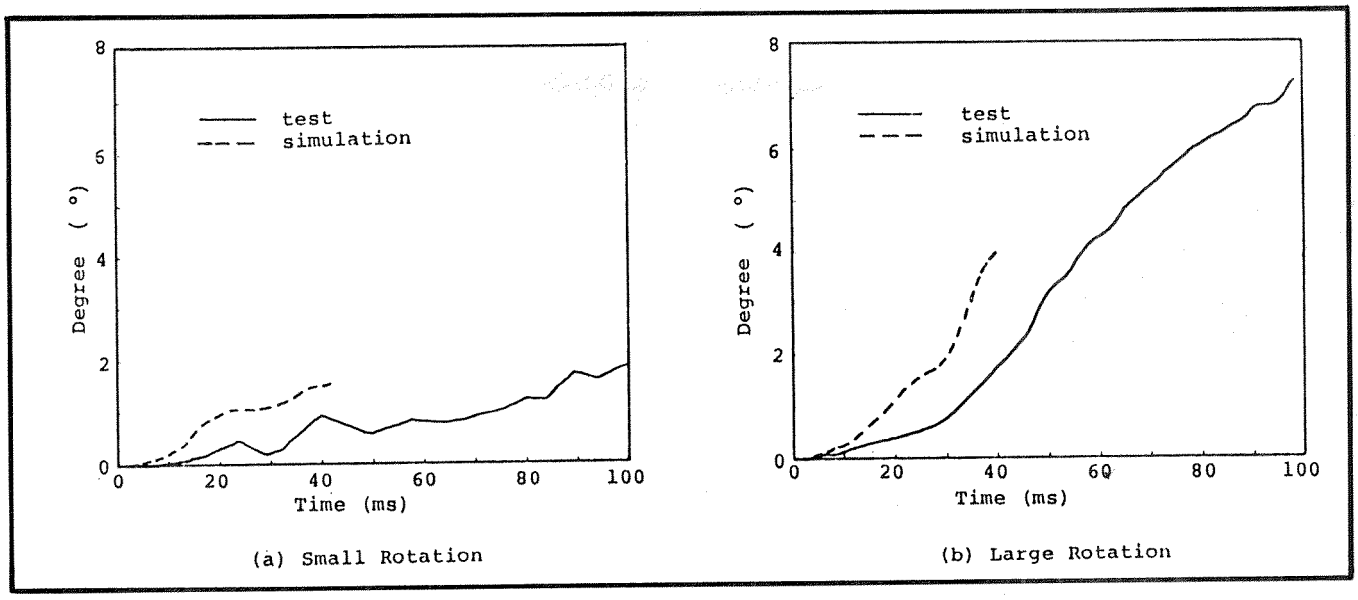


Figure 4. Comparison of passenger compartment rotations

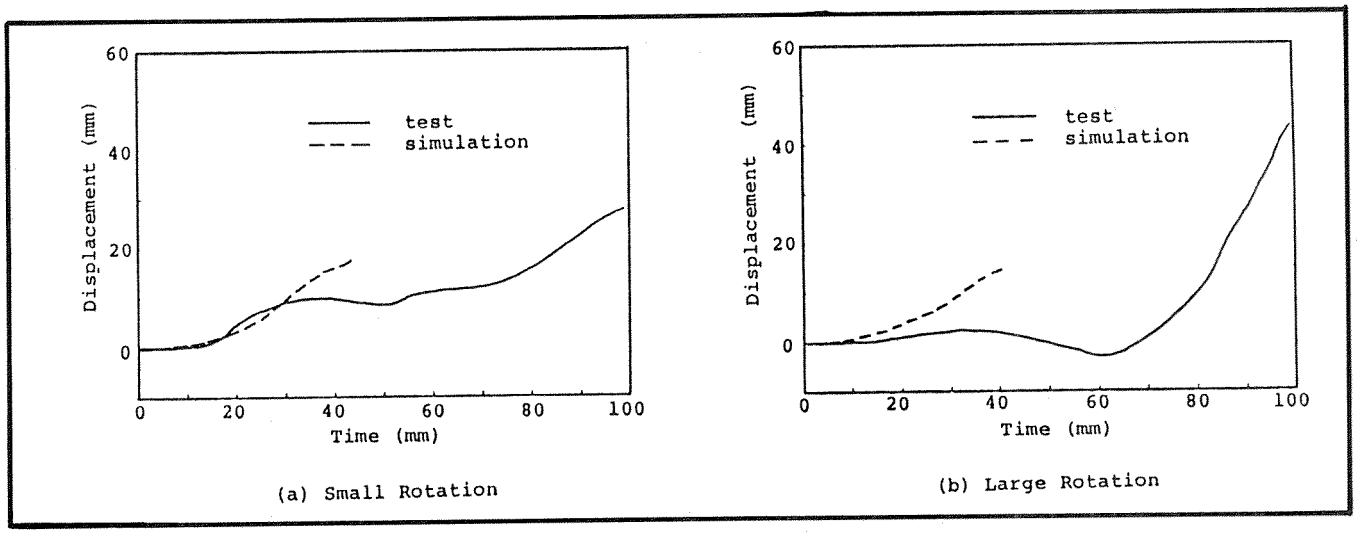

Figure 5. Comparison of passenger compartment vertical movements

characteristics for seat cushion and seatbelts as shown in Figure 6, the computation yields results in good agreement with those by the actual full-scale crash tests. The results are shown in Figures 7 and 8.

Summary and Discussion

The results in this paper indicate that cases exist where the rotation of the passenger compartment gives considerable influence on the performance of restrained occupant under specified frontal crash test, and that simulations for such cases should take the rotation into account.

It is demonstrated that the vehicle model is effectively and conveniently used by inclusion of finite element beams. Among the areas to be examined further is an improvement of vehicle response in the neighborhood of the maximum deformation or the rebound period, which is limited in the present study. An approach to this area may lie in a simplification of the model, based on closer examination of actual phenomena, by eliminating ineffective components.

It is also observed that the occupant model can be used effectively to estimate the responses to frontal crash test in the existence of rotational behavior of the vehicle by considering the displacement of connecting point of restraint devices to the vehicle.

Although there is room for improvement, the computer simulation methods presented here, both for a vehicle and its occupant, are considered acceptable for practical applications, for example, to various parametric studies.

Abstract

This paper presents information on analytical procedures being developed by the National Highway Traffic Safety Administration (NHTSA) to assess the safety problem associated with occupants of passenger cars involved in frontal impacts. This analytical assessment started with the characterization of a baseline vehicle fleet consisting of specific make/model passenger car groupings representative of the in-use fleet in the United States. Newly developed analytical models have been developed and are being run in an automated mode simulating these vehicles in different frontal crash configurations. The output of these automated runs includes measures of injury severity and cause of injury, and is being used to identify the effect of different vehicle attributes on injury causation. Preliminary analytical results are presented on the relationship between steering assembly structural attributes and injury severity. Comparisons of the fleet simulation results and accident data from the National Crash Severity Study (NCSS) and the National Accident Sampling System (NASS) are also presented.

Introduction

The frontal crashworthiness research and development effort at NHTSA is aimed at assessing the safety problem associated with occupants of passenger cars involved in frontal impacts and identifying potential remedies for the problem. The approach being implemented during the present conceptual phase focuses on an analytical characterization of the in-use vehicle fleet involved in frontal crashes. This analytical characterization will be used to identify present injury mechanisms, identify alternative countermeasures, and test the effectiveness of these countermeasures.

The following major tasks were undertaken to develop analytical procedures to distinguish the baseline fleet:

- Characterization of a baseline fleet
- Identification of analytical models to simulate the baseline fleet in a crash environment
- Collection of input data related to the baseline fleet
- Automation of the analytical process to allow for efficiency in running the analytical models and analysis of the results

A detailed description of the developmental work undertaken in each of these areas was presented in a recent paper at the Society of Automotive Engineers International Congress and Exposition in Detroit(1). The following sections summarize briefly details presented in that paper.

Characterization of Baseline Fleet

The intent of this program was to select certain make/model passenger cars that represented a large proportion of vehicles in use at the time the program was initiated. The passenger cars selected were also to be highly represented in the accident files such as the National Crash Severity Study (NCSS), the National Accident Sampling System (NASS), and the Fatal Accident Reporting System (FARS). The model years selected were from 1975 to 1983. The list of specific make/model groupings (passenger cars with similar structural and interior characteristics) is presented in Table 1.

Description of Analytical Models

Occupant Simulation Model

Several analytical models are currently available capable of simulating an occupant in frontal collisions. Several models were evaluated, including the MVMA 2-D, CVS, and PADS (Passenger/Driver Simulation). It was decided to use the PADS model for simulating the driver, primarily because of the detailed steering assembly description and its relatively modest input requirements. (Comparisons of occupant kinematics and responses for PADS and MVMA 2-D are continuing for simulating the right front-seat passenger.) The PADS model has the capability to model unrestrained and restrained drivers and passengers, although at present the analytical effort focuses on the unrestrained occupant. PADS is a two-dimensional model with a four-mass (head/neck, torso, lower body, and sternum) description of the occupant. The vehicle interior compartment is described by a detailed steering assembly and seven contact planes: seat back and bottom, lower, middle, and upper instrument panel, windshield, and header (Figures 1 and 2). The model also is capable of modeling intrusion of the steering assembly, toeboard, and all contact planes except the seat back and bottom. Each contact plane is defined geometrically by its x,y coordinates, angle, and length. Mechanical properties include force-deflection, loading and unloading, surface friction, and damping. The geometric description of the steering assembly includes: x,y coordinates, column and wheel angles, column length, wheel radius, hub location relative to rim of steering wheel, and location of shear capsule and EA unit (Figure 3). Mechanical properties include force-deflection, damping and friction associated with the EA unit, column and wheel torque rotation, normal and tangential force-deflection of the wheel for head, shoulder, abdomen, and whole body loading, and hub force-deflection. A further description of PADS is contained in (2).

Crash Pulse/Intrusion Generator

Crash data matching that of the accident environment were necessary to effectively run PADS to simulate a variety of crash conditions. A crash mode generator was developed, based on a linear scaling algorithm, to

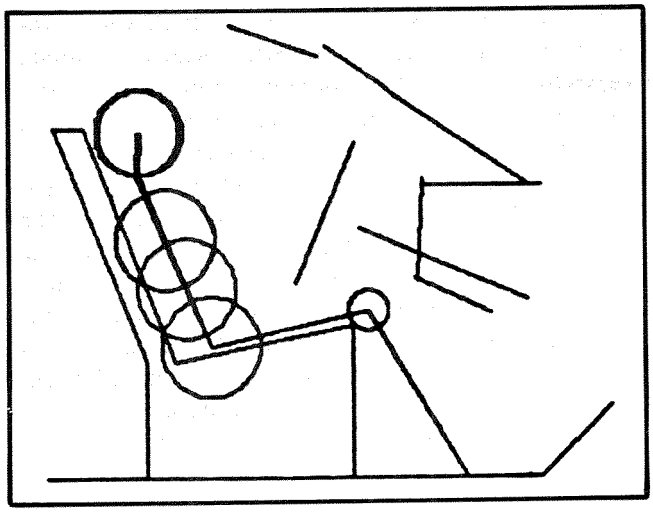

Figure 1. PADS occupant and compartment representation

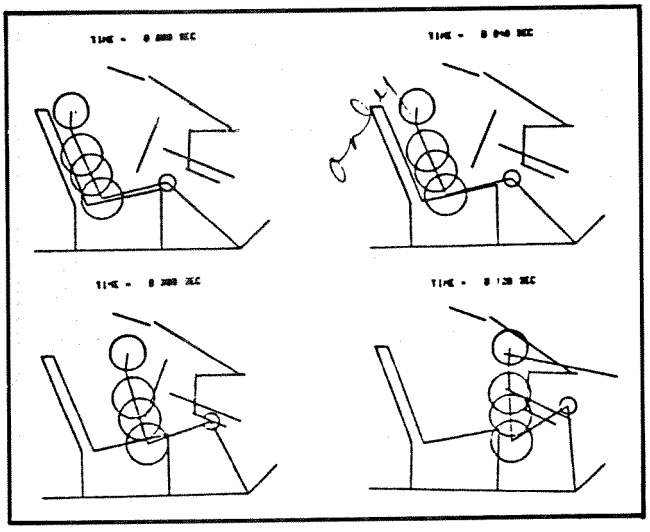

Figure 2. PADS dynamic simulation of unrestrained driver

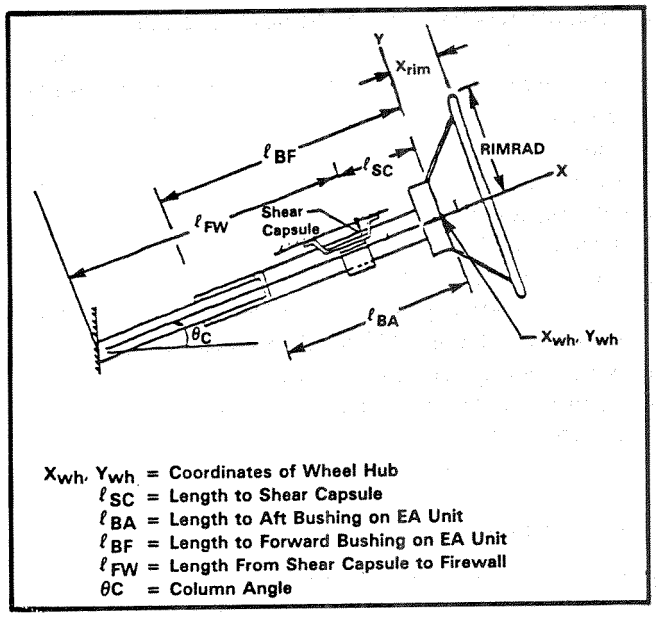

Figure 3. Steering Assembly Representation

generate a series of crash pulses representing different velocity conditions (10 to 35mph) and configuration conditions. The configuration conditions included car-to-car full frontal, car-to-car offset, and car-to-tree/pole. The crash mode scaling consists of amplitude and time scaling by an empirically derived factor dependent on the crash configuration. Algorithms to predict intrusion in different crash conditions have been developed. Further detail on these procedures are presented in this paper.

Simulation Input Data

The primary effort in developing input sets for the driver simulation involved collecting mechanical properties for the steering assembly. This consisted of three areas of testing: (1) steering column, (2) steering wheel tests conducted statically, and (3) dynamic column tests. The Transportation Systems Center (TSC) conducted these test programs as a cooperative effort with the Army Test Center for the first two programs and through a contractual effort with Batelle Columbus Laboratories for the third. Additional properties needed for driver simulation and passenger simulation include the mechanical properties of the instrument panel (lower, mid, and upper), windshield, and header. MGA Research, under contract with TSC, collected the material properties related to windshields and instrument panels. Compartment geometry data were obtained from a program being conducted at TSC(3). Occupant descriptors for the PADS model were compiled for the 5th percentile female, 50th percentile male, and 95th percentile male. All anthropometry data came from NHTSA's Advanced Dummy Program(4).

Crash testing of the 27 baseline vehicles has been conducted over the past 7 years as part of ongoing programs at NHTSA. Test data are stored in the NHTSA data base system. Twenty-five of these tests were conducted at 35mph, one at 30mph, and one at 40mph.

Automated Procedure for Simulating Fleet

Since the analytical procedure to simulate the accident environment requires the creation of numerous input files for PADS, an automated procedure was required to reduce the effort involved in their construction. Input sets required for combinations of the following parameters include: velocity (10 to 35mph), occupant sizes (5th, 50th, 95th), damage locations (distributed, offset, center),

object contact (vehicle or tree/pole), etc. The PADS Control File Generator (PCFG) was developed to automate the procedure for creating and submitting input files. The approach developed was based on storing subfiles of the car characteristics, assembling the subfiles into a complete input set, and inserting the completed input files into a run stream, which can then be submitted for computer simulation.

In addition to developing a procedure to handle effectively the creation of the input data sets, an efficient method was necessary to store and analyze the output. An output option was developed specifically for these automated runs and consists of outputting one line of data for each simulation. The line of data consists of 67 variables and includes information regarding the description of the simulation, selected simulation outputs (contact sources, contact velocities, body region involved, predicted injury levels, etc.), and run diagnostics. As a last step, this output file is converted to Statistical Analysis System (SAS) format to allow for the efficient development of tabular and graphical displays.

Structural Attributes for Crashworthiness Assessment

Identification of Attributes

The effect of the vehicle's frontal structure is being investigated by this program. Included are the effects of both the crash pulse of the compartment and the intrusion of the interior surfaces during the crash event. These are believed to be the major factors (for a given vehicle velocity change) of crash severity. Contributing to these primary factors are the collision partner stiffness, subject partner stiffness, and crash mode. This section will discuss the approach to improving structural crashworthiness, the anticipated safety improvements, and the methods used to evaluate the potential for improvement, while accounting for the complex structural parameters contributing to crashworthiness.

Data Conditioning and Crash Pulse Scaling

To evaluate potential safety improvements, crash mode and intrusion were scaled as previously mentioned. Test data for 27 vehicles tested in barrier crashes (25 at 30mph and 1 each at 30 and 40mph) were used for obtaining the starting pulse and baseline intrusion data. Crash pulse scaling was performed to obtain six velocities and three different crash modes as previously described. In addition to these 18 scaled pulses, intrusion was scaled for various objects struck (stiff, medium, or soft car or nonyielding object), which resulted in a total of 54 crash pulse/intrusion combinations for each of the 27 vehicles and 3 occupant sizes. Before performing the scaling routines, all data were carefully screened and conditioned to be consistent with observed physical phenomena. This process was accomplished by first performing film analysis to determine intrusion parameters and dynamic crush and velocity profiles for each of the vehicles. Signals from the various longitudinal accelerometers mounted in the occupant compartment, usually two to five, were processed and screened for data anomalies, such as time shift, zero bias, excessive noise, excessive data spikes (possible system or transducer overload), etc. Any observed anomalies were then, whenever possible, corrected. The pulses were next compared against film data, with one pulse chosen to represent compartment response based primarily on best agreement with film-derived dynamic displacement. This chosen pulse was further conditioned by applying a constant calibration factor that assured absolute agreement. For most of the 27 vehicles, load cell data were collected from a 36- and and a 40-segment load cell barrier. Due to early calibration problems with some of these load cells, data conditioning to obtain stiffness properties was essential for this effort. Force or load cell data were screened similarly to the crash pulse, then conditioned in the following manner based on impulse calculations. First, the time range for the impulse calculation is defined as the range of time from zero to the time when load cell response returns to zero. Impulse for the compartment pulse, using the entire mass of the vehicle, is determined over this time range. This impulse is compared against the force-time history impulse computed from the sum of the load cells, and a ratio of these impulses is determined. This ratio is used as a constant calibration factor to adjust the load cell response. This load cell response was used to obtain the maximum or peak force value (filtered at 100Hz cutoff frequency). Use of this value for obtaining intrusion will be explained in the following discussion.

After conditioning, scaling is accomplished as follows. First, the pulse is scaled to six velocities from 10 to 35mph. This is accomplished by computing a loading, unloading, and damping coefficient for a simple one-mass model. Next, crash mode scaling is performed for three modes—full frontal, half offset frontal, and pole impacts. Direct amplitude and time scaling are applied to the velocity-scaled pulse using factor, k, as follows: (Crash pulse-time) $\times$ 1/k and (Crash pulse-acceleration) $\times$ k.

Factors used are:

Crash mode	k Factor
Full frontal	1.00
Offset frontal	
-front wheel drive	0.60
-rear wheel drive	0.80
Pole	0.75

An example of velocity scaling alone compared to test data is shown in Figure 4. Velocity scaling combined with crash mode scaling is shown (compared to test data) in Figures 5 and 6.

Intrusion Analysis and Scaling

Next, an algorithm was produced for determining dynamic intrusion related to crush. As before, the baseline data for intrusion scaling were the barrier crash

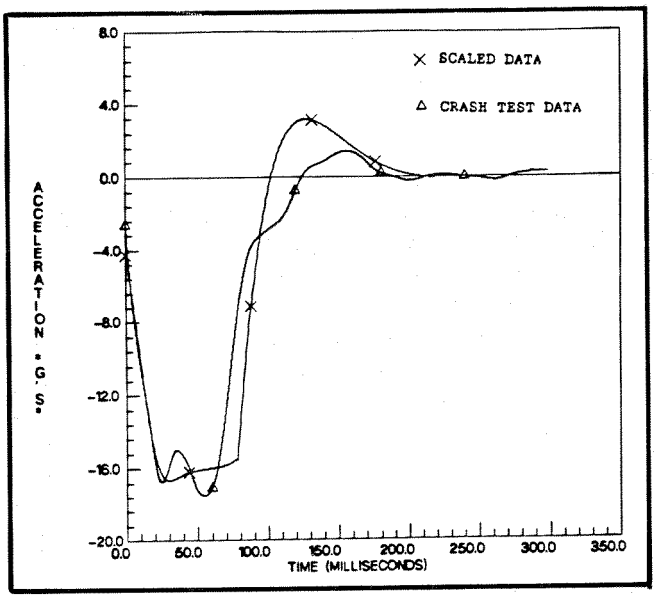

Figure 4. Velocity scaling compared to test data for 1981 AMC Concord car-to-car full frontal crash test at 25mph velocity change

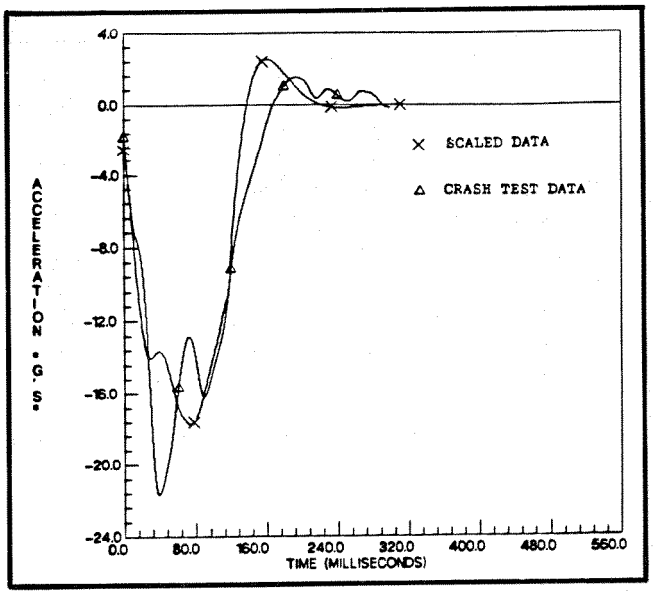

Figure 5. Velocity/crash mode scaling compared to test data for 1981 VW Rabbit car-to-car half offset crash test at 37mph

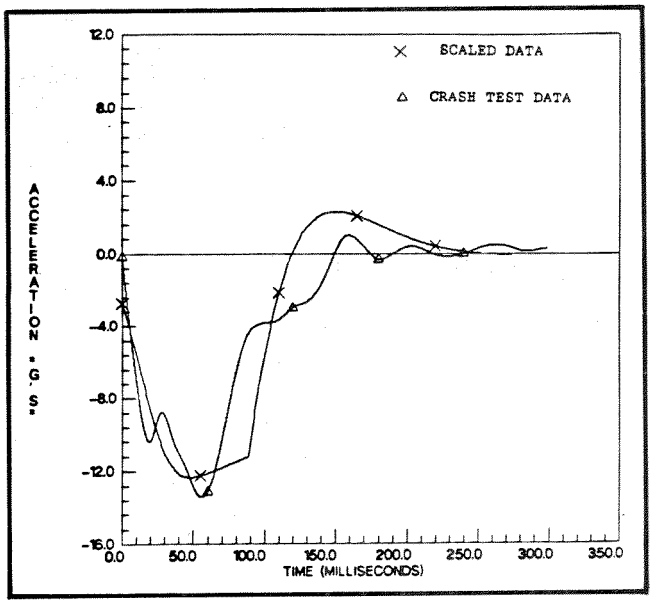

Figure 6. Velocity/crash mode scaling compared to test data for 1981 AMC Concord car-to-car half offset crash at 20mph

tests. Film analysis was performed on these data to determine the crush-related intrusion parameters. Basically, these parameters related to the onset and completion of intrusion in terms of dynamic crush of the subject vehicle. Figure 7 shows the dynamic crush, compartment velocity time, and interior intruding surface velocity time. Also shown on this plot is the film-derived onset and completion of intrusion, identified as C1 and

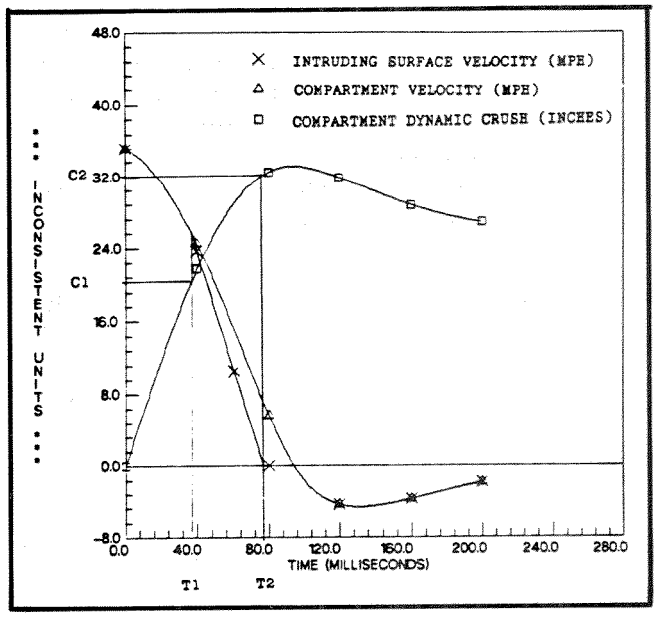

Figure 7. Intrusion relationships between compartment velocity, compartment crush, and intruding surface velocity

C2, and corresponding times T1 and T2. The extrapolation of intrusion became relatively straightforward since crush is determined directly from the velocity-scaled pulses for car-to-barrier, car-to-equivalent car, and car-to-pole type impacts. Not as straightforward, however, was intrusion scaling for car-to-car of different effective stiffness. That is where both cars do not equally share in the energy absorption and, thus, do not crush as they would in a nonyielding object-type collision. Therefore, to account for this difference, the maximum force level recorded by the summed loads from the NHTSA 36 segment load cell barrier appeared to be the best indicator of this effective stiffness. To approximate the crush sharing, the total mutual crush in a hypothetical car-to-car event is ratioed by FMAXp/(FMAXp+FMAXs), where FMAXp and FMAXs are the maximum load cell forces for a collision partner and subject car, respectively.

Evaluation Approach

Evaluation of the structure alone required an approach that would allow all other parameters to be held constant while varying the structural parameters. Since other phases of this research evaluated interior energy absorption, kinematics, etc., it seemed appropriate to ignore these factors and, as a final step, combine structure evaluation with the compartment interior evaluation. Originally, PADS was planned for this entire process, while using the above described structural input data, but the volume of runs and modeling constraints were not feasible within the time constraints. Therefore, a simpler approach was chosen, while selectively using PADS as needed. The approach chosen used PADS to relate the severity of the crash to the velocity with which a theoretical one-mass occupant would contact the interior of the occupant compartment. For purposes of visualizing this parameter, Figure 8 demonstrates the relationship between contact velocity and spacing (the distance traveled before initial contact with the interior surface). Using crash pulse scaling and PADS, a relationship of contact velocity to chest deflection and a potential injury scale were established. This was accomplished by first performing a regression analysis to derive the relationship between chest deflection and contact velocity, both determined from PADS for 18 crash mode and velocity combinations for a large and small car. This relationship, as shown in Figure 9, has an R-squared factor of .944 with a quadratic fit. Next, a regression analysis between contact velocities generated by PADS and the corresponding contact velocities calculated for a one-mass occupant was performed with the resulting linear fit shown in Figure 10. Applying this linear factor to contact velocity in Figure 9, a new quadratic relationship is derived for one-mass occupant contact velocity and chest deflection as shown in Figure 11. By using a previously

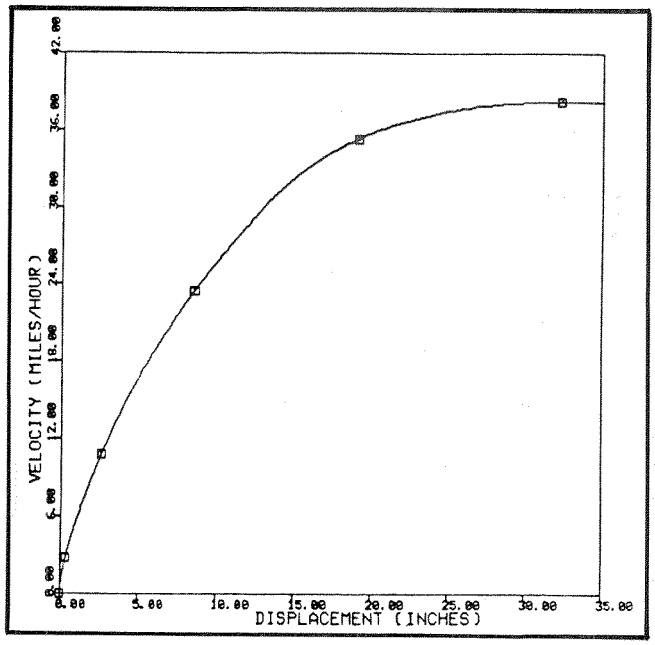

Figure 8. A plot showing contact velocity for a theoretical one-mass occupant versus spacing

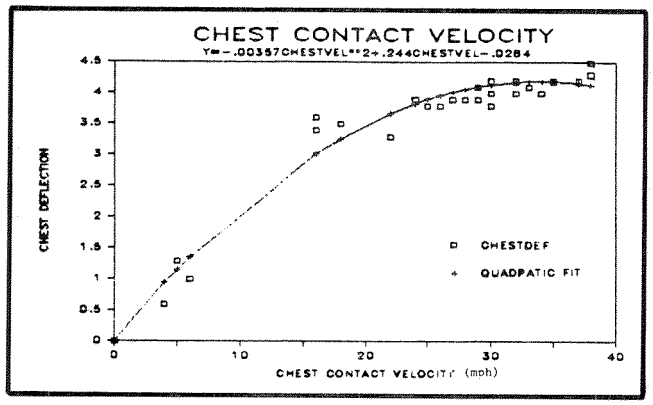

Figure 9. Chest deflection from PADS versus chest contact velocity from PADS showing a quadratic fit of data

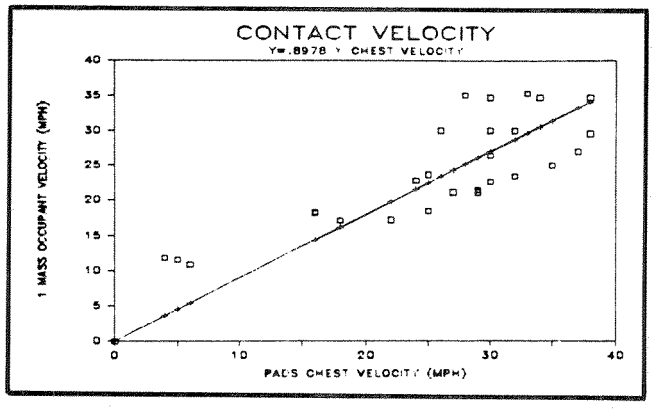

Figure 10. Contact Velocity computed from a theoretical one-mass occupant versus PADS chest contact velocity showing a straight line data fit

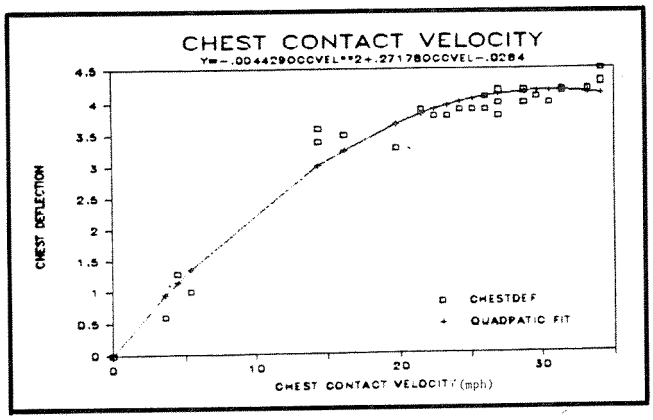

Figure 11. Chest deflection from PADS versus chest contact velocity for a theoretical one-mass occupant (derived by combining Figures 9 and 10)

derived relationship of chest deflection to injury(5), a probability of injury for contact velocity function is derived. Since this is not a true probability of injury relationship, due to other variables such as steering assembly characteristics, etc., this relationship will be referred to as a Structural Severity Index (SSI). This relationship may then be used to determine relative injury potential for a vehicle's given crash pulse and dynamic intrusion. To demonstrate the relationship of frontal structure and contact velocities, the following examples are shown. First, the effect of crash pulse without intrusion is examined using contact velocity. To make the comparisons on vehicles with similar potential for crashworthiness, the selection of 27 vehicles, shown in Table 1, was divided into six weight categories. A comparison of contact velocity versus occupant spacing is shown for the best and worst of a weight group in Figure 12A for one crash mode and velocity. This plot represents the velocity at the instant of impact with the interior surface for a theoretical one-mass occupant varying with the initial distance to the surface. To evaluate crashworthiness potential, Figure 12B shows the same two cars compared in terms of occupant contact velocity with a constant restraining force applied after a prescribed slack distance is traveled by the occupant (represening a theoretical constant force restraint). These plots are shown as extremes of crash pulse effect within a given weight class of 2,500 to 3,000 lb. Additional variations can be shown for other weight classes, and larger variations exist across weight classes (see Figure 13).

To demonstrate intrusion effects, a similar example showing contact velocities is given. To determine dynamic intrusion effects, an algorithm was developed, based on the previously discussed intrusion scaling, that combined the crash pulse with the dynamic intrusion effect to predict the theoretical contact velocity of a one-mass occupant. An example of contact velocity variations is shown in Figures 14A and 14B for two cars with different

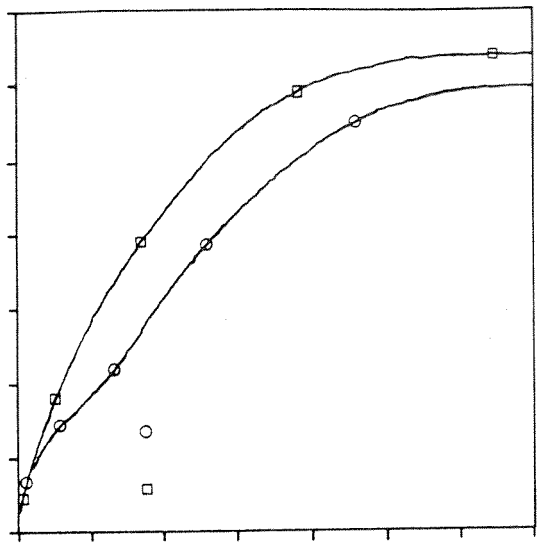

Figure 12A. Contact velocity comparisons of two cars in a weight group for unrestrained case at 30mph velocity change

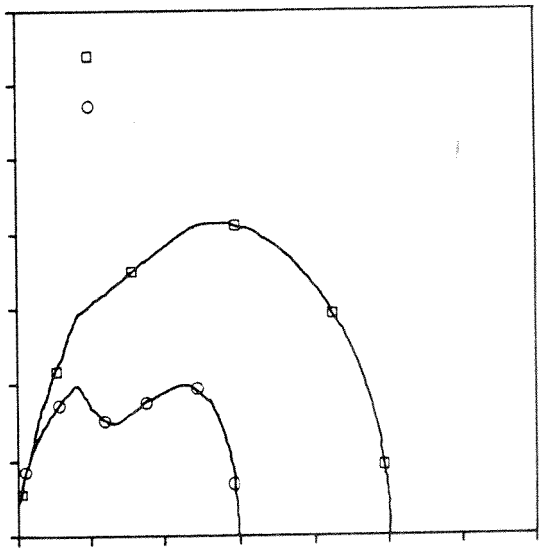

Figure 12B. Contact velocity comparisons of same two cars in Figure 12A for restrained case at 30 mph velocity change

intrusion characteristics, also in the 2,500 to 3,000 lb weight category.

The final step in the structural evaluation process is to determine the combined effect of intrusion and crash pulse throughout the accident scenario using the previously discussed SSI (structural severity index). This will be accomplished in the following manner. First, contact velocities will be established as previously discussed for all vehicles and all crash modes. Next, chest

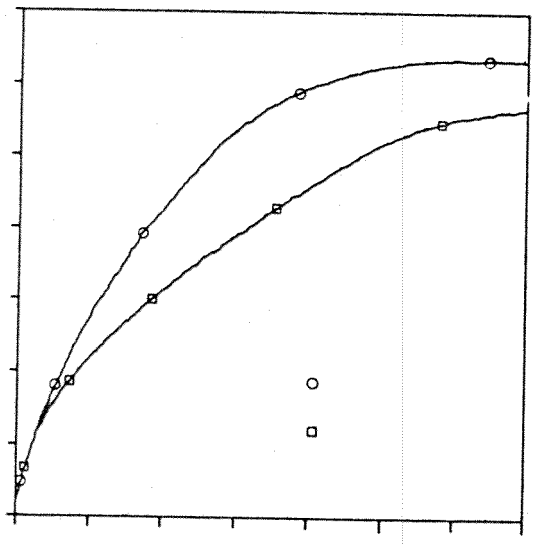

Figure 13. Contact velocity of best (large car) and worst (small car) for unrestrained case at 30 mph velocity change

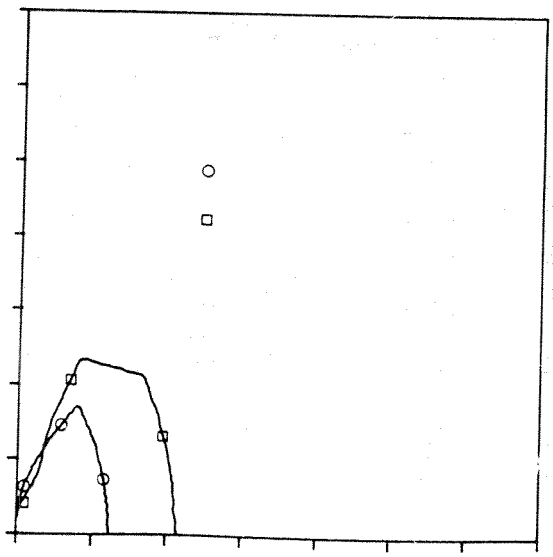

Figure 14B. Contact velocity comparison of same cars and crashmode shown in Figure 14A but with occupant restrained

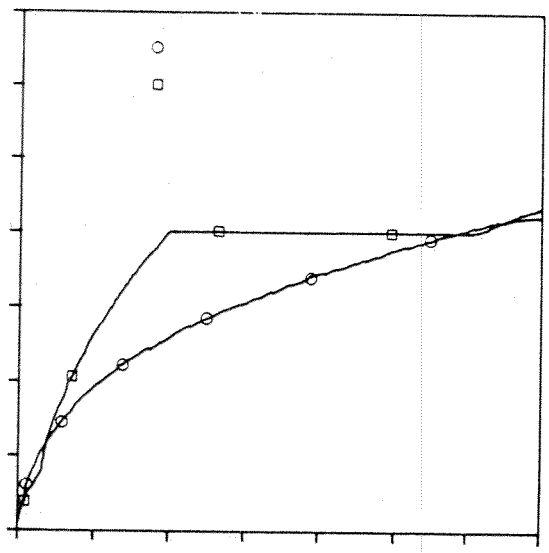

Figure 14A. Contact velocity comparison of two cars in a weight group with good and bad intrusion properties shown for a 20mph/-half offset crash mod and unrestrained

deflection and the corresponding crashworthiness potential, expressed as SSI, are computed from the previously described relationship. Then, for the 54 crash pulse/intrusion combinations for each vehicle, a probability of occurrence will be computed based on NCSS data for delta v distributions over each crash mode, fleet weight distributions, and fleet stiffness distributions. Finally, the overall relative structural attribute SSI will be computed for each vehicle to determine the best and worst performers within each weight group. An example of this approach, shown in Figure 15, compares the SSI versus change in velocity for the two vehicles compared in Figures 14A and 14B. The combined SSI for these two cars in the same weight class shows a relative difference of 40 percent. That is, the driver of car A has a 1.4 times greater potential for injury than the driver of car B based on structural attributes alone. Final results of these analyses are pending completion of ongoing work, which includes validation of the intrusion algorithm, completion and analysis of ongoing crash tests, and processing of all 27 vehicles through the described process.

Once the baseline fleet has been evaluated, changing fleet properties may next be assessed, along with various sensitivity studies of structural parameters. The primary purpose of this task, before proceeding to the PADS approach, is to evaluate the fleetwide effects of changing parameters on the previously identified best and worst performers. Parameters included in this study are stiffness distribution, weight distribution, and restraint usage rates. The last parameter, restraint usage rates, is least effectively analyzed by contact velocity due to large dummy kinematic differences caused by the restraints themselves. For example, a potential chest impact with the steering hub may change to a more lethal head impact with the hub. Once some understanding of the parameters is established, final analysis will rely on PADS on a more limited basis to reevaluate these best and worst structures. In addition, PADS will be used to combine the best and worst structures with the best and worst interiors to determine the overall potential for crashworthiness improvement.

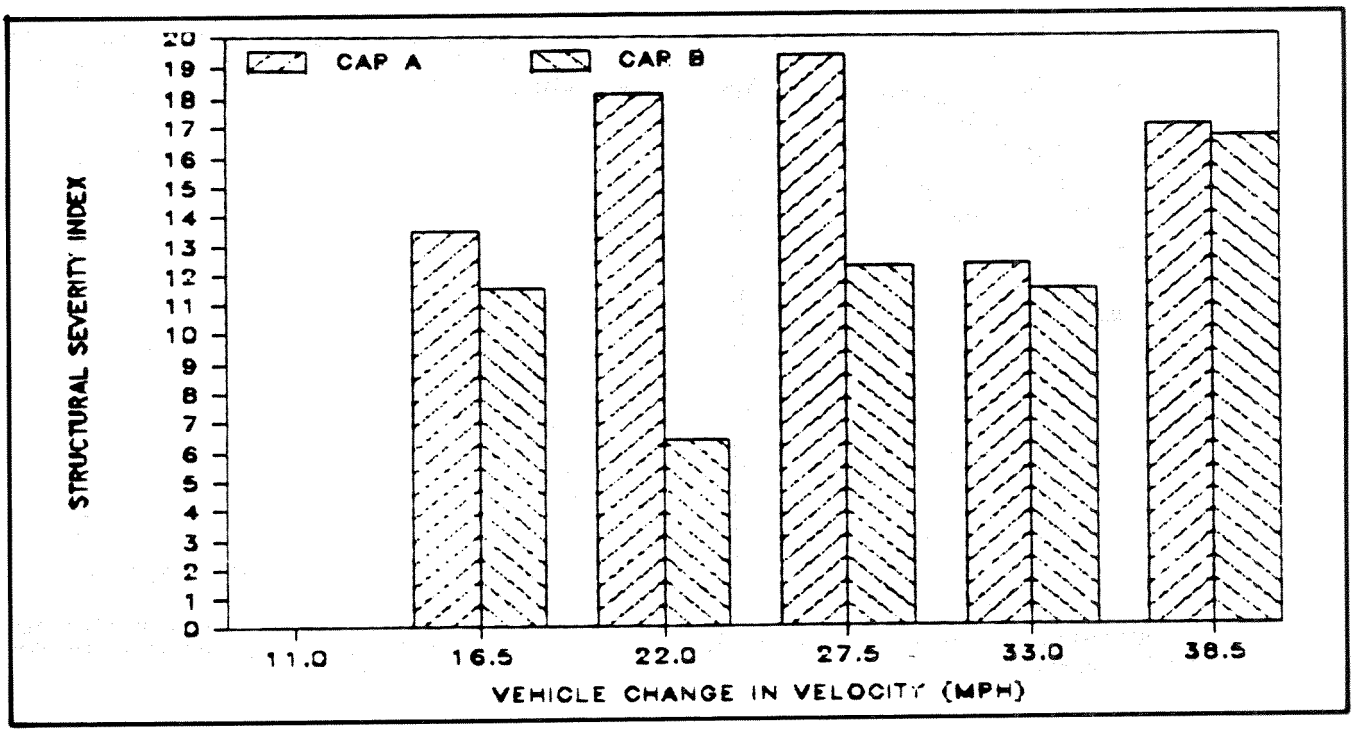

Figure 15. Relative injury potential expressed as structural severity index versus vehicle velocity change for two cars with different intrusion characteristics

Countermeasure Assessment for Driver

The objective of the countermeasure assessment is to determine improvements to the driver compartment, which can then be introduced into the 27-vehicle fleet to predict injury reductions over the baseline. The procedure consists of the following steps:

- Evaluation of contact surface properties and geometry for the 27 vehicles
- Ranking of vehicles by properties and defined parameters
- PADS simulations for comparisons of injury measures between high- and low-ranked vehicles
- Introduction of improved properties to lower ranked vehicles
- Determination of a group of best properties based on results of PADS runs, engineering evaluation, and biomechanical limits
- Selection of one vehicle with high baseline injuries, applying a best set of properties, and comparing simulation results with baseline

The goal of a countermeasure is to reduce injuries for the following body regions:

- Chest—Goal is to get minimum values for chest deflection and chest G's, i.e., lower the forces applied to the chest. Variables that directly influence the force level are—

		Good	Bad
(a)	EA characteristics of the column	high EA, relatively low force	low EA high force
(b)	EA friction	low	high
(c)	Hub recession	fairly deep	shallow or none
(d)	Hub padding	same as (a)	same as (a)
(e)	Wheel + column weight	low	high
(f)	Column damping	low	high

The deeper the hub is recessed, the more potential for abdomen penetration. The wheel/hub geometry should be designed for mitigating both chest and abdomen injuries. Load distribution affects the chest deflection but is not accounted for in the model, so, for the initial assessment, area will not be considered. Variables that indirectly influence the chest force are parameters that lower the impact velocity of the torso and/or alter body region/contact configuration. Geometry and force-deflection properties of the knee restraint and windshield, along with the crash pulse and intrusion, will affect the impact velocity and kinematics.

- Abdomen—Goal is to lower abdomen deflection by reducing the applied force. Since the abdomen is very soft, the force should be as low as possible within design limits. Variables that influence abdomen deflection are—

		Good	Bad
(a)	Hub recession	shallow	deep
(b)	Lower rim characteristics	low force long stroke	high force short stroke

Although a high EA rim would benefit chest injury by lowering chest impact velocity, preventing abdomen penetration is a more important role for the lower rim. Again, the same variables that influence contact velocity and kinematics for the chest also apply to the abdomen.

- Head—Goal is to reduce head G's and HIC's by lowering the force applied to the head. Important variables are—

		Good	Bad
(a)	Windshield characteristics	Low force but some EA	High force
(b)	Upper rim	low force	high force
(c)	Header	low force	high force

- Femur—Femurs can take a fairly high force without injury (about 2,500 lb). The lower instrument panel is the predominant contact. The main purpose of the knee contact is to be an energy absorber, but loads should remain below 2,500 lb. The location and stiffness of the knee contact also heavily influence the kinematics.

Evaluation of Baseline Contact Surface Properties

Data from PADS input sets were extracted to evaluate energy-absorption characteristics and force levels for the 27 vehicles. The objective of the evaluation is to assess characteristics that, from an engineering and biomechanical viewpoint, influence occupant injury. For each contact surface, parameters were either extracted from the force-deflection tables, computed, or developed. These include—

- Energy-absoption potential: the area under the force-deflection curve
- Average force: EA potential divided by the maximum stroke
- Maximum force
- Maximum stroke
- EA efficiency: a parameter defined as percent of the EA potential that lies below the average force level, i.e., a measure of how near the force-deflection curve is to a square wave response

A computer program was developed to extract the data from the PADS input files, compute parameters, and produce data files of these parameters for each contact surface of all 27 vehicles. The contact surfaces evaluated were: head/upper wheel rim (tangential and radial direction), abdomen/lower rim (tangential and radial), chest/wheel hub, whole wheel crush, steering column energy absorber, knee/lower instrument panel, chest/mid instrument panel (passenger), head/upper instrument panel (passenger), head/windshield, and head/header.

As discussed above, the injury potential of a surface is related to the amount of energy that can be absorbed by the surface and the maximum force that is applied to the body region. Obviously, these two parameters tend to contradict each other since a high energy-absorption potential is usually accompanied by high forces. A characteristic that combines these factors was needed to discriminate between the 27 vehicles. To accomplish this, the files were then read into another program that calculated a single parameter (which accounts for EA potential and efficiency, and maximum force) to better describe the injury potential of the contact surface. This defined parameter is equal to the ratio of EA potential to kinetic energy of the torso at 25mph times a force factor (equal to 1 if the maximum force is less than 1,200 lb and equal to the ratio of 1,200 divided by the maximum force if greater than 1,200 lb) times the EA efficiency. In addition, the ratio of the EA potential of the contact surface to the kinetic energy of the appropriate body part

is calculated for 25 and 30mph impacts. The final step in the evaluation is to combine the EA parameter and EA ratios for each contact surface into single values for the complete steering assembly and also for the complete driver compartment (defined as PARAM, EA25, and EA30 in Table 2). For all these parameters, the higher value, theoretically, represents better force-deflection properties.

parameter and EA ratio. The highest and lowest cars based on this criteria are—

	Steering Assembly		Total Compartment

In addition, tables were constructed of geometric relationships and other driver parameters for the 27 vehicles. Geometry includes: knee to lower instrument panel distance, abdomen to rim distance, chest to hub distance, head to windshield distance, vertical distance from head to header, and head to upper rim. Other properties include: wheel + column weight, friction, damping hub recession (also in Table 2), and column angle.

Simulation Results

The 27 vehicles were ranked by steering assembly parameter and EA ratio and by total compartment

Comparison simulations between high- and low-valued cars were conducted using the PADS model. Comparison criteria were selected as HIC, chest deflection, and abdomen deflection. To minimize output data, runs were made with only the 50th percentile occupant, distributed crash pulse at 10, 15, 20, 25, 30, and 35mph, and no intrusion. In comparisons of the total compartment, the results are inconclusive. In these cases, the higher ranked cars had less chest deflection but generally higher HIC's and abdomen deflections. Since the cars with high EA ratio, also, have higher force levels, these results are not unexpected. However, in the case of the EA parameter for the total compartment (Concord versus Chevette), since force is accounted for, lower measures would be expected. It should be noted that the Concord was

highest ranked in this category predominantly because of superior knee restraint properties since it was ninth best for steering assembly alone (at this time only a few windshields had been tested, all with similar force-deflection properties, and therefore the windshield contribution to the EA parameter was similar for all cars). The contribution of the knee restraint may not be as important as the steering assembly and possibly shouldn©t have received equal weighting.

Comparisons based on steering assembly EA properties showed better distinction between high- and low-ranked cars. The Mustang showed significantly lower HIC and chest deflections than the Valiant, although abdomen deflections were higher in the Mustang (the Fuego results were not valid since the simulations aborted prior to significant occupant/compartment interaction). The Granada gave the lowest injury measures of all cars that were simulated. In comparisons with the Valiant, the HIC's in all cases were lower and chest deflections lower by 2in or more in all but the 10mph case, which only had about 1in deflection. The results of all simulations are shown in Table 3, and the comparison of Granada to Valiant is shown in Figure 16. To display HIC and chest deflection on the same graph, they are presented as AIS level. Formulas for chest and abdomen AIS are given in (5); head AIS based on HIC is given in (6).

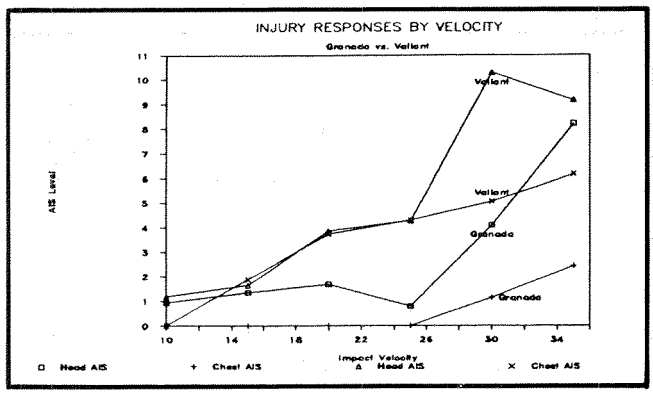

Figure 16. Granada and Valiant responses

Simulation of Other Properties

The Valiant was selected to introduce variations in other steering assembly properties. The same set of simulations, as discussed previously, was conducted for the following parameter variations: 4 lb wheel + column weight; 0 and 4in hub recessions; 0 friction and damping (Valiant has 0 friction as tested); 0 column and wheel angle; and improved column EA properties (LeSabre column). Table 4 shows the results for the runs.

	HIC	145	379	971	1083	1413	9999
0 Damping	Chest Def.	0.9	3.2	4.1	4.3	4.4	4.9
	Abdomen Def.	1.6	1.9	2.0	2.0	2.1	2.1
	HIC	211	459	364	390	567	1025
0 Column	Chest Def.	0.5	0.6	2.0	4.5	4.5	4.8
Angle	Abdomen Def.	0.0	0.0	0.0	0.0	0.0	0.0
	HIC	287	382	1481	1321	9999	2361
LeSabre	Chest Def.	0.9	3.3	4.2	4.5	4.8	4.9
Column	Abdomen Def.	1.6	1.9	2.0	2.0	2.1	2.1

All of the variations simulated produced lower chest deflections. The cases of 4 lb wheel/column weight, 0 hub recess, 0 damping, and addition of the LeSabre column did not improve (or worsen) the other injury measures. The case with the column angle at 0° eliminated abdomen deflection and substantially reduced the HIC. The 4in hub recession had the lowest chest deflections (over 1in reduction in most cases) and somewhat lower HIC values. It appears, at this point, that 0 column angle and 4in hub recession produced the highest reduction in injury measures of those evaluated.

Simulation With Improved Properties

The final set of simulations involved developing a set of driver compartment properties, which should result in the lowest injury measures for the PADS simulations, based on the previous countermeasure evaluation. All the improved properties are judged to be production feasible, since all improvements were similar to the characteristics of at least one of the 27 vehicles. The modifications to the baseline Valiant data set included the following:

Knee Panel		Lower Rim Tangent		Lower Rim Radial		Hub		EA Column	
Force (lb)	Defl. (in)	Force (lb)	Defl. (in)	Force (lb)	Defl. (in)	Force (lb)	Defl. (in)	Force (lb)	Defl. (in)
0.	0.	0.	0.	0.	0.	0.	0.	0.	0.
200.	0.75	250.	0.5	250.	1.0	300.0	1.0	800.	2.0.
500.	3.0	350.	10.0	500.	5.0	500.	5.0	1200.	3.0
1200.	5.0					2000.	5.5	1250.	8.0
3000.	12.0							1600.	8.5
								5000.	9.0

Other modifications include: 4in hub recession; 0 column friction and damping; and 4 lb wheel + column weight. Zero column angle was also tried but, due to occupant/compartment geometry, problems occurred in these runs. This will be resolved in the future.

The results of these simulations (shown below and in Figure 17) with the best properties showed substantial reductions over the baseline Valiant in the three injury measures evaluated.

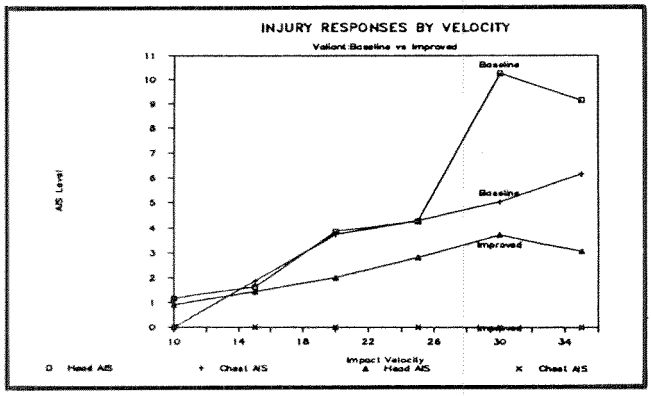

Figure 17. Comparison of baseline Valiant to Valiant with improved properties

frontal crashes. This baseline analytical characterization is being used to—

1. Identify possible relationships between vehicle attributes (structural, steering assembly, interior geometry, etc.) in the baseline fleet and injury causation
2. Test the effectiveness of the best countermeasures (such as those discussed in the previous sections related to the steering assembly and structure) in a fleetwide accident environment.

Baseline Simulation Data Base

The automated procedure for simulating the baseline fleet was implemented using the analytical tools discussed previously. Each of the 27 make/model vehicle groupings that compose the baseline fleet were simulated under varying crash conditions, including a range of velocities (10 to 35mph), damage locations (distributed, offset, and center), and object contacted (vehicle and tree/pole). Three occupant sizes (5th, 50th, and 95th) were considered. While not all combinations of these parameters are required (i.e., vehicle-to-vehicle center impacts), the various combinations resulted in 54 simulations for each make/model vehicle grouping (6 velocity categories, 3 crash distribution/object struck categories, and 3 occupant size categories). Thus, the total simulations amounted to 54 × 27 = 1,458 runs. Not all of the individual simulations successfully ran to completion. A judgment was made to reject any simulations that did not run at least 110ms. Out of the 1,458 possible simulations, 1,175 passed this criterion, which was felt to be extremely successful considering the wide range of environments in which the model was being exercised. Thus, the baseline simulation data base is composed of these 1,175 simulations and was used for all the analyses presented in this paper. As time permits, the simulations that did not meet the run time criteria will be examined to determine the cause of the problem and to determine whether not using these runs leads to any bias in the data when considering the aggregate results.

Case	Criteria	Velocity Change (mph) 10	15	20	25	30	35
Baseline Valiant	HIC	202	387	1192	1331	7986	2722
	Chest Def.	0.8	3.2	4.2	4.5	4.9	5.5
	Abdomen Def.	1.6	1.9	2.0	2.0	2.1	2.1
Valiant with Improvements	HIC	93	314	538	839	1149	925
	Chest Def.	0.5	1.1	1.2	1.3	1.7	1.6
	Abdomen Def.	1.1	1.4	1.4	1.5	1.5	1.5

These results show minimal injury, based on predicted AIS for deflection, for either the chest or abdomen. The HIC at 30mph may result in serious injury; however, in this series of countermeasure evaluations, attention was on chest and abdomen injury and no modifications were made to head impact areas.

Future countermeasure evaluation will be to apply an improved set of countermeasures to the 27 vehicles to predict injury reduction over the baseline.

Analysis of Accident and Simulation Data for Baseline Fleet

As mentioned in the introductory sections of this paper, a primary effort within the frontal crashworthiness research and development program is the analytical characterization of the in-use vehicle fleet involved in

Baseline Fleet Accident Data

Comparison of the results of the simulation data with accident data can provide additional support to the validity of the analytical modeling process and can provide a linking process to help in projecting changes in the accident environment from simulation results. This and the next several sections present results related to performing this comparison.

First, analyses were performed comparing NHTSA's complete accident files, including the NCSS and NASS, with subfiles consisting of accidents involving the vehicles in the 27-vehicle groupings. This was done to insure that the 27 make/model vehicle groupings selected as representative of fleetwide vehicle production are also representative of the accident environment. The 27-vehicle accident file is being compared to the complete files for crash, occupant, and vehicle factors and also as to injury consequences.

Figure 18 presents a comparison of the probability of receiving an AIS 3 or greater injury for the 27-Vehicle,

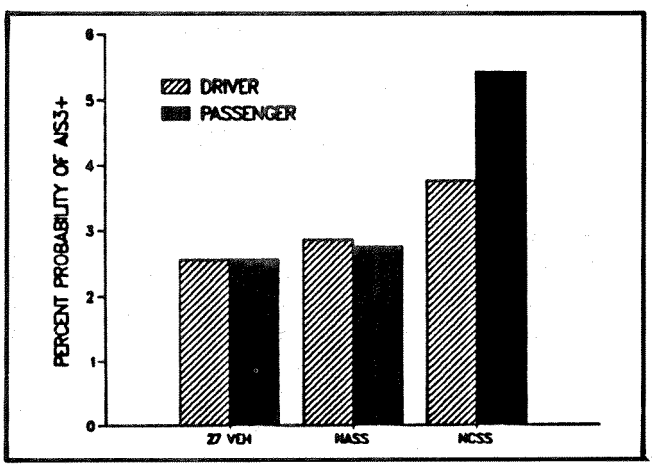

Figure 18. Probability of receiving an AIS injury of 3 or greater

NASS, and NCSS files. The 27-vehicle file was constructed from the NASS file, and thus better agreement can be expected between these files. Remaining comparisons focus on the driver seating position since this is the main focus of this effort. Table 5 compares the three files for body region injured for serious (AIS 3 or greater) injuries received by drivers. The distributions are based on a count of injuries and not occupants (i.e., one occupant could have received more than one injury at an AIS 3 or greater level). Table 6 compares the files for the source of serious injuries. The distributions in both figures show good agreement.

Figures 19 to 21 compare the delta v, damage location/distribution, and object-contacted distributions for the three files related to crashes in which a driver received a serious injury (AIS 3 to 6). As seen from these figures,

Table 5. Distribution of body regions injured (AIS 3+) for drivers

Body Region	27 Vehicle	NASS	NCSS
Chest	22%	27%	31%
Head	7	13	8
Lower Extremities	30	22	20
Upper Extremities	5	6	6
Abdomen	14	14	17

Table 6. Distribution of body regions injured (AIS 3+) for drivers

Injury Source	27 Vehicle	NASS	NCSS
Steering Assembly	42%	44%	54%
Windshield	9	5	4
Instrument Panel	22	18	18
A-Pillar	2	2	2
Header	1	2	2
Unknown	9	15	6

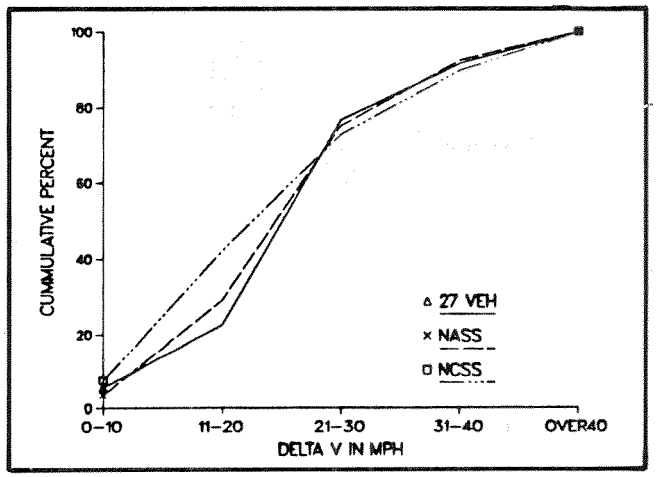

Figure 19. Distribution of delta v for seriously injured drivers

there is excellent agreement between all distributions. While additional comparisons between these files are continuing, it appears the 27 make/model vehicle groupings are representative of the accident environment.

For the remaining analyses between the simulation results and the accident data, the total NCSS and NASS files were utilized rather than the 27-vehicle accident file. Since the files appear to agree with each other on several variables, the use of the complete files offers a larger sample size, which, in turn, will permit more disaggregate analyses.

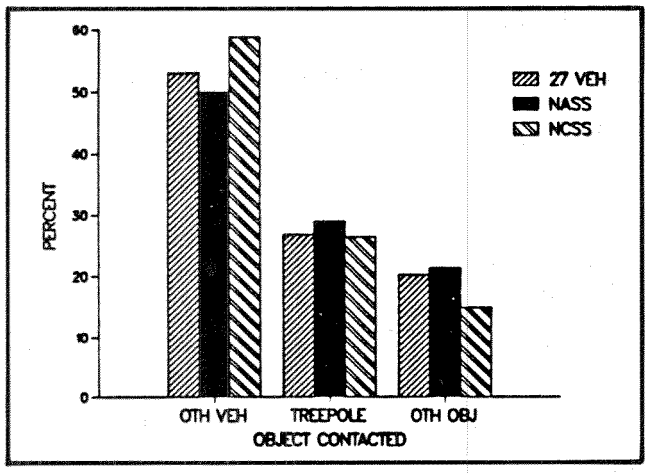

Figure 20. Distribution of object contacted for seriously injured drivers

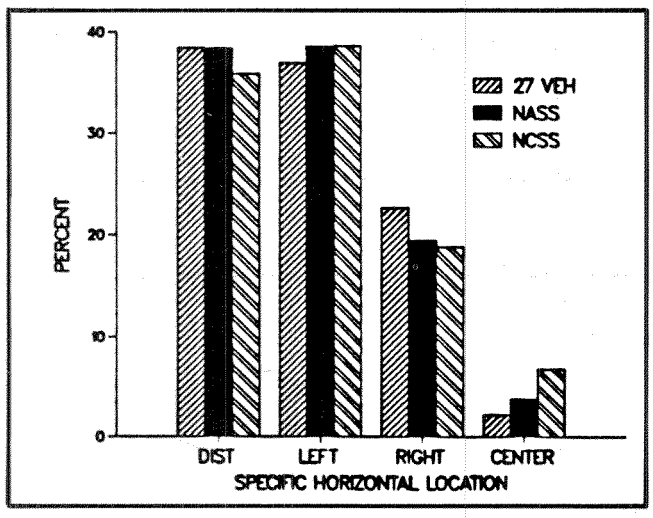

Figure 21. Distribution of location of vehicle damage for seriously injured drivers

Extrapolation of Simulated Runs To Reflect Accident Environment

As discussed, the PADS model was run for the 27 vehicles, several occupant sizes, different crash conditions, and different velocities. Each run represents a specific condition in the accident environment. Since each run does not represent equally occurring events in the environment, each run must be assigned a weighting or expansion factor to allow meaningful comparisons with accident files. The NASS file is being used to develop weighting factors associated with each simulation. The overall weighting factor is based on the specific make/model, the occupant size, the object struck, the location of damage, the delta v, and the weight of the vehicle. Many of these variables are interrelated, and the weighting factors were developed for combinations of the factors.

Comparison of Simulated Baseline With Accident Data

The focus of the comparisons presented in this section is on chest, abdominal, and head body regions, which account for the greatest harm to drivers in frontal crashes.

Initial comparisons focused on sources of injury predicted by the simulation data base and the accident files. For the chest and abdomen, as could be expected, the steering assembly was the primary area of injury. In comparing head contacts between the simulation results and the accident data, the following items must be considered:

1. PADS is limited to simulating contacts only with frontal surfaces and cannot consider contacts with A-pillars, side interiors, etc.
2. There are a large number of unknown contact sources in the accident data that need to be distributed.
3. For the PADS simulations, multiple contact sources are indicated for each body region impact. Thus, if the head contacts the header and windshield, the PADS simulation will indicate both sources as a possible injury source. For the accident data, only one contact source per injury is coded.

Table 7 indicates the source of serious head injuries (AIS 3 to 6) for drivers in frontal impacts as indicated by NCSS and NASS. Only the most serious head injury is considered. That is, if a driver received an AIS 3 and an AIS 4 head injury, only the source of the AIS 4 injury was considered. The first column in the table shows the distribution of sources including unknown sources. For NASS, this amounts to approximately 25 percent of the injuries. The second column presents the distribution of sources excluding the unknown category. The third column presents the distribution for only those sources of injury for the head that are modeled in the PADS simulations—the windshield, header, steering assembly, and upper instrument panel. Table 8 indicates the source of serious injury as predicted by the PADS simulations. As discussed above, multiple sources of injury are reported if the head contacts more than one interior surface. To compare these results with those of NCSS and NASS, the multiple sources had to be distributed among the steering assembly, windshield, and header. The second column shown in this table was constructed by equally distributing the multiple sources to each of the appropriate sources. Table 9 presents the distributions developed in the previous tables, which focus on the four contact sources. Considering the high percentage of unknown contact sources in the accident data and the subjective manner of dividing the multiple contact sources in the PADS simulations, the distributions for NCSS,

Table 10. Injury severity by delta v indicated by NASS and PADS

Injury Severity	Body Region Injured					
	Chest		Head		Abdomen	
	PADS	NASS	PADS	NASS	PADS	NASS
AIS 0	29%	63%	12%	73%	17%	91%
AIS 1-6	71%	37%	88%	27%	83%	9%

examine the probability of a serious injury given a contact occurred. Since the accident files do not indicate contacts unless an injury occurred, this type of analysis could not be accomplished. However, a reasonably close estimate of this can be obtained assuming that, if contact is made, at least an AIS 1 injury would have resulted. This would seem to be a reasonable assumption, especially at the higher delta v levels. Thus, the different files were compared on the basis of the probability of a serious injury given that an injury occurred (AIS 1 to 6).

Figure 23 presents the comparisons for the three files for the head, chest, and abdomen. The comparisons are for the probability of receiving an AIS 3 or greater injury. As can be seen, while there still exist fairly large differences in specific categories, the three files are in much closer agreement than in previous comparisons.

Figure 24 presents the results of an additional analysis related to explaining these differences. The accident files were rerun using filters that more closely matched the crash conditions being simulated by PADS. The crash pulses used in PADS tend to overrepresent the severe types of crashes (head-on). In addition to the filter of the general area of damage equal to front, filters were added to limit crash conditions to 12 o'clock direction of force, head-on car-to-car, and car-to-tree/pole conditions. The figure only presents the results for one delta v (26 to 35mph) and only for the NASS file. As can be seen, the probabilities for the chest and abdomen increase by approximately 40 percent, while the probability for head injuries decreases by about 10 percent. In general, the addition of these filters would further close the differences between PADS and the accident files.

Additional analyses are continuing in an attempt to understand the differences between PADS, NCSS, and NASS. Based on the results of the analyses presented, it is felt that the PADS automated runs scaled to the accident data can be considered a useful tool in developing information for predicting how vehicle modifications can affect the consequences of injury in the accident environment.

Future Analysis of PADS and Accident Data

Disaggregate Analyses

The previous sections examined the accident and simulation data at an aggregate level. It is planned to also examine the results at a disaggregate level (i.e., at a make/model vehicle group level).

For the accident data, it is not possible to use NASS and NCSS at this disaggregate level because of limitations in sample size. FARS and various State accident files will be examined for potential use in these analyses.

At the time of preparing this paper, these analyses have just been initiated, and results are not available. The analyses underway are using the injury severities predicted by PADS and accident files for the individual make/model groups and examining correlations with the vehicle attributes identified in the previous sections on structures and steering assemblies. The results of these analyses should help further in the identification of important attributes to consider in mitigating injuries.

Harm Reduction

The results presented above relate to the complete baseline PADS simulations. It is planned to make a number of complete simulations with a modified fleet that includes the best countermeasures as determined through the analyses described earlier relating to structures and steering assemblies. Total fleetwide harm reduction can be estimated by comparing the injury consequences of the baseline fleet to the modified fleet.

Conclusion

Structural Improvements

The findings in this research effort are preliminary since research is continuing. However, results to date show significant overall fleet safety improvements may

NASS, and PADS appear fairly similar. (Differences in these distributions may be attributed to the planar representation used in PADS as discussed later.)

The next series of figures presents comparisons for the three files related to the probability of receiving serious injuries. Since PADS does not predict injuries for all body regions, the overall probability of receiving a serious injury to any body region could not be compared between PADS and the accident files. Thus, the comparisons analyzed were for the probability of receiving a serious injury to specific body regions. The body regions considered included the head, chest, and abdominal areas. The comparisons are shown in Figure 22. While the probability of being severely injured in crashes with high delta v's is high, the probability of getting a severe injury to any one specific body region is much lower. From the figure, it is noted that for all files the probability of serious injury increases with increasing delta v in a similar manner; however, the probabilities predicted by PADS are much larger than for NASS and NCSS.

A number of analyses are being undertaken to understand the differences in probabilities between PADS, NASS, and NCSS. Table 10 presents detailed data related to injury severity by delta v for the PADS and NASS files. The example given is for a delta v range of 26 to 35mph. As can be seen, NASS has a much higher percentage of occupants receiving no injury to a particular body region.

These differences could be attributed to differences in the probability that a certain body region contacts a specific interior component. PADS is a two-dimensional model with the occupant seated directly in front of the steering assembly, and the kinematics of the occupant represent those expected in a 12 o'clock, head-on type impact. The simulations almost always produce contact with the steering assembly. In the accident data bases, however, conditions exist in which the occupant might not contact the steering assembly directly. These conditions include—

- Direction of force at 11 or 1 o'clock
- Off-center impacts
- Occupant protective actions
- Submarining
- Out-of-position seating position

Thus, it was felt that a more appropriate comparison between PADS and the accident files would be to

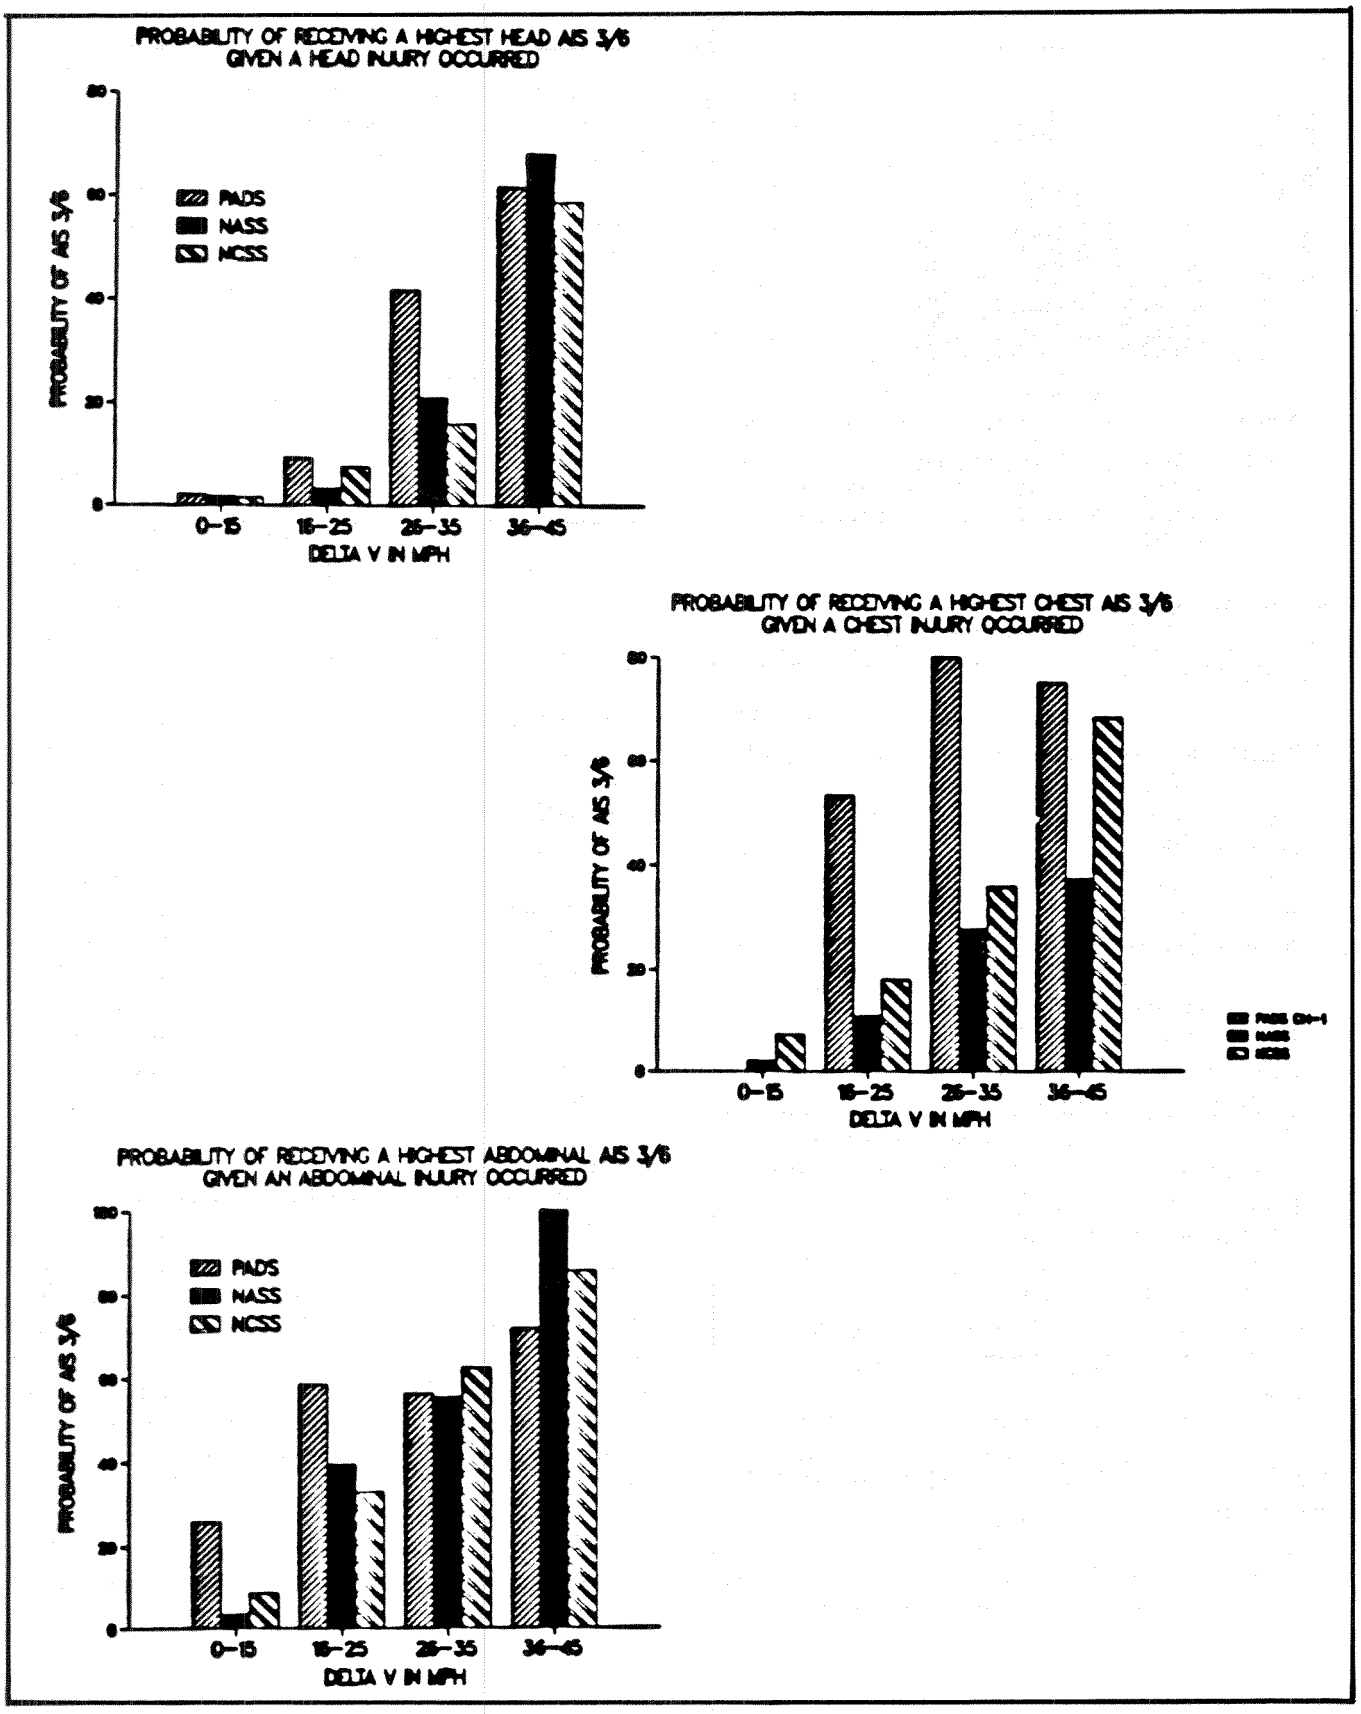

Figure 23. Probability of driver receiving a serious head, chest, or abdominal injury given a serious injury to that body region

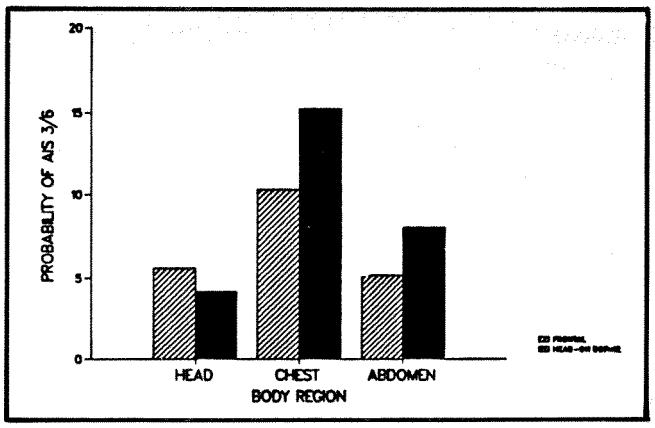

Figure 24. Probability of driver receiving a serious injury to the head, chest, or abdomen at a delta v of 26 to 35 mph for different crash conditions

be made by changes in structure. Furthermore, these potential structural changes are identified by vehicle properties in the fleet.

Accident and Simulated Data for the 27 Vehicles

1. The automated PADS simulation procedure was implemented. Eighty percent of the almost 1,500 runs that represent the vehicle and accident environment ran successfully.
2. Accident data related to the 27 make/model groupings appear to be representative of the complete NCSS and NASS files.
3. While there are differences between the simulated data and the accident data base as to injury severity predictions, it is felt that through the application of adjustment factors the PADS automated procedure is a useful tool in developing information for predicting how vehicle modifications can affect the consequences of injury in the accident environment.
4. Analyses are continuing using the simulation and accident data bases on a disaggregate level to correlate injury rates at a make/model level with vehicle attributes particularly related to structure and steering assembly.

Steering Assembly and Driver Compartment Improvements

1. Comparison of simulation results for high- and low-ranked vehicles, based on an analytically derived parameter for the steering assembly, showed significantly lower injury measures for the high- ranked car. This parameter was computed from the EA characteristics and force levels of potential impact surfaces.
2. PADS simulations with variations of other steering assembly properties (wheel/column weight, column angle, column friction and damping, and hub recession) produced the lowest injury measures for a column angle of 0° and a 4in hub recession.
3. Based on results of previous simulations and other factors, a best set of steering assembly and knee restraint properties was developed. Simulations of a baseline vehicle and the same vehicle with these improvements resulted in dramatic reductions in injury measures.

Based on computer simulations using PADS, the countermeasure evaluation has shown that by applying certain exterior structural and/or compartment interior improvements, injury measures can be reduced significantly. The next phase of this project is to apply these countermeasures to the entire 27-vehicle fleet to estimate fleetwide injury reductions.

Comparative Evaluation of the MVMA2D and the MADYMO2D Occupant Simulation Models With MADYMO-Test Comparisons

Priya Prasad
Ford Motor Company

Abstract

This paper compares and contrasts the modeling features present in the MVMA2D and the MADYM02D occupant simulation models. Simulations of a series of sled tests with a Hybrid II test dummy restrained with a 3-point belt system have been conducted using the MADYM02D model. The simulation results agree with the test results.

Introduction

Several mathematical models have been developed to simulate both vehicle occupants in crashes and pedestrian impacts. Over the years, the MVMA2D occupant simulation model(1) has been used extensively in the automobile industry for two-dimensional simulation of occupants or pedestrians involved in crashes. In recent years, a new two-dimensional model—the MADYM02D(2)—has been under development at TNO, Holland. Even in its current stage, it appears to be a powerful tool for simulation of vehicle occupants or pedestrians involved in crashes. Both these models contain some common features as well as some features that are unique.

This paper compares and contrasts the two models so further developments in these models may incorporate the features missing in one but present in the other. Additionally, simulations with the MADYM0 model of a series of sled tests have been carried out and compared to test results.

General Description and Comparison

Occupant Model

Both models treat the vehicle occupant as being made up of a collection of rigid bodies interacting with one another through hinged joints. Basically, the occupant is described as an open chain or tree. In the MVMA2D, the occupant is described by nine rigid bodies representing the head, neck, upper torso (chest, thoracic spine), mid-torso (abdomen and lumbar spine), lower torso (pelvis), upper leg (femur), lower leg (tibia and fibula), upper arm (humerus), and forearm (ulna and radius). The current formulation of the MVMA2D model does not permit the addition of any more rigid bodies to the occupant (e.g., the foot or a multi segment neck as in the Hybrid III dummy). Also, the MVMA2D model cannot be simplified to have less than nine rigid bodies.

In the MADYM0 model, the occupant can be described by one to any number of rigid bodies depending on the capacity of the computer, as long as the tree structure is maintained, i.e., no closed loops are allowed (Figure 1). Furthermore, in the MADYM0 model, several tree structures interacting with one another can be simulated.

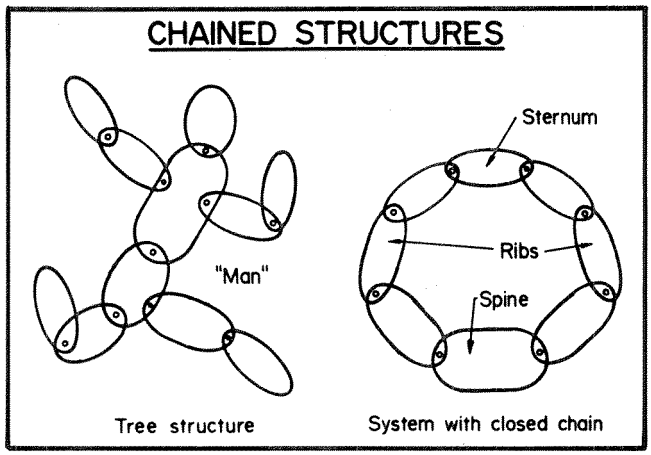

Figure 1. Pictorial representation of a tree structure and a closed loop system

The importance of this feature in the MADYM0 model is that collapsible (energy-absorbing) steering columns, children belted in child seats that in turn are belted in a car, etc.; can be simulated by proper definition of various trees. It should be noted that although the MVMA2D does have a collapsible steering column module, this module has not produced acceptable simulations and thus requires considerable debugging.

Two features used in the MVMA2D to describe the occupant are not currently in the MADYM0. The MVMA2D has extensible neck and shoulders, which are useful features for human and cadaver simulations. Additionally, active muscle tensions in the neck joints can be simulated in the MVMA2D(3). Although the MADYM0 manuals state that muscle tensions can be simulated by negative damping, its use has not been demonstrated in the literature.

Joint Model

Both the models treat the joints between the rigid bodies in similar ways. In both models, the joints can develop elastic, viscous, and frictional torques. The

elastic torque model in the MVMA2D is shown in Figure 2. As shown in the figure, the joint torques are described by a linear and nonlinear range by means of polynomials. Also in the nonlinear range, the joints can dissipate energy through hysteresis. The elastic joint torques in the MADYM0 model are described in tabular form. Therefore, complex shapes of joint torque versus relative angular deflections can be described. However, in the version available from TNO, there is no mechanism to dissipate the stored elastic energy as in the MVMA2D model. A simple algorithm to dissipate the elastic energy has been incorporated in the model at Ford.

The viscous and frictional torques in the joints are handled essentially the same in both models. Both models use ramps to avoid numerical instabilities in the frictional models.

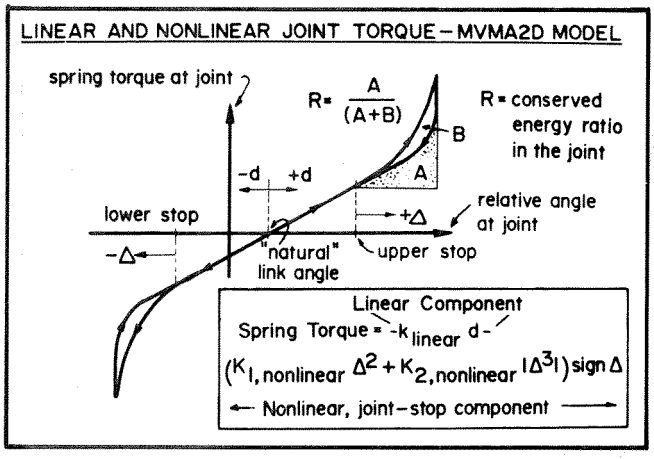

Figure 2. Joint torque description

Contact Model

The interaction between the occupant and the vehicle interior is detected by contact ellipses and planes. In the MVMA2D model, the vehicle interior is described by planes. Ellipses are attached to the occupant to sense and develop contact forces. When contact between the ellipses and planes takes place, reaction forces between the occupant and the vehicle are generated. These forces can be described by polynomials or in tabular form as a function of the depth of penetration of the occupant ellipses into the planes. Hysteresis can be simulated by assigning "R" and "G" factors as shown in Figure 3. There is no provision for rate-dependent reaction forces, such as viscous forces. Additionally, ellipse-to-ellipse contacts can also take place and reaction forces generated. This is useful for simulating chin/chest, head/knee, thigh/chest, etc., contact forces.

In the MADYM0 model, all the above features are present with the addition of a few other features. Perhaps the most useful additional feature is the ability to attach

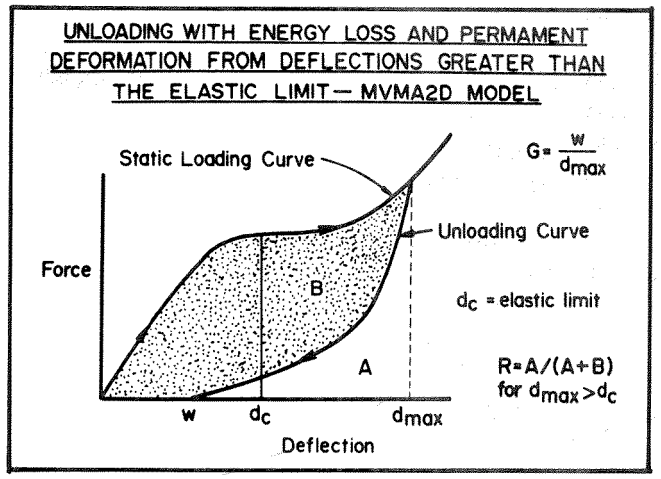

Figure 3. Description of hysteresis

ellipses or hyperellipses to the vehicle interior to simulate curved surfaces, and to attach planes (as well as ellipses) to the occupant. In addition to the linear or nonlinear contact forces, viscous forces also can be developed during contact. Hysteresis is simulated by unloading stiffnesses specified in the contact model.

Frictional forces can be developed in both models. The friction model in the MVMA2D is more general than that in the MADYM0. Whereas the coefficient of friction in the MADYM0 can be only a constant value, the coefficient of friction in the MVMA2D can be varied as a function of penetration. This feature of the MVMA2D has been used by many modelers to simulate the ploughing effect between the pelvis and the seat cushion as the pelvis moves with respect to the seat cushion in a crash.

The contact planes in the MVMA2D models can be moved as a function of time to simulate intrusion of vehicle components likely to be contacted by the occupant. This feature is not currently available in the version of the MADYM0 from TNO. However, this feature, along with the ability to prescribe motion to the contact ellipses, has been incorporated in the model at Ford.

Restraint Systems

Belt Restraint

The MVMA2D and the MADYM0 models have advanced belt subroutines that simulate the three-dimensional aspect of commonly used 3-point belt restraint systems. Inertia-locking retractors can be simulated in both models. However, neither can simulate pyrotechnic retractors, which tighten the belt during the crash sequence. Both can allow a user to study the effects of belt slack or pretension on occupant responses.

Both models can simulate continuous loop belt restraint systems. The MVMA2D belt system allows for the

simulation of the roof-mounted slings found in some cars and a buc le strap on the lower inboard side. The MADYM currently does not have these features. In the MADYMU, the inboard belt buckle is simulated, but the buckle is fixed to the vehicle. The general description of the belt systems and the data required for simulating the belt geometry are shown in Figures 4 and 5. It should be noted that in both models, the shoulder belt and lapbelt are prescribed to pass through fixed attachment points on the chest and pelvis. In both models, the belts can be attached to other body segments, if required.

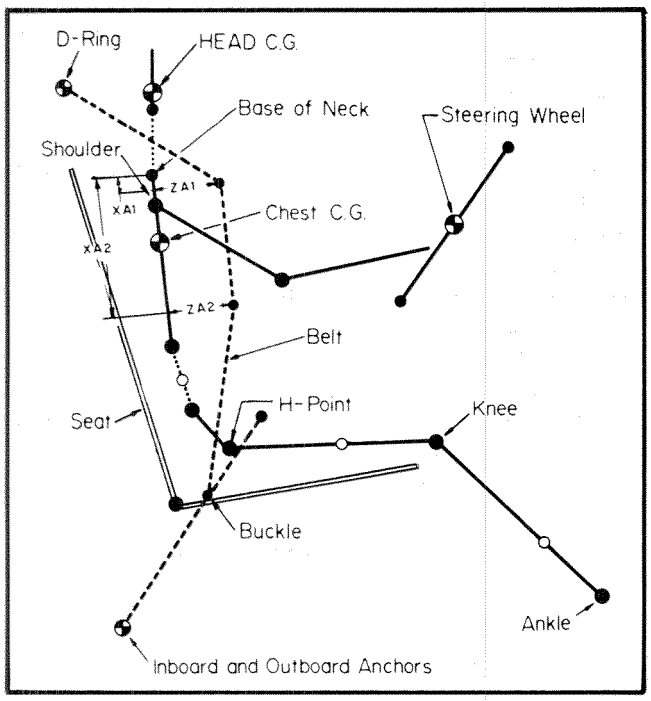

Figure 4. Initial geometry for a 5-segment belt simulation—side view

An important feature of the belt simulation not present in the MVMA2D is the incorporation of the film spool effect in the MADYM0 model. This feature is useful for simulating the effect of various amounts of webbing extension from the retractor under loading.

Airbag

The MVMA2D contains an airbag model originally described by Hammond(4). The airbag model can be used for the driver or the passenger, although the bag cannot be mounted on a collapsible column. An advanced airbag model is being developed for the MVMA2D.

The MADYM0 does not currently have an airbag model. Under contract with Ford, a driver-side airbag that can be mounted on a collapsible steering column is being developed at TNO, Holland. This model incorporates the features of DRACR(5)—an airbag/column model.

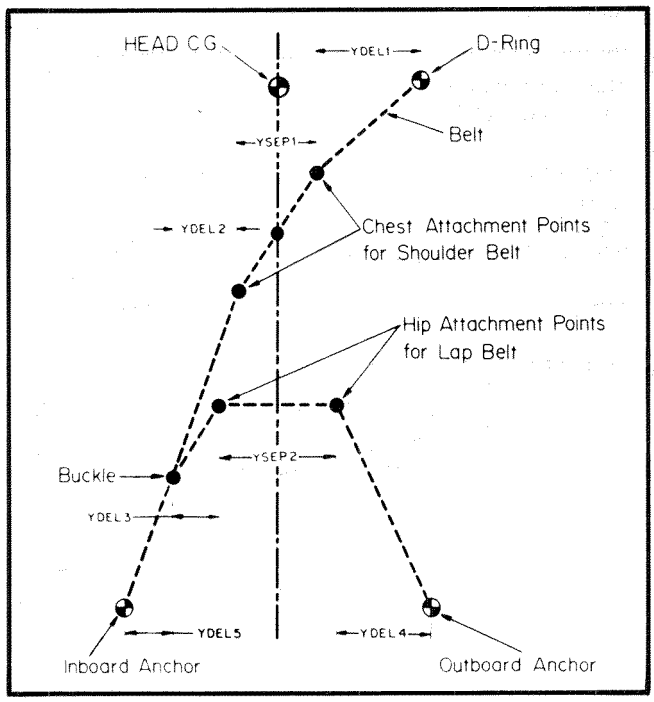

Figure 5. Initial geometry for a 5-segment belt simulation—front view

MADYM0 Simulations

Various studies utilizing the MADYM02D model have been reported in the literature(6,7,8). However, none has addressed the use of the MADYM0 for simulating the Hybrid II (Part 572) dummy in the automotive environment during sled or full-scale crash tests. A series of sled tests using the Hybrid II dummy and a production type 3-point harness system was conducted for comparing MADYM0 simulation results with actual tests. The goal of these tests was to provide restrained dummy responses to three levels of sled accelerations in a highly controlled laboratory environment.

The initial velocity of the sled was nominally 56km/h (35mph). The sled was brought to rest with a series of essentially trapezoidal acceleration pulses (Figure 6). The sled stopping distances were 915, 810, and 700mm (36, 32, and 27in). The restraint system geometry and the initial seated position of the Hybrid II dummy are shown in Figure 7. The lateral dimensions required for the simulations of the belt system geometry are shown in Table 1. A horizontal hard seat pan was used in the tests. The nominal elongation of the belt was 7.5 percent (i.e., 7.5 percent stretch at an applied load of 11.1kN (2,500 lb)).

Table 1. Lateral belt system dimensions.

Lateral Separation From Dummy Mid-Saggital Plane (mm)			
Retractor	399	Upper Chest Attachment	110
D-ring	254	Lower Chest Attachment	69
Inboard Anchor	229	Inboard Pelvis Attach.	140
Outboard Anchor	305	Outboard Pelvis Attach.	170

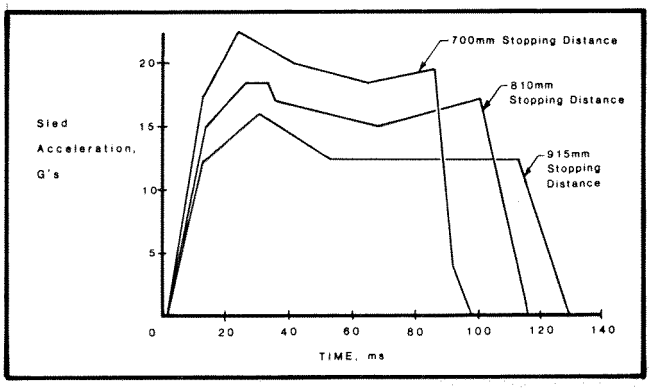

Figure 6. Sled acceleration pulses

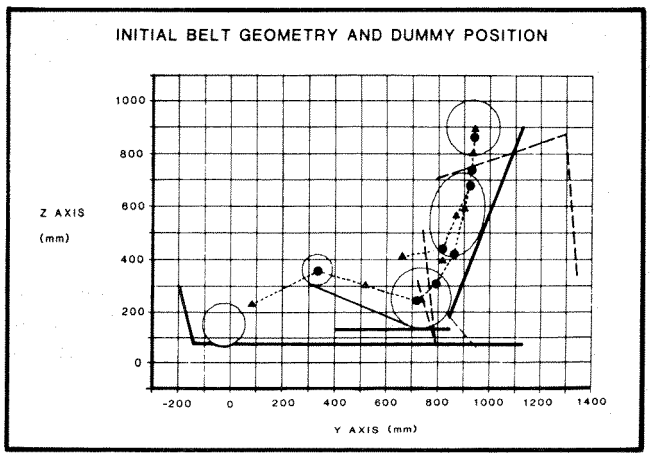

Figure 7. Dummy and restraint system test geometry

Modeling Assumptions

Dummy

To be compatible with the MVMA2D model, a nine rigid link representation of the dummy was used for this study. Thus, the feet of the dummy were not simulated. The inertial and joint torque characterization used for the dummy were those published in the literature(9). It should be noted that the neck and lumbar spine of the dummy are actually flexible elements. Their representation in the model by rigid links with two joints each is a simplification of the system. The dummy link lengths and joint torque characteristics used in the simulations were those determined by Calspan(9).

Restraint System

The anchor locations for the restraint system were simulated exactly as in the tests. However, the inboard strap used in the test was not simulated since the MADYM0 does not have this feature. As a result, the part of the shoulder belt leading from the chest to the inboard buckle was assumed in the model to extend from the chest to the inboard floor-tunnel anchor point. Similarly, the inboard portion of the lapbelt also was assumed to extend from the pelvis to the same inboard anchor point. These simplifications of the belt geometry are not expected to have a major effect on the model results since the inboard strap is made of an 8in piece of webbing that can stretch also.

The webbing stiffness of the shoulder portion of the belt from the retractor to the inboard anchor location was assumed to be 10 percent to account for the deflection of the chest. The retractor outlet function ("film spool effect") was measured in one test with a belt load cell and a string potentiometer. This function was assumed to be the same for all the tests and is shown in Figure 8.

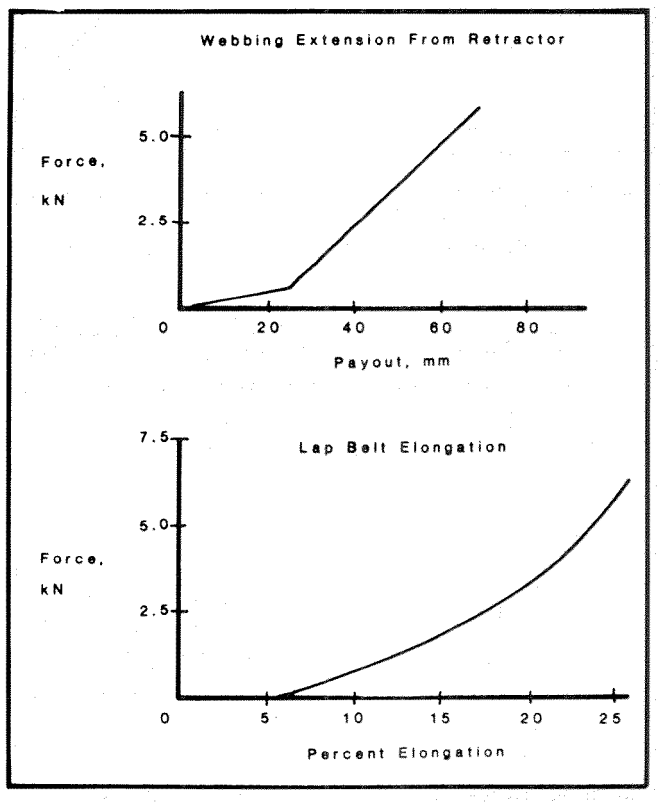

Figure 8. Belt system characteristics

Since there is considerable compression of the dummy pelvic flesh when loaded by the lapbelt, the effective lapbelt characteristics were determined by a static test. They are shown in Figure 8. Also, the effective points of application of the belt loads were assumed to be in the deformed position of the pelvic flesh.

New sets of belts and associated hardware (retractor and buckle) were used in all the tests. It is possible that the webbing stiffnesses and retractor characteristics were not identical in all the tests. Also, high-speed movies of the tests showed deformation of some of the anchor hardware. However, for the model exercises, the belt system characteristics were assumed constant in all the tests and hardware deformation was not simulated.

Seat

A hard seat pan without foam was used in the tests. Therefore, a high stiffness of 710N/mm (4,000 lb/in) was assumed for the seat material. The exact stiffness of the seat-pelvis system is not known.

Model Results and Comparison to Tests

The results of the simulations and their comparisons with test results are shown in Table 2 and Figures 9 through 20. It can be seen from the table that the peak head accelerations predicted by the model are within 5g's of those measured in the tests. The general shapes of the head acceleration-time histories agree well with the tests. The HIC's predicted by the model deviate by a maximum of 67 out of 595 when compared with the test results. The horizontal movement of the head center of gravity predicted by the model is within 20mm of those observed in the tests. However, the vertical movement of the head center of gravity predicted by the model appears to be 75 to 100mm more than those observed in the tests. Three main factors appear to explain the differences. Some out-of-plane movement of the dummy was observed in the tests but cannot be simulated with a two-dimensional model. Chin-chest contact appears to have occurred in the tests but has not been simulated by the model due to lack of chin-chest stiffness data. Also, the model predicts

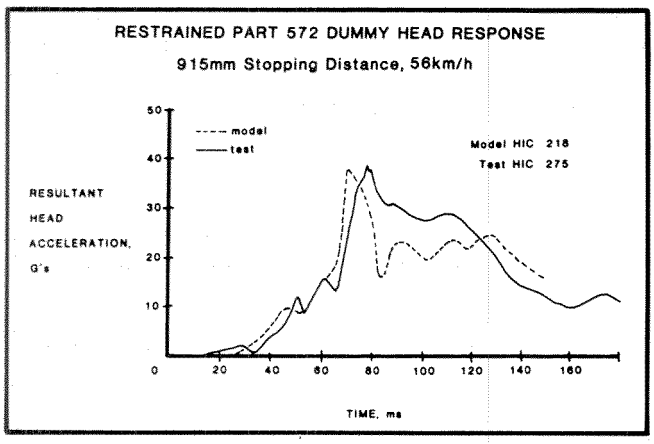

Figure 9. Model and test comparisons—head acceleration—low severity pulse

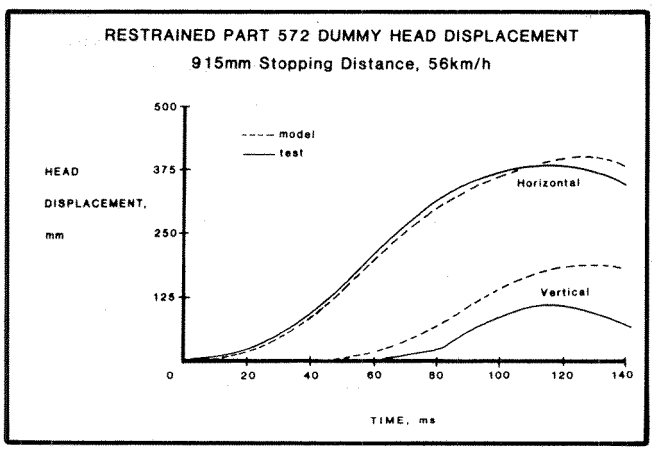

Figure 12. Model and test comparisons—head displacement—low severity pulse

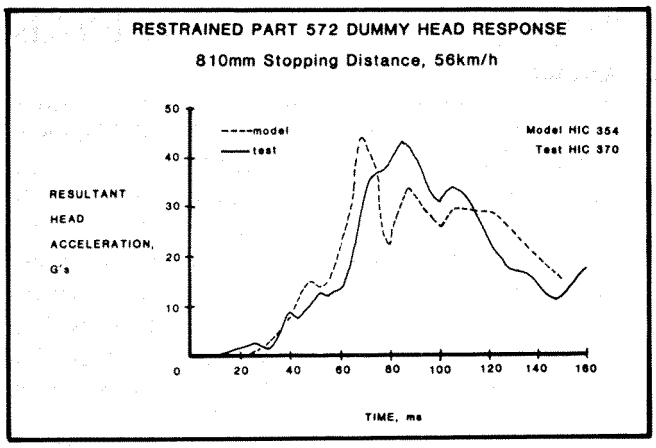

Figure 13. Model and test comparisons—head acceleration—medium severity pulse

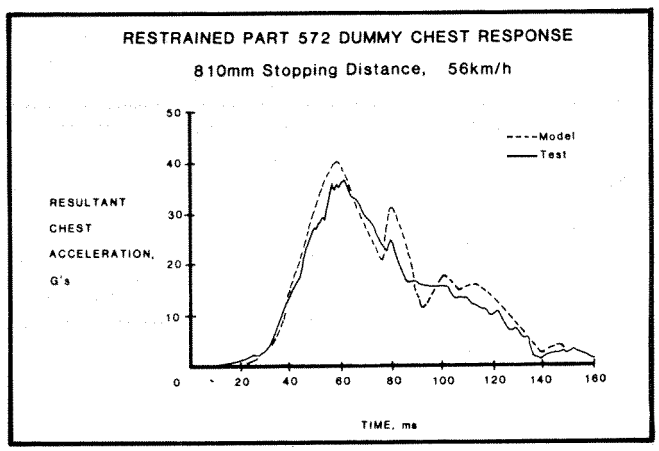

Figure 14. Model and test comparisons—chest acceleration—medium severity pulse

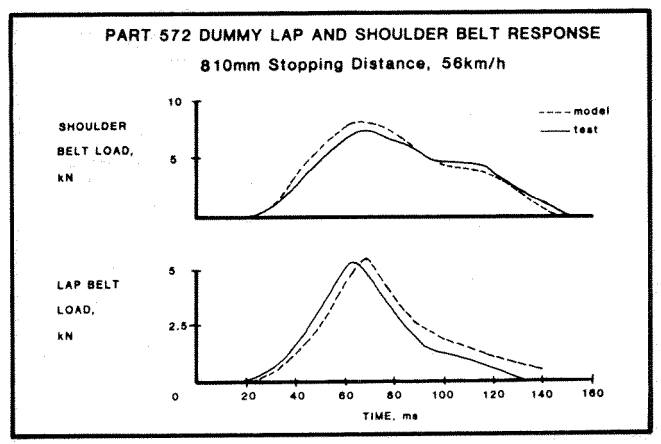

Figure 15. Model and test comparisons—belt loads--medium severity pulse

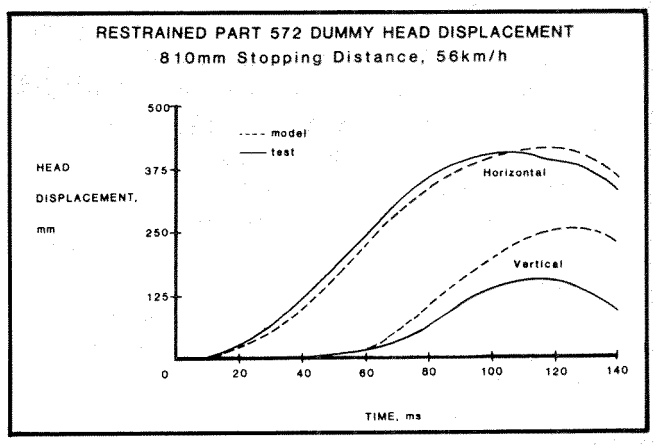

Figure 16. Model and test comparisons—head displacement—medium severity pulse

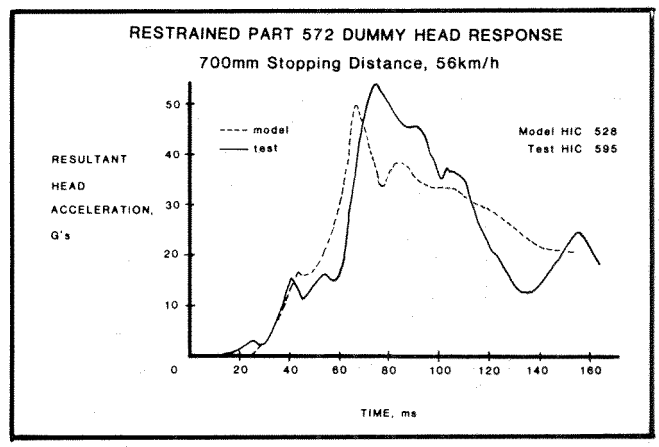

Figure 17. Model and test comparisons—head acceleration—high severity pulse

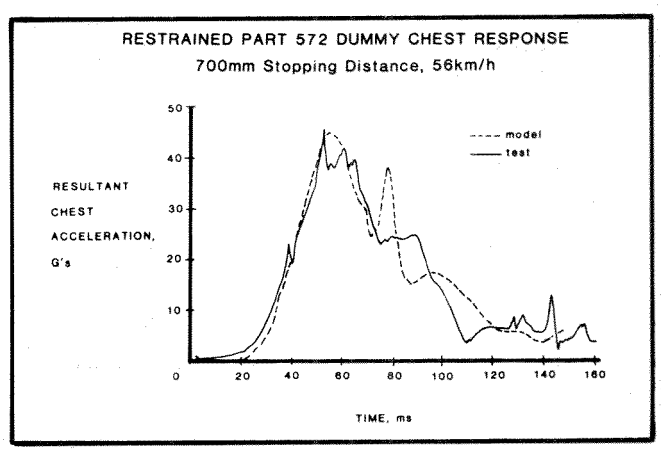

Figure 18. Model and test comparisons—chest acceleration—high severity pulse

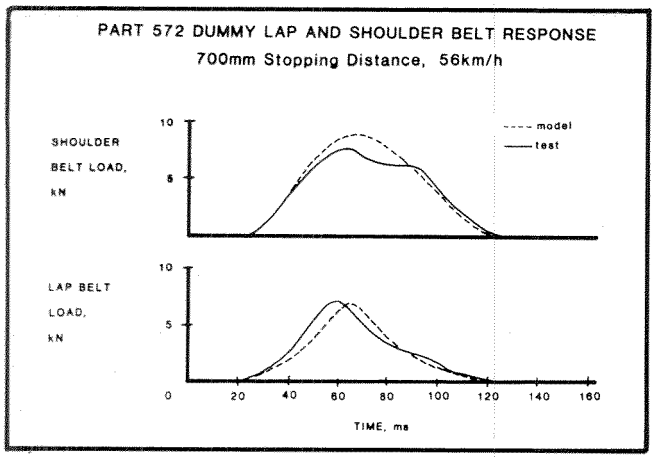

Figure 19. Model and test comparisons—belt loads—high severity pulse

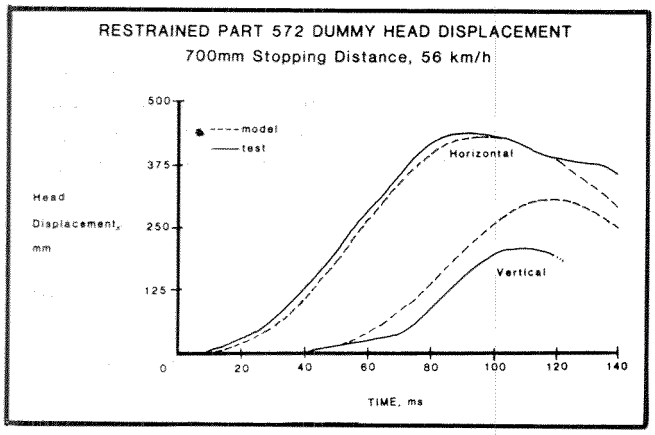

Figure 20. Model and test comparisons—head displacement—high severity pulse

approximately 20° greater rearward pelvic rotations than observed in the tests.

The chest accelerations predicted by the model are within 0.62g's in two tests and within 3.3g's in one test (810mm stopping distance). A calibration error might be present in the latter test since the peak test acceleration is 1g less than that observed in the 915mm stopping distance test, a less severe test. The shapes of the chest acceleration-time histories predicted by the model agree well with the test results.

As shown in Table 2 and in Figures 11, 15, and 19, the difference between the model-predicted and the test shoulder belt loads increases as the sled stopping distance decreases. It is felt that the differences are due to deformation in the belt attachment hardware in the tests, which deformation is not simulated in the model.

The lapbelt loads predicted by the model agree with the test results. The maximum variation from the test results is from only -180N to +785N (-40 to +176 lb) out of peak belt loads in the 6 to 8kN (1,350 to 1,800 lb) range.

Based on the above model and test result comparisons, it is felt that for the belt system geometry and the range of stopping distances tested, the model results agree with the test results.

Discussion and Recommendations

The current series of simulations with the MADYM02D model have shown that the model can be used for simulating dummy responses in frontal sled tests. Further modeling exercises and tests are required to determine the reasons for greater predicted head excursions in the vertical direction and pelvic rotations when compared

Table 2. Test and model dummy data

	915mm Stopping Distance		810mm Stopping Distance		700mm Stopping Distance	
	Test	Model	Test	Model	Test	Model
Peak Head Acceleration, G's	37.5	37.5	43.1	44.	54.9	50.0
Peak Chest Acceleration, G's	37.7	37.75	36.7	40.	45.62	44.0
Peak Shoulder Belt Load, kN	6.4	6.6	7.3	8.0	8.00	9.30
Peak Lap Belt Load, kN	4.2	5.0	5.3	5.5	7.1	6.9
Head C.G. Movement, mm						
Horizonal	387	409	409	412	445	442
Vertical	114	193	158	250	208	310
HIC	275	218	370	354	595	528

with test data. It is the experience of the author that both of the above dummy movements are very sensitive to the belt attachment points on the dummy. These attachment points are functions of the anchor locations. It should also be noted that the belt attachment points on the dummy are fixed in the simulations but can move in actual tests. Hence, a series of tests with a number of different anchor locations and their mathematical simulations is suggested for future studies.

Enough subtle differences between MADYM02D and the MVMA2D models exist that, at the time of writing, identical data sets for comparing the responses of the two models could not be prepared. Preliminary efforts indicate that the two models can yield comparable, but not identical, results. The differences between the two model results are due mainly to the differences in the restraint system models listed below:

1. No retractor outlet function ("film spool effect") is possible in the MVMA2D model.
2. No inboard strap simulation is possible in the MADYM0.
3. The MVMA2D treats the shoulder harness as one belt extending from the D-ring to the inboard buckle. The MADYM0 treats the shoulder harness as being made up of two belts—one between the D-ring and the upper chest attachment point and the other between the lower chest attachment point and the inboard buckle.
4. The inboard buckle can move in the MVMA2D but is fixed in the MADYM0.
5. The unloading function of the belt is described by "R" and "G" ratios in the MVMA2D, but it is described by tabular functions in the MADYM0.

Summary and Conclusion

The MVMA2D and the MADYM02D occupant simulation models have been compared to each other so that further developments in these models may incorporate the features missing in one but present in the other. A series of sled tests with the Hybrid II dummy and 3-point belt restraint systems was simulated using the MADYM02D model. The results of the simulations agree with the test results.

Acknowledgments

The author gratefully acknowledges the help provided by Mr. Roger Daniel in the discussions of the paper and preparation of the manuscript. Special thanks are due to Mr. Max Koga for his dedicated care in insuring that the sled tests were conducted in a highly controlled manner.

The Safe Transportation of Wheelchair Occupants in the United Kingdom

S.P.F. Petty
Transport and Road Research Laboratory

Abstract

In 1981, "The Year of Disabled People," the Department of Transport issued a Code of Practice and Special Provisions for the Carriage of Passengers in Wheelchairs on Public Service Vehicles. The safety aspects of the code are considered in this paper. Research has shown that the travelling space required for each wheelchair is 700mm wide and 1,200mm long.

Accident data have shown that the priority requirements for a wheelchair restraint are to hold the chair and occupant in place during normal driving and in 10g frontal impacts for full-sized public service coaches. The details are given of five different restraint designs and of the results from static and dynamic testing. The removal of one restraint design from the market as a result of testing to the Code of Practice highlights the need for a formal standard.

Introduction

Year 1981, "The Year of Disabled People," gave an increased incentive to both the transport industries and the organisations helping the handicapped to make transport more accessible to the wheelchair-bound disabled. British Rail has completed a study of restraint designs and is evaluating specific restraints for general use in trains. The Department of Transport proposed, and then contributed toward, the development of a new design of taxi, which it is evaluating. The number of Community Transport Operators and Local Authorities carrying wheelchairs in minibuses (9 to 16 seats) is increasing to form a nationwide network. Approximately 3,800 minibuses regularly carry passengers in wheelchairs(1). Certain bus and coach operators have introduced modified vehicles into their fleets. The Department of Transport has issued a Code of Practice and Special Provisions for the Carriage of Passengers in Wheelchairs on Public Service Vehicles(2) as an initial guide on access and safety. It is the safety aspects of that code that are considered in this paper.

Access

The dimensions for the entrance/exit, gangways, and designated positions for wheelchair accommodation are based on the British Standard BS 5568: 1978 for folding wheelchairs with principal dimensions of overall width 660mm and a maximum overall length of 1,065mm. Current anthropometric data are used. The space occupied by any wheelchair in its travelling position is defined as 700mm wide and 1,200mm long. This allows any wheelchair in a row to enter or leave without disturbing the others. In special cases, these dimensions have been changed. Under contract to the Transport and Road Research Laboratory (TRRL), Middlesex Polytechnic evaluated the dimensions using as subjects the wheelchair occupants who were visiting TRRL for an exhibition of Mobility Aids for the Disabled. The two main conclusions were: "Reducing the length to 1,150mm and 1,100mm did not reduce the time to enter but the wheelchair hit those in front and behind and this was not satisfactory"; "Also some certain types of wheelchair restraint were difficult to fit within the 1,200mm space and any reduction would only increase that difficulty".

Accident Data

The data related to Public Service Vehicle (PSV) passengers, excluding those injured while they were boarding or alighting, were obtained from the police STATS 19 form. This form gives nationwide coverage but cannot identify if the injured person was disabled. It relates the number of injured to the location of the first point of vehicle impact and is a guide to the main direction of deceleration. The breakdown for the year 1981 is typical and is given in Table 1, which highlights the two most important types of accident that should be covered by a code of practice.

Table 1. Injuries in 1981 to PSV passengers

First point of impact on vehicle	Severity of injury		
	Fatal	Serious	Total
Front	0	171	171
Back	1	6	7
Offside	0	16	16
Nearside	2	7	9
Rollover	2	60	62
MPD*	2	82	84
No impact	3	186	189
Total	10	528	538

* The Metropolitan Police Department data cannot be coded for direction of impact.

The first is an injury happening when no vehicle impact takes place, but emergency braking or sudden manoeuvres to avoid an accident cause passengers to be thrown against an unpadded part of the bus structure. Unrestrained wheelchairs would be free to roll and represent a

danger not only to their occupants but also to other users of the PSV. The second is the direct frontal impact. The restraint should be adequate in the frontal mode but still function at lower levels in side and rear loading. The restraint should also be designed so that the chair cannot rotate about an axle or revolve.

Restraint Systems and Tests

For a restraint system to be successful, it must not only be able to withstand the impact forces but also be easy to use. As such it should—

- Hold the wheelchair and occupant in place during normal driving
- Be simple to fit by untrained helpers who may not themselves be physically strong
- Be adaptable for use on different designs of wheelchair
- Be comfortable to use and wear
- Be so designed that it cannot be incorrectly assembled
- Be capable of being released quickly in abnormal conditions in a crashed vehicle

Restraint systems can be subdivided into three groups:

- Wheelchair restraints that are attached to the vehicle structure and hold only the wheelchair against forward, rearward, and sideway movements.
- Passenger restraints that are independent of the wheelchair and must withstand deceleration forces in a forward direction relative to the vehicle.
- Combined restraints that share some components for both wheelchair and passenger restraint. This will result in increased loads through the wheelchair restraint.

The Code of Practice that has been issued uses a rigid trolley to statically test the restraint anchorage strengths. The mass of the wheelchair is taken to be that of an electric chair weighing 90kg and the mass of the occupant as a slightly overweight adult also at 90kg. Previous work on coach seat safety(3) has shown that a deceleration of 10g from a speed of 30km/h using a 50th percentile dummy was required to reproduce the seat failures found in real impacts. Thus, the 10g deceleration level has been used acting through the centres of gravity of the two masses to give the test loading on the restraint in frontal impacts. For side and rear impacts, the level has been halved. Allowance has been made for the use of rearward facing wheelchairs held firmly against a bulkhead. Sideway-facing chairs are not recommended as the arm of the chair and any occupant webbing restraint will react on the soft tissues of the human body rather than on its skeleton.

Using a rigid trolley is useful for repeatability and is a low-cost test, but it can only test separately the wheelchair and occupant lapbelts. The trolley cannot be used to test combined restraints because it cannot measure the changing load due to movement of the occupant in relation to his seat. At present, such restraints are tested dynamically by the Department of Transport using a 50th percentile dummy in a standard Department of Health and Social Security (DHSS) type 8L wheelchair. Static testing with a dummy restrained in a wheelchair produces unrealistic modes of chair failure. Reinforcing the chair still does not overcome the problems. Further development of a static test is being examined.

Four types of restraint have been tested statically using the trolley. They are—

- A webbing belt system adapted from a cargo restraint design, strapping the wheelchair frame to steel rails bolted onto the floor and/or walls of the PSV. This is shown schematically in use on a wheelchair in Figure 1. The webbing is looped round the lower bar of this chair, clamped onto the rail, and then pulled tight.

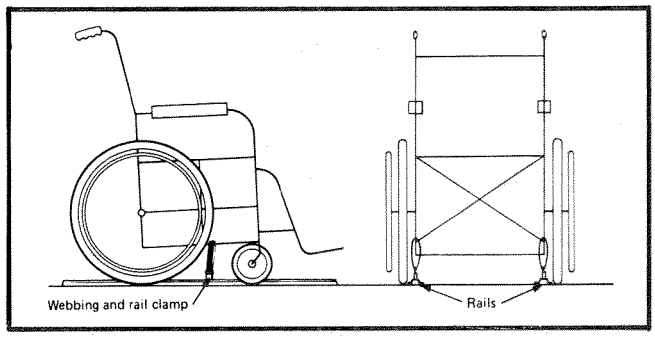

Figure 1. Type A restraint

- A system using a clamp on one side of the wheelchair and a separate webbing belt on the other side, anchored to the opposite corner of the wheelchair frame and mounted in the floor in an extruded aluminum alloy rail. This is shown schematically in Figure 2.

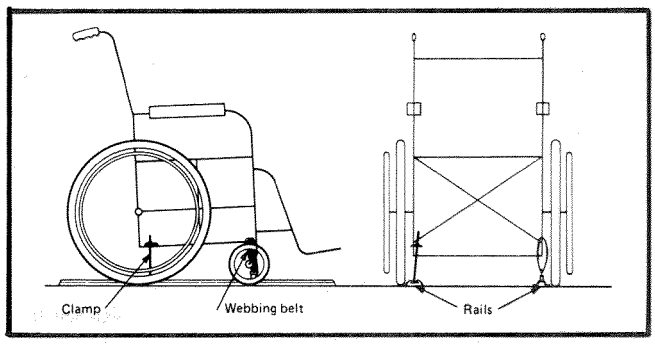

Figure 2. Type B restraint

- A system using a vertical clamp on each side of the wheelchair frame. The clamps could be attached to the floor either in their own special sockets, in the rails used for type A or B restraints, or in a modified aircraft seat rail extrusion. This is shown in Figure 3 using the special fixings and with one of the belt systems used in the dynamic tests.

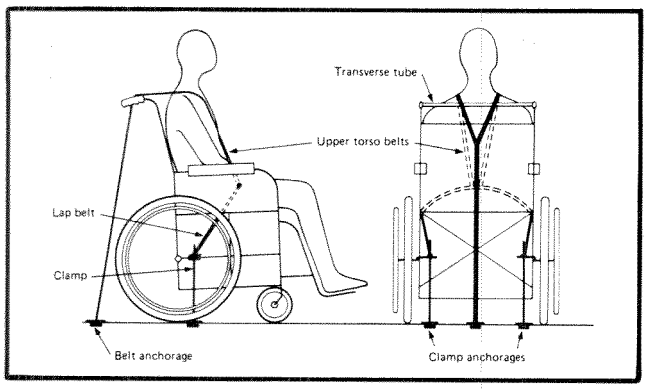

Figure 3. Type C restraint

- A system using type C restraints for the wheelchair but an independently designed lapbelt and anchorage.

As a result of the tests used to evaluate the new code, the type B restraint has been withdrawn from sale as it failed prematurely, and the other designs have been modified to improve their performance.

The two designs of restraint were tested dynamically. The type C restraint used the various anchorage rails with a lapbelt only and with a full harness. To prevent lumbar compression fractures, an adaptor was clipped onto the wheelchair handles. This adaptor can also be used to hold a headrest. A type E is a system using an adjustable A frame (Figure 4) that can be placed at the back of the wheelchair in sockets in the floor and roof of the vehicle. The wheelchair can then be held onto the A frame either by webbing or by clamps. This is shown schematically in Figure 4 with a belt system similar to those used in the dynamic tests.

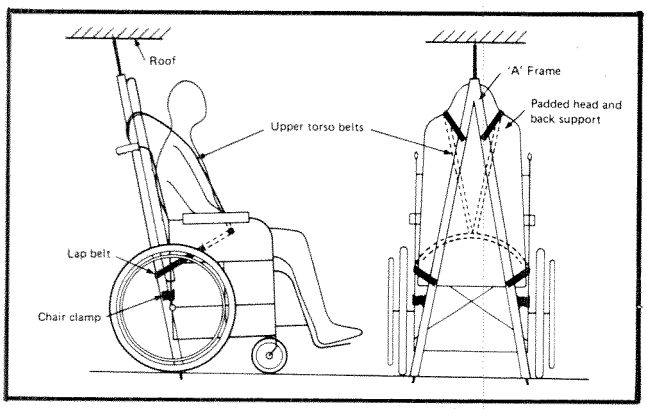

Figure 4. Type E restraint

The dynamic tests highlighted certain important aspects:

1. Using a lapbelt allows the upper torso to jacknife forward with the potential danger of the occupant hitting his head on the seat in front. The total forward movement allowed must relate to the 1,200mm seat spacing given in the Code of Practice.
2. When the upper torso is restrained by floor-mounted belts, care must be taken to insure that the lumbar spine is not damaged under compression loading.
3. Loads transmitted through the wheelchair can result in its frame collapsing. This started at a level of about 13g. As the frame failed, the loads on the wheelchair restraint changed with the possibility of sudden failure. Minor modifications to the wheelchair structure can delay the start of failure.
4. The floor structure must be sufficiently strong not only to hold the restraint anchorages but also to withstand the reaction forces through the wheelchair wheels.
5. During an impact, the vehicle structure will distort. The design of the anchorages must give a positive fixing and should not rely on the "peg in a hole" concept.
6. There is a need for continued quality control. In one test, a buckle made by a well-known car seatbelt manufacturer had been incorrectly modified by a third firm before it was presented for testing by a restraint manufacturer. It failed catastrophically.

Future Progress

It is recognised that the present Code of Practice requires updating and rewording to remove ambiguities. Also a static test method for combined restraints would be very convenient. The test levels using the 10g deceleration and the heavy electric wheelchair and the overweight occupant may be thought to be high for use on full-sized coaches but will not be so when applied to lighter vehicles with higher decelerations.

The continuing demand on manufacturers to make their restraints more user-friendly is resulting in a steady improvement in design. One design being developed for rapid wheelchair loading has a headrest and occupant restraint prefitted to the wheelchair. The whole assembly can be easily clipped to an arm mounted on the wall of the vehicle. In cold weather, this is particularly useful if a number of wheelchairs have to be loaded at one time.

In the longer term, the British Standards Institution is working with the Department of Transport, manufacturers, vehicle operators, and their passengers to make use of the experience gained from the Code of Practice to produce a formal wheelchair standard.

Discerning the State of Crashworthiness in the Accident Experience

A.C. Malliaris
Office of Vehicle Research, National Highway Traffic Safety Administration

Abstract

This paper addresses the risks of occupant casualties in highway accidents. Such risks are determined from U.S. accident experience in the past 10 years. Risks are analyzed as a function of vehicle type, car market class, make, nameplate, and model year for crashes of various impact types and various severities. Both absolute risks, per unit exposure, and relative risks are addressed. The influence of many exposure variables is examined and necessary adjustments, to a common set of exposure conditions, are made. The control variables for this purpose are: calendar year and car age; occupant's seating position, restraint status, and age; time and place of travel; and various roadway characteristics. Adjusted risks are reviewed versus major characteristics of cars as implied by make, nameplate, and model year. Occupant ejections and rollovers receive special attention due to their risk sensitivity to car class.

Introduction

In the past 10 years, the motor vehicle fleet in the United States has undergone significant changes in the mix of vehicle types on the road, the mix of car classes, the design and engineering of cars, and the introduction of new components and equipment. In addition, strong factors were at work in the early 1980's that individually or collectively had and have the potential to influence highway safety significantly. A depressed economy inhibited travel growth, especially for the higher risk discretionary travel. Highway safety programs, e.g., campaigns against drunken drivers and seatbelt use programs, were initiated and pursued vigorously. The questions we are addressing in this paper are whether or not and how all these changes affect occupant casualty risks, as determined from the accident experience of motor vehicles on U.S. roads in the past 10 years.

We treat occupant casualty risks as dependent variables where the independent variables are: calendar years, vehicle impact types, and severities; motor vehicle attributes such as vehicle types, market classes, makes, models, and model years; and occupant attributes such as seating position, restraint use, and age. Exposure attributes such as time and place of travel, roadway characteristics, etc., are also used in a supplemental fashion, especially as proxies for crash severity. A companion paper(12) addresses the risks of motor vehicle involvement in accidents as a function of accident type and severity; driver attributes, such as driver's age, sex, and alcohol involvement; and vehicle attributes as mentioned above.

Major Changes in the Motor Vehicle Fleet and Travel

Two car characteristics—weight and wheelbase—are given special consideration because they are frequently

discussed and analyzed in connection with casualty risks. A summary of changes in these characteristics for new cars retailed in the United States is given in Table 1 by market class. The changes refer to mean values of those characteristics between model years introduced in the early 1970's and model year 1983.

Table 1. Percent change in mean weight and mean wheelbase of model year 1983 cars by comparison to new cars of the early 1970's

Market Class	Percent Change Mean Weight	Mean Wheelbase
U.S. Subcompact	-18.0%	-2.5%
Compact	-23.5	-8.1
Intermediate	-22.8	-6.8
Standard	-11.5	-4.3
European Subcompact	+5.9	+1.9
Other	+9.9	+2.2
Japanese Subcompact	0.0	+1.6
Other	+5.8	0.0

Note in Table 1 that the domestically produced fleet shows substantial reductions of weight and wheelbase, all across the board, while this is not the case for the fleets of European or Japanese origin. Apparently, redesign practices and market shifts in the latter fleets, which consist of predominantly subcompact cars, led to modest increases in weight and wheelbase.

As a result of these developments, subcompact cars of U.S., European, or Japanese origin have become virtually indistinguishable when viewed in terms of the major characteristics discussed above. Moreover, the standard, intermediate, and compact U.S.-produced cars of model year 1983 have essentially assumed the weight and wheelbase characteristics of the intermediate, compact, and subcompact cars of the early 1970's, respectively.

Because of the prominence of car weight and wheelbase in safety reviews, we treat the changes summarized above with more detail and more quantitatively in Appendix A. In the same appendix, we also address changes that took place in the travel of motor vehicles and in the various aspects of exposure to casualty risks.

Occupant Risks and Risk Descriptors

Consider the definitions:

E_{jk} = Motor Vehicle Exposure (usually travel)

V_{ijk} = Accident-involved Vehicles

M_{ijkm} = Occupants in Accident-involved Vehicles

N_{ijkmn} = Occupant Casualties

where the subscripts are shorthand for groups of influential attributes.

- j designates vehicle attributes such as vehicle type (e.g., car, truck, etc.), market class, make, model, model year, etc.
- k designates travel attributes such as time and place, roadway characteristics, etc.
- i designates vehicle impact type (e.g., front, side, etc.) and impact severity
- m designates occupant attributes such as seating position, restraint status, age, etc.
- n designates occupant casualty attributes such as overall injury severity (e.g., fatal, major, minor, none) and, whenever the information is available, may designate an occupant's complete set of injuries by severity, body region, etc. Also, the same subscript may be used for certain intermediate outcomes such as ejection instead of the final outcome, which is an overall injury of certain severity.

Furthermore, consider the following additional definitions:

$$R_{ijk} = V_{ijk}/E_{jk} \quad (1)$$

$$S_{ijkm} = M_{ijkm}/V_{ijk} \quad (2)$$

$$T_{ijkmn} = N_{ijkmn}/M_{ijkm} \quad (3)$$

Equation (1) defines an absolute riskof accident involvement for motor vehicles. This type of risk is discussed extensively in (12). The occupancy, i.e., the number of occupants per accident-involved vehicle, is defined by Equation (2), according to occupant attributes represented by subscript m. Equation (3) defines the conditional risk of an occupant casualty with attribute n, given the occupant's inclusion in an accident-involved vehicle.

An overall occupant casualty risk may be defined by the product of Equations (1), (2), and (3), i.e.,

$$W_{ijkmn} = R_{ijk} * S_{ijkm} * T_{ijkmn} \quad (4)$$

or

$$W_{ijkmn} = N_{ijkmn}/E_{jk} \quad (5)$$

which is expressed in occupant casualties, with attributes implied by the subscripts, per unit travel exposure.

Equation (3) is one of the most commonly used descriptors of crashworthiness, and we shall apply it extensively in this paper for occupant risk determinations with as much resolution of subscribed attributes as the available data bases allow. We shall also apply extensively Equation (5) in determinations of overall occupant risk. As is evident in Equation (4), the overall occupant risk reflects in a composite fashion both the occupant casualty risk, given an accident-involved vehicle, and the accident involvement risk of the vehicle.

Occupant Fatality Risks by Vehicle Type

We address first the conditional risks of occupant fatality, i.e., the risks determined with the help of Equation (3).

A motor vehicle occupant's risk of fatality stood at about 2.41 ± .07 per 1,000 occupants involved in all police-reported accidents on U.S. highways.[2] This is the mean and standard error derived from six individual values, each obtained from the data for each of the 6 years 1979 to 1984. It refers to all accident, all vehicle, and all occupant attributes. It varies little within the specified time period (see Figure 1) in spite of the significant changes in the fleet and travel patterns discussed earlier.

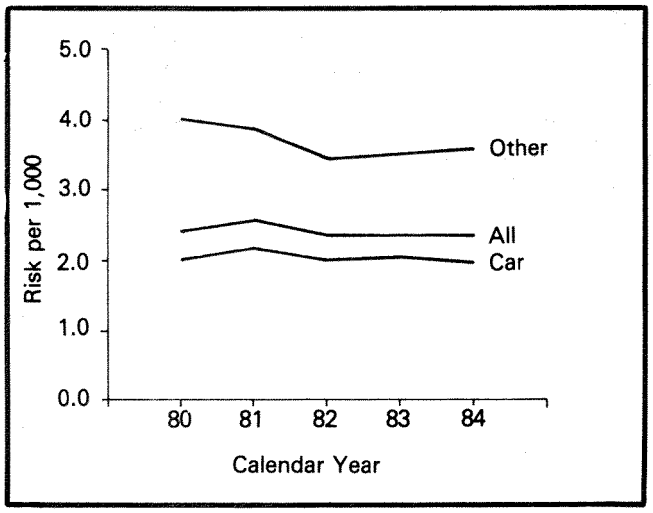

Figure 1. Risk of occupant fatality per 1,000 occupants involved in police-reported accidents of cars, other vehicles, and all vehicles

The data for the determination of this conditional risk are provided by two accident files of national scope, i.e., by FARS and NASS(1,2). Specifically, a total count of all occupant fatalities (national census) is obtained from FARS, and this is divided by a national estimate of all motor vehicle occupants involved in all police-reported accidents, as recorded in NASS. This process is repeated for each of the calendar years 1979 to 1984.

When resolved by vehicle type, the risk under consideration varies within a wide range as the data in Table 2 show. In this table, pickups and vans are vehicles with a gross vehicle weight rating under 10,000 lb. Straight trucks are nonarticulated trucks and vans over 10,000 lb.

Bus and motorcycle occupant risks are at the two extremes, lowest and highest, respectively, for obvious reasons. Car occupant risks are at about the middle of the range. Occupants of vans and straight trucks show substantially lower risks than car occupants, while the risks of pickup truck and especially of combination truck occupants are substantially higher than car occupant risks.

[2]The risk of fatality for all people, i.e., motor vehicle occupants, plus pedestrians and bicyclists, is higher: 2.93 ± .07.

Table 2. Fatality risk per 1,000 vehicle occupants involved in police-reported accidents as a function of vehicle type

Vehicle Type	Percent of Occupants*	Risk Per Thousand in Row
Cars	78.7 ± .08	2.01 ± .02
Pickups	12.1 .22	2.92 .06
Vans	3.29 .05	1.55 .03
Straight Trucks	1.53 .19	1.37 .11
Combination Trucks	1.46 .10	3.73 .42
Buses	1.53 .58	.27 .13
Motorcycles	1.42 .04	21.4 .77
Total	100.	2.41 .07

* In all police-reported accidents

It may sound ludicrous that occupants of pickups and especially occupants of such heavy commercial vehicles as combination trucks incur substantially higher fatality risks than car occupants, but there may be good reasons for it. Articulated trucks and pickups are likely to operate more on rural land and high-speed roadways. Consequently, they are likely to experience higher crash severities than cars, vans, or straight trucks. Nevertheless, on an aggregated basis, occupants of pickups and combination trucks incur higher fatality risks than cars. Furthermore, this pattern holds for all types of impacts, whether frontal, side, rear, or other.

Car Occupant Fatality Risks

Because of their overwhelming share of the vehicles in all police-reported accidents, cars are receiving further attention in this paper in connection with occupant fatality risks. According to Table 2, the fatality risk for car occupants is 2.01 ± .02 per 1,000 car occupants involved in all police-reported accidents. This is the mean and standard error for the 6 years 1979 to 1984. The smallness of the error indicates relatively little variation of the risk, whether random or systematic, in this period. This is also shown in Figure 1. However, the subject of risk variation versus calendar year will receive further attention in a later section.

Car occupant fatality risks are influenced by crash attributes, as well as by vehicle and occupant attributes. Crash severity is one of the most influential variables. However, the data we are dealing with do not allow an explicit and categorical description of this variable. The FARS data do not make any reference to crash severity, while the NASS data provide crash severity information

only for a small portion of the national sample. Accordingly, to characterize crash severity, we use as a rough proxy the time and location of the crash. It is well known that rural crashes are more severe than urban crashes and night crashes are more severe than daylight crashes. Rural night crashes are the most severe, while urban daytime crashes are the least severe.

Under these qualifications, we have resolved the overall fatality risk for car occupants as shown in Table 3. In addition, we have resolved the occupant's seating position into that of the driver, right-front passenger, and all other (primarily rear-seat) passengers. The risk values shown in this table are mean and standard errors over the early 1980's. For each calendar year, Equation (3) has been applied with numerator data provided by FARS and denominator data provided by NASS.

Most of the results and trends shown in Table 4 are intuitively expected, at least qualitatively. Fatality risks associated with side impacts or with rollover-type impacts (predominant component of "other") are substantially higher than the risk in frontal impacts, as shown in the last row of the table. The risk for rear impacts is much lower. This pattern holds for all car occupants regardless of seating position and restraint status, without significant exceptions.

The overall fatality risk for the right-front passenger, i.e., the passenger averaged over all restraint conditions and types of impact, is no different than that of the driver under the same aggregation conditions and within the reported error bounds. This is also what we concluded from Table 3. However, Table 4 shows several cases where the two risks might not be equal. For example, the

Table 3. Car occupant fatality risk per 1,000 involved in police-reported accidents resolved by accident attributes and occupant's seating position

Accident Attributes	Car Occupant's Seating Position: Driver	Front Passenger	Other	All
Urban				
Day	.57 ± .03	.68 ± .05	.43 ± .03	.56 ± .03
Night	1.89 .08	1.82 .14	1.42 .17	1.81 .10
All	1.00 .03	1.10 .07	.78 .06	.99 .04
Rural				
Day	5.33 ± .40	5.00 ± .36	3.34 ± .54	4.92 ± .33
Night	9.82 .43	7.85 .87	5.22 .61	8.48 .56
All	7.13 .18	6.16 .50	4.05 .38	6.37 .18
All				
Day	1.32 ± .04	1.57 ± .06	1.08 ± .08	1.35 ± .05
Night	3.59 .14	3.26 .26	2.48 .23	3.33 .18
All	2.10 .04	2.20 .08	1.59 .06	2.01 .02

The results in Table 3 show that car drivers run essentially the same risks as front passengers all across the spectrum of crash severities, or more precisely of exposure severities. This is so for all practical purposes if the shown error bounds are taken into account. Occupants in other seating positions, primarily rear-seat occupants, incur fatality risks that are substantially lower: about 30 percent lower in urban crashes and about 60 percent lower in the more severe rural crashes.

Risks for any one or all seating positions are very sensitive to exposure severity, i.e., to the shown accident attributes. This sensitivity is consistent across the board and shows differences by factors 10 to 20 between the least severe crashes, i.e., urban daylight crashes, and the most severe, i.e., rural night crashes. Next to impact severity, we address the type of impact, i.e., frontal, side, rear, or other, as an influencing factor. This is done in Table 4. In addition, we resolve two of the most important occupant attributes: seating position and restraint status. The entire table refers to car occupants, and the results have been obtained by the same procedure used in Table 3.

right-front passenger appears to incur higher risks in side impacts, whether restrained or not. Also, restrained front passengers appear to incur higher risks than restrained drivers. However, these differences are not large enough in view of the reported errors. Furthermore, their significance and a discussion of their possible origin requires further control and study beyond the scope of this paper.

As noted, the most striking feature of Table 4 is the much lower risk shown for restrained car occupants in comparison to unrestrained occupants, for any seating position and any type of impact. This trend is not only consistent all across rows and columns of the table but also implies generous values of restraint effectiveness. The great majority of the restraints under consideration here are manual seatbelts. Their effectiveness in casualty prevention is defined as the relative risk reduction, i.e., (unrestrained-restrained)/unrestrained. According to this definition, the effectiveness values implied by the data of Table 4 range from about 50 percent to over 80 percent.

However, a word of caution is appropriate. It has been recognized in the safety literature(13) that restrained car occupants traveling on U.S. roads are also occupants

Table 4. Car occupant fatality risk per 1,000 involved in police-reported accidents resolved by type of impact, occupant's seating position, and restraint status

Car Occupant's Seating Position and Restraint	Car's Type of Impact: Frontal	Side	Rear	Other	All
Driver					
Unrestrained	2.48 ± .06	3.08 ± .10	.55 ± .03	3.36 ± .25	2.54 ± .06
Restrained	.61 .03	.83 .08	.16 .03	.50 .07	.42 .01
All	2.24 .07	2.77 .07	.51 .05	2.96 .18	2.10 .04
Right Front Passenger					
Unrestrained	2.05 ± .07	3.39 ± .07	.54 ± .05	2.85 ± .16	2.35 ± .06
Restrained	.94 .02	1.37 .19	.19 .03	1.03 .21	.63 .08
All	1.95 .08	3.11 .05	.51 .06	2.65 .16	2.20 .08
All					
Unrestrained	2.24 ± .04	3.13 ± .09	.58 ± .03	3.14 ± .16	2.39 ± .03
Restrained	.64 .03	.92 .07	.20 .04	.60 .12	.45 .02
All	2.05 .06	2.83 .07	.54 .05	2.81 .14	2.01 .02

experiencing lower crash severities than unrestrained occupants. Thus, although the risk differentials shown in Table 4 between restrained and unrestrained occupants may be quite factual, part of these differentials may be due to lower crash severities, which would lower the risks of occupants even in the absence of the restraint. The issue under consideration would be clarified if the data of Table 4 could be controlled and adjusted for crash severity. However, although such control is possible and has been used in NASS data on several occasions, it is the lack of crash severity information in FARS that prevents the adjustment of the results in Table 4.

A person's age has been recognized as an attribute that influences significantly the person's risk of fatality. Table 5 resolves the overall fatality risk of car occupants in two major age slots for each of the seating positions and restraint conditions examined so far. Higher risks for the older occupants are evident across the board. Given that older occupants experience, in general, lower crash severities, the risk differentials under identical crash severities may be larger than those shown in Table 5.

Restraint Use Rates

This is one of the most timely subjects to address in a review of crash protection in the early 1980's because of the initiation and vigorous pursuit of seatbelt use programs in the United States during this period. The NASS and FARS raw data used for the risk determinations reported so far can also be used for straightforward determinations of restraint use rates for accident-involved car occupants.

Results for the overall restraint use rates are shown in Figure 2 as a function of the calendar year. The upper plot shows the rates observed for car occupants involved in all police-reported accidents, while the lower plot

Table 5. Car occupant fatality risk per 1,000 involved in police-reported accidents resolved by occupant's seating position, restraint status, and age

Car Occupant's Restraint and Age	Car Occupant's Seating Position: Driver	Front Passenger	Other	All
Unrestrained				
Under 45 Yrs.	2.34 ± .05	2.05 ± .07	1.67 ± .08	2.17 ± .03
45 Yrs. or Older	3.14 .11	4.06 .09	3.35 .11	3.31 .09
All	2.54 .06	2.35 .06	1.79 .08	2.39 .03
Restrained				
Under 45 Yrs.	.36 ± .01	.45 ± .06	.46 ± .13	.37 ± .02

All	.42 .01	.63 .08	.49 .13	.45 .02
All				
Under 45 Yrs.	1.97 ± .06	1.89 ± .10	1.44 ± .04	1.89 ± .05
45 Yrs. or Older	2.53 .03	3.59 .09	2.95 .21	2.73 .03
All	2.10 .04	2.20 .08	1.59 .06	2.01 .02

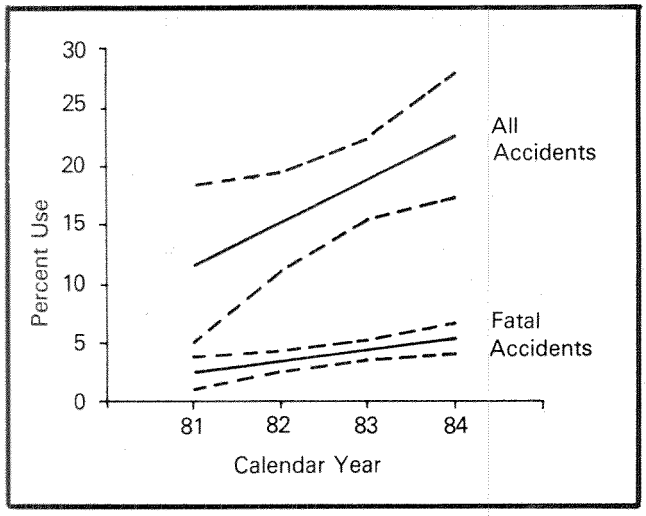

Figure 2. Safety belt use by accident-involved car occupants versus calendar year

refers to car occupants in fatal accidents. In each case, the rate is averaged over all other attributes and shown as the mean by the solid line, together with the 95 percent confidence bounds (dashed corridors).

The observed increase of the restraint use rate is both substantial and statistically significant. However, the reader should be aware that a potential bias is inherent in these data. The determination of restraint status, for the majority of car occupants, is made on the basis of answers given by occupants to investigating officers. Not only might there be an inherent bias in favor of a "yes" answer, but the bias may be increasing in recent years due to general publicity and awareness that seatbelt use may soon become mandatory. Note also the large difference between the upper and lower plots in Figure 2. There are at least two confounding factors that may contribute to this difference.

One confounding effect may arise from the possibility that restraint users are usually safety conscious and less likely to be involved in fatal accidents and appear as FARS statistics. The second confounding effect is the result of restraint effectiveness. Due to this effectiveness, restrained car occupants are underrepresented in a file with a fatal accident threshold, such as the FARS file.

Fatality Risk Variation in the Early 1980's

In spite of much change in influencing factors during the past 5 to 10 years, the overall fatality risk of all car occupants has not changed substantially. This is summarized in Figure 1. When the data of Figure 1, appropriately weighted for sample size, are fitted by a least square linear regression, the resulting slope is -.008 ± .032 per year for cars. This is zero for all practical purposes. An identical result has been reported(14).

To enhance resolution and relate the overall risk to post-1980 developments, we eliminated the 1979-1980 data and repeated our analysis for the 1981-1984 period. The elimination of the 1979-1980 data does not reduce much the overall sample of weighted data given that NASS in these years was only in partial implementation. A larger slope is obtained for this case, namely: -.056 ± .023, which is still marginally different than zero if one desires 95 percent confidence.

The year-by-year fitted values of the car occupant risk (car occupant fatalities per 1,000 involved in all accidents) and their standard error are—

1981	2.14 ± .05
1982	2.08 .03
1983	2.02 .03
1984	1.97 .04

A plot of this risk variation with the 95 percent confidence bounds is shown in Figure 3.

The nominal reduction of the risk in this period is about 8.5 percent, which is appreciable but also rather difficult to assign definitively to any single known influence, even if we disregard all questions of statistical significance. For example, we find this risk reduction entirely consistent with the rate increase of restraint use shown in Figure 2 for all accidents. However, other influences, some positive and some negative, were also in effect from 1981 to 1984. For example, an overall indicator of exposure severity (see Table A-7 in Appendix A) was declining during this period. On the other hand, travel speeds may have been increasing according to data shown in Table A-6 of Appendix A. A more extensive but equally frustrating discussion of crashworthiness and crash severity variations in the early 1980's is presented in (14).

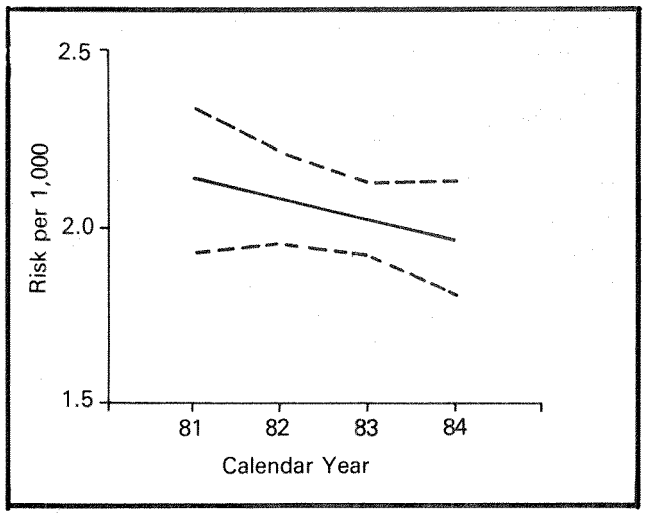

Figure 3. Risk of occupant fatality per 1,000 occupants of all cars involved in police-reported accidents—least-squares pitted mean and 95th percentile confidence rounds versus calendar year

Determination of Absolute Risks

To address the influence of car attributes on car occupant casualty experience, we focus our analysis on the new cars that traveled on U.S. roads from 1975 to 1984. This is also the period during which major changes took place in car attributes, as discussed earlier and as detailed further in Appendix A. For our analysis, we define new cars as those with an age (i.e., with a calendar year/model year difference) not exceeding 3 years. This is a compromise between retaining as much uniformity as possible in travel and exposure attributes while dealing with sufficiently large samples in the accident experience.

Under these constraints, we found it difficult to make the conditional risk determinations, by a combined examination of FARS and NASS data, as applied so far in the paper. This is so for several reasons: NASS data for car characterization (e.g., by make and model) are not available in a form compatible with FARS data until about 1981; NASS cell populations become rather small when the accident experience is subdivided by the many combinations of car market classes, makes, nameplates, and other specific attributes, especially when these subdivisions are made on new cars only. Furthermore, there are good reasons to suspect that NASS, as a sample of the national accident experience, may be biased in connection with car make/model content. For example, California and the West Coast in the United States are underrepresented in NASS, while the same regions are overrepresented in imported makes.

The conclusion is we may not apply Equation (3) for the task under consideration here because we have no means of obtaining reliable values for the denominator. This is another reason for using Equation (5), which is appropriate for the determination of absolute risks. In dealing, however, with the absolute risks of car occupant casualties, i.e., risks per car registration or per mile traveled, we must keep in mind these risks reflect in a composite fashion both the risk of casualty, given an accident-involved vehicle, and the accident involvement risk of the vehicle. We shall apply Equation (5) integrated over all attributes, except i and j. Thus, we write:

$$W_{ij} = N_{ij}/E_j \qquad (6)$$

where i and j represent impact type and vehicle-related attributes, respectively. Later we will examine the influence of other attributes.

The raw data necessary for the application of Equation (6) for car occupant fatality risks are provided by FARS(1) for the numerator and by (4) for the denominator. FARS contains records of about 60,000 occupant fatalities for new cars alone in the 10 years between 1975 and 1984. Car impact type and car nameplate are known for the great majority of these cases. Furthermore, their total count is generally adequate for analyses that demand disaggregation by several additional attributes of interest here.

Car registrations from (4) are used to quantify the denominator in Equation (6) by car descriptor j (nameplate and model year) for each of the calendar years included in the analysis. Although car exposure in general may not be characterized accurately by car registrations alone, our constraining the analysis to new cars only introduces a uniformity in the travel per car and other attributes sensitive to car age. Furthermore, a set of adjustments is made to the risks (determined for each model/calendar year) to bring them all under a common reference exposure.

The selected reference exposure is that experienced by 1-year-old cars in calendar year 1980. The adjustments, detailed in the first part of Appendix B, account for travel and exposure severity variations taking place in the 10 calendar years under consideration for new cars (i.e., 1-, 2-, and 3-year-old cars). Risk adjustment factors are shown in Table B-2 of Appendix B, as a function of calendar year and car age or model year. The most significant adjustment is that shown in column B of Table B-1. This covers the major decline in exposure severity (serious accidents per 100 million miles of travel) observed on U.S. highways in the early 1980's. There is little doubt that meaningful comparisons of car occupant risk for travel over the 1975 to 1983 period should incorporate an adjustment for exposure severity. Whether the adjustment applied here is the most appropriate is a matter that requires further consideration.

To achieve numerator/denominator compatibility in the application of Equation (6), we disaggregate both the occupant fatality car data (numerator) and the car registration data (denominator) by car nameplate, model year, and calendar year. We found nameplate, i.e., make and model, disaggregation more suitable than disaggregation by weight or wheelbase. Disaggregation by weight often introduces ambiguities due to weight variations on account of optional engine sizes and other optional equipment. Furthermore, when disaggregating by weight, borderline cases may fall in one weight slot for the numerator data but in a different weight slot for the denominator data. However, the main advantages of disaggregation by nameplate are that more information is potentially available about the car under consideration, even if this information is not always publicly available, and the number of unknowns is very small.

Risk determinations may be made at the nameplate, model year, and calendar year level by straightforward applications of Equation (6), with subsequent adjustments as discussed earlier. At this level, sample sizes are generally adequate for most purposes. Given that our analysis is focused on new cars, we calculate risks separately for the 1-, 2- and 3-year-old cars, all adjusted to the common reference exposure conditions, and form the mean of the three. In the process, we obtain the standard error of this mean.

In many instances, risks for new cars, whether by

nameplate or by higher levels of aggregation, are available for several calendar years within the 1975 to 1984 span. In such cases, we also calculate means and standard errors, in addition to reviewing the data for systematic variation versus calendar year. Thus, the standard errors we report are more conservative, given that they embrace not only purely statistical fluctuations but all other variations, whether random or systematic.

Results for levels of aggregation above nameplate are obtained as follows. The raw data, whether car occupant casualties or car registrations, are pooled together and the procedures described above are repeated. This leads to risk determinations for new cars aggregated by make, car body family designation, market class, origin of make, and the entire fleet of new cars. The market class designations used are those commonly used in the automotive trade literature. Furthermore, all traditional sports car nameplates and other low-volume specialty cars have been excluded from consideration because of possibly singular characteristics and circumstances.

Absolute Risks of Fatality for New Car Occupants

Results obtained according to the procedures described above are presented and discussed here for new cars. The absolute risk of fatality for new car occupants per 10,000 registrations is 2.36 ± .10 when averaged over all car market classes and all types of car impacts that occurred in the period 1975 to 1983. First we shall resolve this risk by car impact type and by car market class within each impact type. The results of this resolution are shown in Figures 4 to 8. Each figure refers to a type of impact: frontal, side, rear, other, and all types. Within each figure, the risk is resolved by market class of new cars.

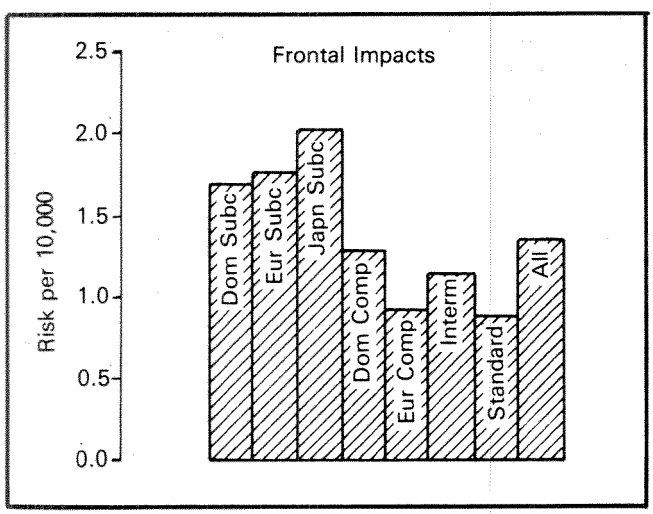

Figure 4. Fatality risk of new car occupants per 10,000 registrations by market class—frontal impacts

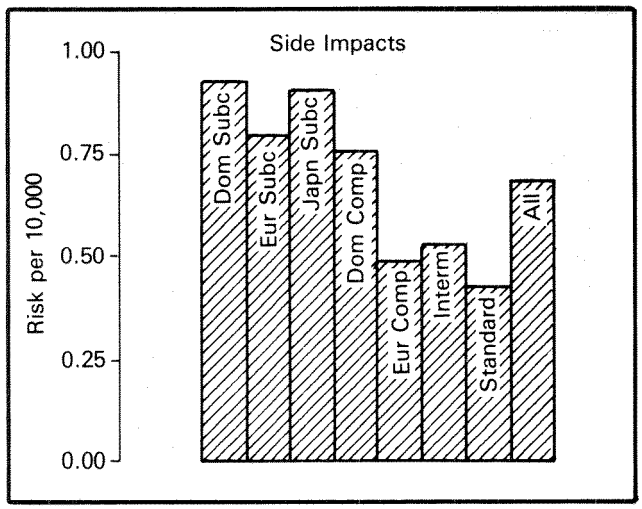

Figure 5. Fatality risk of new car occupants per 10,000 registrations by market class—side impacts

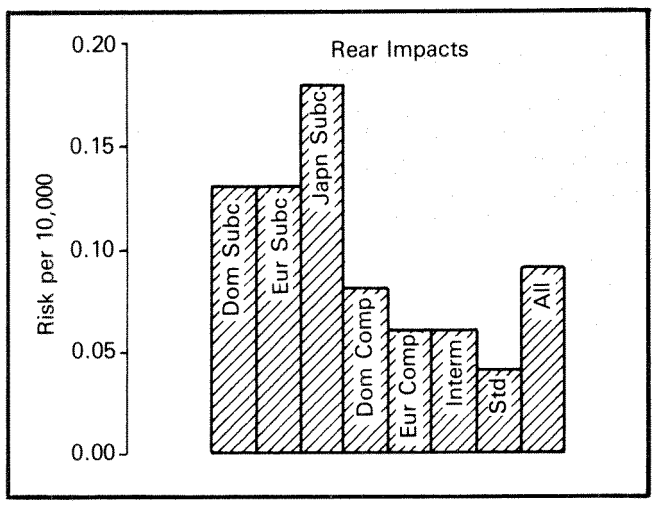

Figure 6. Fatality risk of new car occupants per 10,000 registrations by market class—rear impacts

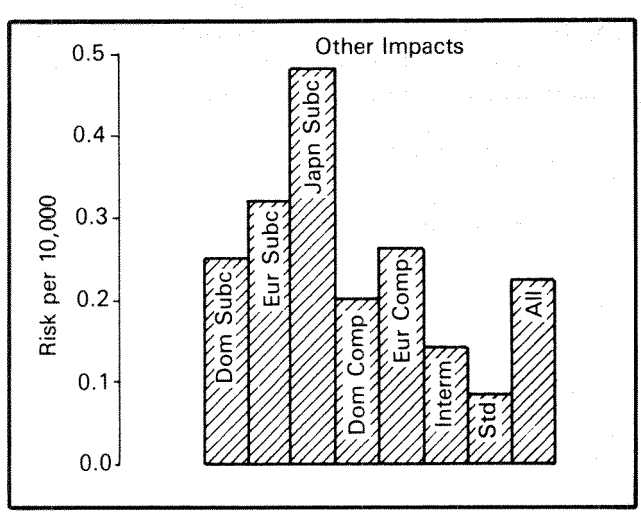

Figure 7. Fatality risk of new car occupants per 10,000 registrations by market class—other impacts (primarily rollover)

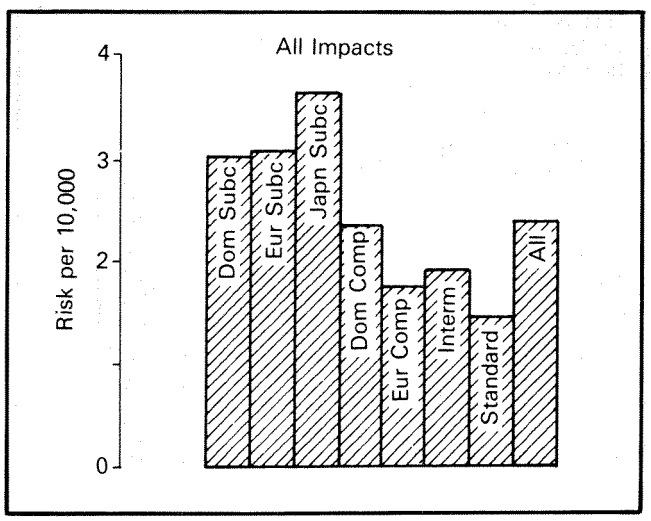

Figure 8. Fatality risk of new car occupants per 10,000 registrations by market class—all impacts

The last bar in each figure refers to all market classes together.

Keeping in mind the differences in the scales of these illustrations, we see that when all market classes are averaged (last bar), the principal contributions to the overall risk are made by frontal and side impacts. Smaller contributions are made by other impacts and rear impacts. Note that in other impacts, the principal component is rollover.

Each figure displays the sensitivity of the risk components mentioned above to the car market class. A general pattern is evident in all figures, namely higher risks for lighter cars and lower risks for heavier cars. This is not surprising; however, superimposed on this general pattern there are other sensitivities as is evident in Figure 6 and especially in Figure 7. Most of the risk differentials shown in Figures 4 to 8 may be established well beyond the statistical or other fluctuations that may be contained in the results. This is evident in the data shown in Table 6, which displays the risk values appearing in these figures together with their standard errors.

The data included in the overviews of Figures 4 to 8 and in Table 6 represent the national census of car occupant fatality experience of over 250 million new-car years. This total is subdivided into the market classes discussed above as shown in Table 7, which is formatted as Table 6 for reference convience. Table 7 also presents information about the major characteristics—weight and wheelbase—of new cars in each of the market classes under consideration. Keep in mind these are weighted means over the 1975 to 1983 period.

In addition to the sensitivity of fatality risks to car market class, there is a strong sensitivity to nameplates within each market class. This is especially true for the market classes of smaller new cars. Relevant results are given in Table 8, which displays fatality risks of new car occupants in the first column. These risks are in terms of occupant fatalities per 10,000 new car registrations. The second column tabulates occupant fatalities per occupant involved in the car. This descriptor is, in general, most appropriate for evaluating crashworthiness, based on the data of any file, except that a distorted scale is introduced when the descriptor is applied to the data of a file that records only fatal accidents, such as FARS.

The distortion comes as a result of the requirement that at least one fatality must occur in a crash before the data are entered into FARS. Usually this is an occupant fatality. An example will clarify further the shortcoming of applying the descriptor under consideration to FARS data. Consider the fatal accidents of single vehicles with the driver as the only occupant. This is not a very uncommon occurrence. In FARS, these vehicles appear

always with a driver fatality, or else they would not be recorded in this file. However, at the same time these vehicles show a value (occupant fatalities per occupant) equal to one, always and regardless of any vehicle characteristic.

The above discussion explains why the data in the second column of Table 8 show a very limited sensitivity to car nameplates. However, in spite of this shortcoming, the information is still worth reviewing as it tends to supplement our evaluation. The third column in Table 8 displays the values of ejected occupants, fatal or not, per 10,000 new car registrations. As formulated, this rather important descriptor is free of file-imposed biases of the type discussed above.

To put into perspective the data shown in the first three columns of Table 8, dealing with car occupant outcomes, we provide the data in the fourth column showing the corresponding car involvement risks. This last descriptor has been discussed and analyzed in more detail(12). The last three columns of Table 8 display the exposure and the major car characteristics of new cars for each entry.

Rollovers, Ejections, and Fires

These events are some of all possible intermediate outcomes between the crash initiation and the final outcomes, which are occupant casualties. They are singled out here for special consideration due to the traumatic experiences associated with their occurrence in car crashes. Rollovers in the context of this discussion are postimpact events, i.e., events taking place following a car collision either with another motor vehicle or with an object. They are distinguished from overturns, which take place in the absence of a noticeable impact before the car overturn. Summary evaluations of these risks are shown in Figures 9, 10, and 11 for rollovers, ejections, and fires, respectively. The results are resolved by car market class and refer to new cars, Figures 9 and 11, or new car occupants, Figure 10, involved in fatal accidents in the 1975 to 1983 period, per 10,000 registrations.

All three risk descriptors are sensitive to car market class; the risks of rollover and ejections show high sensitivity. The risk of fire or explosion shows a lower but still noticeable sensitivity. As expected, the pattern of ejection risk sensitivity is well correlated with the pattern of rollover sensitivity. This is especially true when, in addition to the risk of rollover as a subsequent event, the risk of overturn is also considered. The data shown in Table 9 are relevant.

This table summarizes the risks of overturn in column 1, the risks of postimpact rollover in column 2, and the sum of (1) plus (2) in column 3. The occupant ejection risks are shown in column 4, while the ratio of ejection to total rollover risk is shown in column 5. It is evident that, although rollover and ejections have risks that show a high sensitivity to car market class, the ratio of these two risks is virtually invariant. The ratio under consideration here is not necessarily the number of ejectees per car rollover, because there are car impact types other than rollover that contribute to occupant ejections. However, not unexpectedly, the rollover mode appears to be the principal contributor to ejections since it accounts for most of the ejection risk variability.

Table 8. Casualty risks, exposure, and major characteristics of new cars by nameplate in the 1975 to 1983 period. (Risks are shown per 10,000 car registrations except in column 2 where they are given per FARS-involved occupant)

* Occupant fatalities in new cars per 10,000 registrations
**Occupant fatalities in new cars per occupant involved in a fatal accident

Risk Changes Versus Model Year

The results discussed so far, especially those shown in Figures 4 to 11 and Tables 6 to 9, are averaged over all calendar years 1975 to 1983. In spite of the fact they address new cars only, they are essentially averaged over as many as 10 model years. Given that much change has taken place in new car design during this period, the question arises whether the risks under consideration are changing. To address this question, we examine the data as a function of calendar year and thus as a function of model year for new cars.

Figure 12 displays the variation of the total risk of occupant fatality for all types of impact and for all new cars, regardless of market class. The actual data, available by calendar year, have been treated here by a linear regression that yields the fit, shown by the solid line, and the 95 percent confidence bounds, shown by the dashed corridor. The slope is statistically significant and equal to .099 ± .019 per year. In a 10-year period, this amounts to .99 ± .19 occupant fatalities per 10,000 new car registrations. This is rather substantial when compared to the mean of the risk for the same period: 2.36 ± .10 shown in the last entry of Table 6.

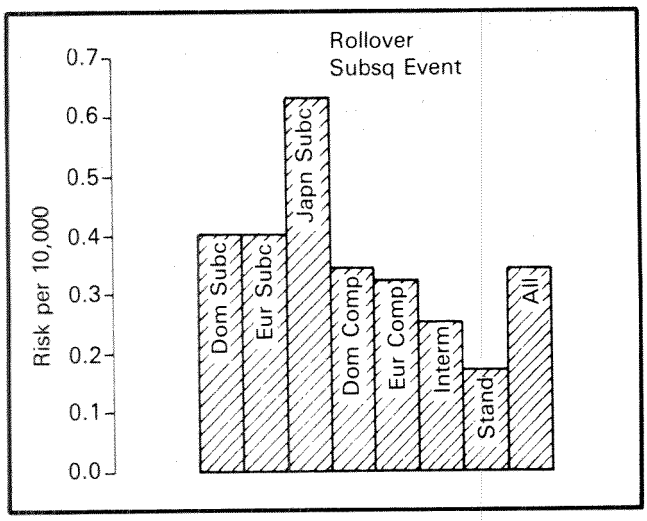

Figure 9. Fatal involvement risk of new cars in post-impact rollover per 10,000 registrations by market class

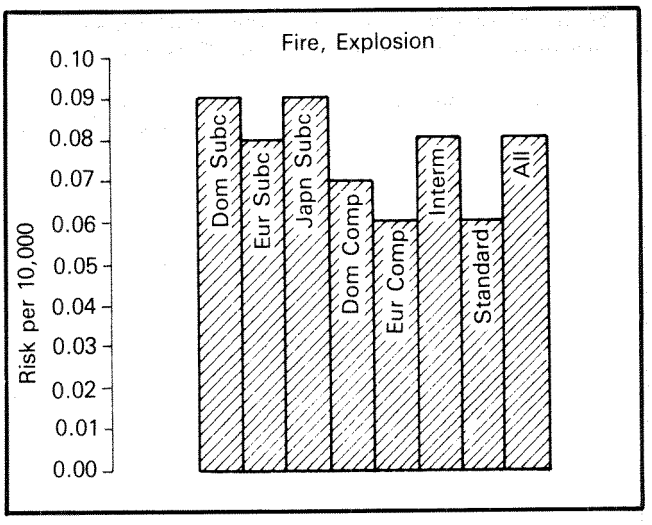

Figure 11. Risk of fire or explosion of new cars involved in fatal accidents per 10,000 registrations by market class

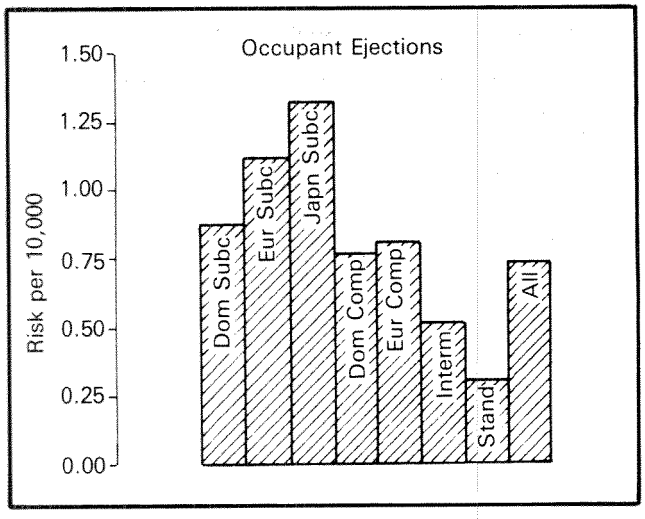

Figure 10. Ejection risk of new car occupants involved in fatal accidents per 10,000 registrations by market class

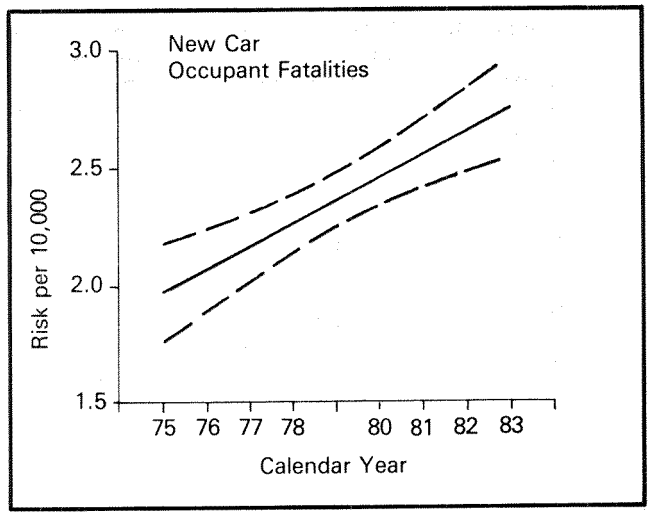

Figure 12. Fatality risk of new car occupants per 10,000 registrations—least-squares pitted mean and 95th percentile confidence rounds versus calendar year

In spite of the statistical significance of the above estimates, the reader should keep in mind that the risks under consideration, obtained from the raw data for each of the past 10 calendar years, have been adjusted for variations in travel and exposure severity. These adjustments, discussed earlier and detailed in the first part of Appendix B, are necessary to secure comparability of exposure and exposure severity for new cars in the period 1975 to 1983. There is no certainty these adjustments are the most appropriate or that they are free of error.

With full awareness of these uncertainties and for information purposes only, we have proceeded to examine the possible origins of the estimated risk increase by impact type and market class of new cars. For this purpose, we repeated the procedure discussed above in connection with Figure 12. The results are shown in Table 10 as estimates of the risk increase for a 10-year period. The units in this table are occupant fatalities per 10,000 new car registrations. Only cases with statistically significant (95 percent confidence) results are shown. All other cases are either omitted or show the entry "none." Note that Table 10 has an entry-by-entry correspondence with Table 6. The latter displays means, while the former displays change within the 10-year period under consideration.

The calendar year variation of the risk by market class is shown in Figure 13, which essentially resolves Figure 12 by market class. It also resolves the last column of

Table 10 by calendar year. Note that the slope for the entire fleet of new cars, evident in Figure 13, is the result of two factors: (1) a contribution from individual market class slopes, most of which are significantly different than zero, and (2) market class shifts that took place between 1975 and 1983. For example, the share of fleet component 3, highest risk shown in Figure 13, increased by a factor about 2.5 between 1975 and 1983, while the share of fleet component 7 (lowest risk) was reduced by over 50 percent in the same period. Such market class shifts by themselves account for a significant part of the overall risk increase observed for new cars in Figure 12.

The risk increase observed in the past 10 years for new cars is not necessarily inconsistent with the observation made earlier that the risk for all cars remained unchanged, or changed very little, during this period. The difference between all cars and new cars, let us say the older cars, is a substantial fraction of all cars, accounting for about two-thirds of the exposure to risk. Although we have made no specific determinations yet, we have good reasons to believe that the older cars of calendar year 1983 may show lower risks than the older cars of 1975. Our reasons are based on the fact that the latter subfleet is dominated by cars produced in the 1960's and very early 1970's, i.e., before the manufacturers had the opportunity to fully implement an extensive set of safety improvements.

Occupant ejection risks for new cars have been examined by the same procedure, as a function of calendar year 1975 to 1983. The resulting slope is .036 ± .006 per year in occupant ejections per 10,000 new

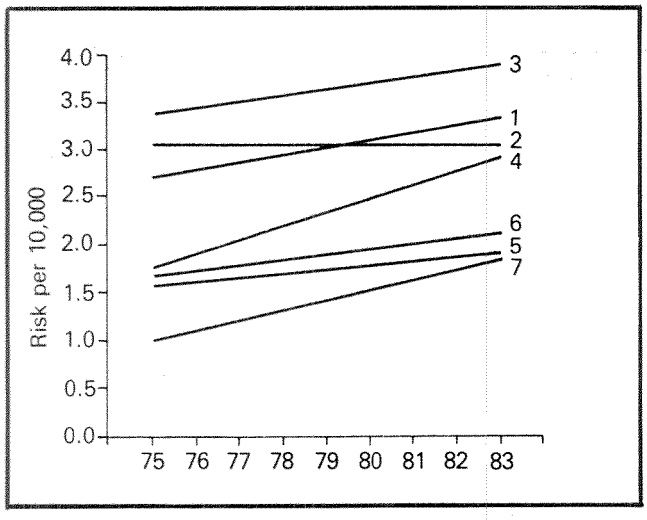

Figure 13. Fatality risk of new car occupants per 10,000 registrations by market class—linear least-squares fits to variation versus calendar year (plots 1, 2, and 3—domestic, European, and Japanese subcompact, respectively; plots 4 and 5—domestic and European compacts; plots 6 and 7—intermediate and standard cars)

car registrations. The risk increase for a 10-year period is .36 ± .06, which is also rather substantial when compared to the mean risk .73 ± .03 of occupant ejections for the same period. This increase appears to be as unevenly distributed among car market classes as the overall fatality risk is (see Table 10). A similar examination of the risk for crash events such as fire or explosion showed no statistically significant variation in the calendar years under consideration.

Influences of Car Weight and Wheelbase

An examination of Table 8 leads us to believe that market class and especially nameplate designations appear to influence the risk of fatal accident involvement as much, if not more, than weight and wheelbase. To quantify these notions, we have examined the data—risk versus car weight and/or car wheelbase—for over 500 nameplate model year combinations, each weighted with exposure (registered car years). We have applied log-linear regressions and have segregated the data by type of impact in addition to examining them for all accident types combined.

The results of these regressions are shown in Table 11 as regression coefficients and their standard errors. The upper part of the table shows the coefficients of separate regressions, i.e., the effect of weight with no control over wheelbase variation and vice versa. The striking similarity between the weight and wheelbase effects is no mystery, given these two variables are covariant in the fleet of cars. Accordingly, the question arises whether one and which one of the two effects is dominant. Thus the risk data were also regressed versus weight and wheelbase concurrently.

The coefficients of these regressions are given in the lower part of Table 11. They show the effect of car weight when the wheelbase variation is controlled and vice versa. It is evident in these results that the car weight influence is not only small in general and smaller than the wheelbase influence but also contrary to a popular notion that risk increases sharply with weight reduction. Note, in Table 11, negative coefficients indicate a risk reduction per unit weight reduction. This is what is observed for the car

Table 11. Occupant fatality risk variation for new cars by impact type as a function of car weight and wheelbase

Impact Type	Percent Risk Increase Per 500 Pounds of Car Weight Reduction	Per 5 Inches of Wheelbase Reduction

Other	-14.6 5.9	41.8 5.0
All Types	.9 3.0	15.7 2.5

weight influence on occupant fatality risks for the (predominantly rollover) other impacts. Front, side, and rear impacts show a very small sensitivity, positive or negative, that is not easily distinguishable from zero within the stated standard error. Overall, the risk sensitivity to car weight, at fixed wheelbase, is zero for all practical purposes.

On physical grounds, lighter cars, colliding with heavier cars or other vehicles, experience a momentum disadvantage and thus a crash severity disadvantage by comparison to the heavier cars. On these grounds, a substantial risk sensitivity to car weight is expected, but it appears to be masked by other factors with a stronger influence. The influence of car wheelbase, at fixed car weight, appears to be substantial and quite sensitive to the type of impact. Although there may be certain physical reasons for expecting this influence, a much stronger influence may be attributed to nameplate or market class designations, as is evident in the results shown in Table 8.

The Possibility of Confounding Factors

The observed sensitivity of car occupant casualty risks to car class or nameplate is not immune from the confounding effects due to variations in the distribution of circumstantial but influential attributes among the car occupants and the car classes or nameplates under consideration. Included in these confounding factors is any attribute that: (1) has a substantial influence on the risk, and (2) has a significantly varying distribution among the car classes under examination.

A more detailed discussion of this subject is given in Appendix B in connection with Equations (B-1) to (B-8). In the same part of this appendix, we address what determinations are necessary to estimate the likelihood of confounding effects and what adjustments are appropriate to control their influence. We have applied these procedures in the examination of the data concerning sensitivity of car occupant risks to car class.

The number of circumstantial attributes that may influence the outcome of a car occupant involvement in fatal accidents is large, and their complexity is also large. Given that the occupant casualty risks under consideration here are on a per registered car basis, confounding effects may originate from attributes that influence car involvement in a crash, as well as from attributes that influence the casualty outcome, given a crash. The extent of the influence of the former type of attributes has been addressed (12), at least in connection with types of accidents showing a high sensitivity to market class. The adjustments necessitated by these considerations were found to be small in comparison to risk differentials between market classes.

We estimate the magnitude of the effects due to differences in the distribution of attributes that influence casualty outcome, given a crash. Among the most likely to be influential, we consider the time and place of the crash as proxies of crash severity, the restraint status of car occupants, and the age of car occupants. Table 12 shows the frequency of these attributes among car occupants involved in fatal crashes by car market class. Note that for brevity in this table, the shown circumstantial attributes have a binary categorization and the shown frequency values, in percent, concern the shown category. The percent value for the not-shown category is obviously 100 percent minus the shown percent.

It is evident in the data of Table 12 that the distribution of circumstantial attributes among car market classes shows no significant variation or any pattern conspiring to enhance an occupant's susceptibility to harm, given a crash. On this basis alone, we may expect no substantial

Table 12. Frequency of circumstantial attributes in fatal accidents of new cars, 1975-1983

European	60.5 2.0	53.3 2.5	18.4 1.9	11.7 1.0
Intermediate	55.5 ± 1.4	57.1 ± 1.3	25.6 ± 2.3	6.6 ± .9
Standard	49.2 ± .6	58.6 ± .9	41.2 ± .7	8.0 ± 1.0
Entire Fleet	55.1 ± .7	58.8 ± 1.2	24.2 ± .4	7.2 ± .8

confounding effects. However, we have proceeded to apply the estimation procedure, discussed in the second half of Appendix B, for arriving at risk values adjusted for the differences in the distribution of influential attributes shown in Table 12.

We computed the occupant risk adjustment factors shown in Table 13. These are ratios of the adjusted to unadjusted values of the risk by market class. An account is given for each influential attribute taken individually and for all attributes combined. As is evident in this table, the effects are noticeable but not very large.

Table 13. Occupant fatality risk adjustments accounting for differences in the frequency of influential attributes

Market Class	Risk Adjustment Factor by Attribute				
	Night Accident	Rural Accident	Occupant Age Over 45 Yrs	Occupant Restrained	All Combined
Subcompact					
Domestic	.992	.979	1.035	.995	.999
European	.974	.996	1.040	1.022	1.031
Japanese	.973	.995	1.045	1.010	1.021
Compact					
Domestic	.997	.992	.999	.995	.984
European	.958	1.076	1.024	1.040	1.099
Intermediate	.997	1.022	.994	.995	1.008
Standard	1.050	1.003	.936	1.007	.991
Entire Fleet	1.00	1.00	1.00	1.00	1.00

The above analysis leads to the conclusion that no major confounding influences are in effect in the determination of occupant casualty risks when cars are aggregated by market class. However, the reader should not generalize this conclusion. First, it should be kept in mind there is no automatic assurance that all potentially influential confounding factors have been examined. In addition to possible unsuspected factors recorded in the accident files, there may be influential factors not recorded.

Another equally important consideration is the degree of desired disaggregation of the data in relation to the magnitude of the risk differentials we are attempting to examine. When relatively small differentials must be examined for a large number of classes and subclasses, the procedure of controlling for confounding factors can be very frustrating.

Appendix A

Major Changes in the Motor Vehicle Fleet and Travel

While the resident population in the United States grew at an average rate of 1.1 percent per year in the past 15 to 20 years, the number of licensed drivers grew faster, at an average rate of about 3 percent per year. An even faster growth took place in the number of registered motor vehicles and in the miles of travel of these vehicles each year. These grew at a rate of about 4.5 percent per year. In addition to growth, significant changes took place during this period in the composition and major characteristics of the motor vehicle fleet as discussed next.

Shifts in Fleet Shares by Vehicle Type

Between the early 1960's and 1980's, the mix of vehicle types in the fleet on the road changed significantly. In the early 1960's, vehicles other than cars were a relatively small fraction of the fleet. Since then, two fleet components, trucks and motorcycles, have grown and are growing faster, as shown below:

	Registration (Millions)		
	Cars	Trucks (All Types)	Motorcycles
Early 1960's	55-65	10-13	1.3
Early 1980's	105-110	35-39	5.8

It is evident that while car registrations have barely doubled in 20 years, truck registrations have easily tripled and motorcycle registrations have more than quadrupled. Furthermore, new truck sales as a percent of all motor vehicle sales have risen from about 12 percent in the early 1960's to about 22 percent in the early 1980's.

These two vehicle types have been and still are of concern in the safety community because they are, in general, substantially more involved in accidents than the average vehicle type (see Table 2 in the main text). They also present special problems that are size-related. Trucks are more aggressive and motorcycles more vulnerable than the average vehicle type.

Changes in Major Car Characteristics

Two car characteristics—weight and wheelbase—are singled out for general consideration because they are often discussed and analyzed in connection with accident and casualty risks. Significant changes have taken place in these characteristics in the past 10 years for most makes and market class categories, especially of the domestically produced new cars. Table A-1 shows car weight changes, and Table A-2 displays the wheelbase changes in an identical format.

For the market class characterization in these tables, we have followed the practice of the domestic car trade literature, i.e., a classification by nameplate or car line into market class categories. European makes are classified as subcompact except for makes with a wheelbase above 100in (e.g., Mercedes Benz, Audi, BMW, Volvo, and a few others). Also, the great majority of the Japanese makes are subcompacts with a few low volume exceptions. We have used the R.L. Polk registration counts by nameplate and model year for obtaining weighted means of car weight and wheelbase and for the percentages of front-wheel-drive cars.

Travel and Exposure Pattern Changes

Gasoline supply disruptions, the 55mph speed limit, the rising cost of highway travel, and various cycles in the economy have influenced travel and exposure patterns in the past 15 years. The resulting variations are noticeable but lesser than the changes in the motor vehicle fleet discussed above.

The average annual travel per vehicle has fluctuated by less than 5 percent in the period under consideration. However, larger fluctuations have been observed for specific vehicle categories as shown in Table A-3. The source of the data in this table is (5). The annual travel of cars, for example, shows a significant reduction between 1973 and 1974 and again between 1978 and 1981. Car travel is generally more responsive to and follows the pattern of major influencing factors.

In the late 1960's and early 1970's, car travel showed minor fluctuations around 10M/mi/yr. A significant decline occurred between 1973 and 1974 due to the oil embargo at that time. From 1974 to 1978, car travel per year increased slowly but steadily until 1979, when another oil crisis forced an abrupt reduction. This reduction was prolonged and deepened well into 1981 due to a depressed economy.

The increase of annual travel per car, starting in 1982, has coincided with the economic recovery that also started at that time. Note the annual travel for other

1983	9.64	9.71	52.4	2.15	9.73

vehicles, especially trucks, is much less discretionary and does not necessarily follow the pattern of car travel. The pattern for all motor vehicles agrees with that of cars because car travel dominates.

Annual travel per car is known to vary substantially as a function of car age (or of model year in a fixed calendar year). Variations may also exist as a function of market class. The data for a detailed and systematic examination of these patterns and their variation in the past 10 to 15 years are not at hand. However, the available information is generally consistent with the summary shown in Table A-4, which addresses relatively new cars, i.e., of age 3 years or less.

Table A-4. Annual travel per car as a function of car age and car market class

Car Market Class	1st Yr. Travel Thousand Miles/Car	Travel Ratio 2nd Yr./1st Yr.	Travel Ratio 3rd Yr./1st Yr.
Subcompact	13.2 ± .47	1.00 ± .02	.95 ± .03
Compact	12.1 .51	.91 .05	.89 .07
Intermediate	13.3 .60	.89 .02	.82 .03
Standard	13.6 .36	.91 .03	.84 .02
All	13.0 .2	.94 .02	.87 .03

The data in each entry of this table are averages of corresponding values provided by a large number of sources(2,3,6,7,9,10) spread over several years between the mid-1970's and early 1980's. The raw data in these sources have very dissimilar origins. In spite of this, fair agreement is observed for car ages up to 3 years or with respect to car market classes. This is reflected in the relatively small errors that arise when data from all these sources are averaged, as shown in Table A-4. Furthermore, no significant or systematic trend has been found in the data with respect to calendar year variations, again for car travel categorized as in Table A-4.

Travel speed patterns have also changed substantially in the past 10 to 15 years. The 55mph speed limit went into effect nationwide early in 1974. Before that time, the prevailing average speed on interstate highways was about 65mph. This average speed dropped to about 57.5mph in 1974. In the following years, this speed increased steadily, slowly in the second half of the 1970's but faster in the early 1980's. Table A-5 shows the percentage of motor vehicles noncomplying with the 55mph speed limit while driving on U.S. highways. The source of these data is (5).

Travel speed is one of the factors that influence the severity of the exposure to accident and casualty risks. Many other factors, driver-, environment-, and vehicle-related, may also be influential with varying strengths. As an overall descriptor of exposure severity, we have considered the rate of accidents per unit travel for all vehicles on U.S. roads. Table A-6 shows how this rate has varied in the past 10 years. The source of these data is (11).

Table A-5. Percent of motor vehicles on U.S. highways exceeding shown speed in the early 1980's

Year	55 MPH	65 MPH	75 MPH
1980	49.3	16.8	4.1
1981	48.5	18.4	5.2
1982	52.6	24.2	7.9
1983	54.1	25.4	8.5

Table A-6. Fatal accidents and nonfatal injury accident rates per 100 million vehicle-miles traveled on U.S. roads, by calendar year

Year	Accidents Per 100 Million Miles Fatal	Nonfatal Injury
1975	2.85	133.0
1976	2.87	133.3
1977	2.91	129.8
1978	2.92	135.9
1979	2.97	137.5
1980	2.96	132.8
1981	2.84	130.1
1982	2.45	123.6
1983	2.30	121.6

Appendix B

Errors and Adjustments in Risk Determinations

The most common and serious source of error in the estimation of absolute risks, in any application of Equations (1) to (6), is the absence of coincidence in the categorization of vehicle attributes represented by subscript j between the numerator and denominator. The steps taken to minimize this type of error have been outlined in the main text in connection with absolute risk determinations.

A second, but separate, concern is the number of vehicle, accident, and occupant categories that must be introduced to obtain the desirable resolution in the computation of risks. It is desirable, although not always feasible, to resolve the entire data base into as many cells as necessary to obtain fairly uniform risks within each population. This, however, must be traded off against the statistically insignificant results obtained when a large number of cells yields populations that are too small.

Even after the concerns discussed above are satisfied, further adjustments may be appropriate to deal with nonuniformities in the exposure conditions relevant to risk determinations. This appendix discusses such adjustments.

We consider first a normalization procedure used for relatively new cars (1 to 3 years old) traveling on U.S. roads in any of the calendar years 1975 to 1983. The exposure variations experienced by these subfleets were discussed in the last section of Appendix A. Tables A-3, A-4, and A-6 display relevant data. When comparing or aggregating these subfleets, it is convenient and appropriate to normalize their accident experience to an arbitrary but common basis. For this purpose, we have selected the 1-year-old cars, under the travel and exposure severity conditions of calendar year 1980.

In practice, normalization is performed through factors that multiply the risks of accident involvement per vehicle registration to normalize them to the reference exposure conditions. Table B-1 shows normalizing factors A and B for annual travel per car by calendar year and for exposure severity, respectively. Factor A is obtained from the car travel data shown in the first column of Table A-3, by making 1980 the reference year. Similarly, Factor B is obtained from the data of Table A-6.

The product of Factors A and B is the composite normalization factor for 1-year-old cars. This product appears in the first column of Table B-2. The other two columns of this table show the composite normalization factors for 2- and 3-year-old cars, respectively. These factors have higher values, which reflect the travel reduction taking place as the car age increases. The relevant data for these transformations are shown in the last row of Table A-4.

Table B-1. Normalization factors by calendar year for annual travel per car (column A) and for exposure severity (column B)

Calendar Year	A	B
1975	.95	1.04
1976	.94	1.03
1977	.93	1.02
1978	.91	1.01
1979	.96	1.00
1980	1.00	1.00
1981	1.02	1.04
1982	.96	1.21
1983	.95	1.29

Table B-2. Normalization factors for travel and exposure by car age and calendar year

Calendar Year	Car Age 1 Year	2 Years	3 Years
1975	.99	1.05	1.14
1976	.97	1.03	1.11
1977	.95	1.01	1.09
1978	.92	.98	1.06
1979	.96	1.02	1.10
1980	1.00	1.06	1.15
1981	1.06	1.13	1.22
1982	1.16	1.23	1.33
1983	1.23	1.31	1.41

In addition to travel per vehicle and exposure severity in general that show variations from year to year, there are many exposure attributes that influence accident risks, even in the absence of calendar year or model year considerations. Accordingly, adjustments would be necessary to bring the determination of risks under

exposure conditions as comparable as possible, when such comparability is desired. When necessary, these adjustments are made according to the procedure discussed below. Consider first the risks R_1 and R_2 concerning two different vehicle classes 1 and 2, as determined from aggregated data of casualty counts C and exposure E:

$$R_1 = \text{Sum } C_{1q}/\text{Sum } E_{1q} \quad \text{(B-1)}$$
$$R_2 = \text{Sum } C_{2q}/\text{Sum } E_{2q} \quad \text{(B-2)}$$

The summations in these relations are over all exposure conditions designated by q. Note that in Equations (B-1) or (B-2) as well as in the following discussion, E, referred to as exposure, is not necessarily limited to travel or registrations but could be any variable used in the denominator of a risk determination. See, for example, the denominators in Equations (3) or (5). Furthermore, subscript q is a generalization representing any exposure attribute that may influence the risk. It is now helpful to introduce the exposure distribution frequencies:

$$F_{1q} = E_{1q}/\text{Sum } E_{1q} \quad \text{(B-3)}$$
$$F_{2q} = E_{2q}/\text{Sum } E_{2q} \quad \text{(B-4)}$$

Note that the sum of all F_{1q} or all F_{2q} values equals unity.

The use of these equations in (B-1) and (B-2) yields:

$$R_1 = \text{Sum } (F_{1q}R_{1q}) \quad \text{(B-5)}$$
$$R_2 = \text{Sum } (F_{2q}R_{2q}) \quad \text{(B-6)}$$

where the risks R_{1q} and R_{2q} are defined by $R_{1q} = (C_{1q}/E_{1q}$ and $R_{2q} = (C_{2q}/E_{2q})$. Equations (B-5) and (B-6), which are fully equivalent to (B-1) and (B-2), are more informative. They show that, in each case 1 or 2, the aggregated risk is the sum of risks corresponding to individual exposure conditions, with each such risk weighted by the frequency of occurrence of the corresponding exposure condition.

When risks R_1 and R_2 are determined under aggregated exposure conditions, i.e., by Equations (B-1) and (B-2), any difference between them may be not entirely due to risk differentials under specific exposure conditions. As shown in Equations (B-5) and (B-6), differences between R_1 and R_2 may arise from differences between R_{1q} and R_{2q}, or from differences between F_{1q} and F_{2q}, or from both sources.

A numerical example will clarify these points. Let subscripts 1 and 2 represent two different vehicle types and subscripts a and b represent two different exposure conditions, say urban and rural travel. Furthermore, suppose the data we are dealing with are:

$F_{1a} = 90\%$,
$F_{1b} = 10\%$;
$F_{2a} = 10\%$,
$F_{2b} = 90\%$

for the frequencies of occurrence of the exposure and:

$R_{1a} = 3$,
$R_{1b} = 1$;
$R_{2a} = 5$,
$R_{2b} = 2$

for the individual risks, in accidents per unit exposure. The risks R_1 and R_2, integrated over both exposure conditions for each vehicle type, are:

$R_1 = 2.8$ and $R_2 = 2.3$.

This answer may be fine if we wish to compare the risks of vehicle categories 1 and 2 under their recorded exposure conditions. However, this answer is absurd if it is meant to be a risk comparison under exposure conditions assumed to be fairly similar. It is absurd because R_{1a} is lower than R_{2a} and R_{1b} is lower than R_{2b} so R_1 is also expected to be lower than R_2, but it is not. This very substantial distortion is introduced because the frequencies of occurrence of exposure categories differ significantly between vehicle types 1 and 2.

Whenever risk calculations and comparisons, vehicle category 1 versus 2, are made over aggregated exposure conditions, it is essential as a minimum to determine and review the frequency distributions of exposure conditions for each of the vehicle categories 1 and 2. If these distributions are fairly similar, the possibility of distorted results is minimized. However, if the distributions differ substantially, then Equations (B-1) and (B-2) or their equivalent (B-5) and (B-6) as written are inappropriate for risk determinations.

Equations (B-5) and (B-6) may be used but only after an adjustment. The necessary adjustment requires that F_{1q} and F_{2q} must be made identical. This can be done either by retaining F_{1q} in (B-5) but also using the same in (B-6) instead of F_{2q}, or by retaining F_{2q} in (B-6) and also using the same in (B-5) instead of F_{1q}. These two alternatives correspond to risk comparisons either under the exposure conditions of vehicle category 1 all across the board or under those of vehicle category 2 also all across the board. A third alternative may be considered by pooling the exposure conditions of both vehicle categories together and determining a frequency distribution F_q for the pooled populations. For this alternative, the appropriate version of Equations (B-5) and (B-6) is:

$$R_{\bar{1}} \quad \text{Sum } (F_qR_{1q}) \quad \text{(B-7)}$$
$$R_{\bar{2}} \quad \text{Sum } (F_qR_{2q}) \quad \text{(B-8)}$$

Note that the risks R_{1q} and R_{2q} must be determined for each exposure category q and then used in conjunction with the common frequency distribution F_q for the determination of R_1 and R_2. Other alternatives are possible for introducing a common frequency distribution. Which alternative is selected depends on the terms under which we wish to compare risks.

Accident Research Unit, Birmingham University, West Midlands, U.K.

Abstract

A major study is currently underway in Britain, funded jointly by the Department of Transport, Ford, and BL Technology, to investigate the causes of injury to occupants in car accidents. The Accident Research Units at the Institute for Consumer Ergonomics, Loughborough, and at Birmingham University each have a team of researchers who, together with the Department of Transport Traffic Area teams, investigate approximately 700 accidents each year. The data are collected in a uniform manner by all investigators, and the data bases are compatible. The accidents are strictly sampled from a predominately urban (Birmingham) and a rural (Loughborough) catchment area.

High-quality data are collected on the performance of the vehicles in crashes by detailed investigations after the accident; occupant injury details are provided by hospital consultants and coroners, sometimes by the occupants; sources of injury are assigned by the ARU teams.

The computerised data can be structured in an analysis from the point of view of the vehicle's performance in the accident, to which occupant's details can be applied, or an occupant's performance, to which vehicle details can be applied.

This paper describes the organisation of the study and provides some preliminary data on accident circumstances, occupant injuries, and vehicle performance.

Introduction

The detailed, objective investigation of the causes and mechanisms of injuries in traffic crashes originated in the United States in the 1950's. The pioneering work of Hugh de Haven and the Automotive Crash Injury Research (ACIR) group at Cornell University illustrated the potential knowledge that can be gained from such studies. Similar work did not begin in Europe until the 1960's.

Following that work in the United States of ACIR, and of Huelke and Gikas on fatal crashes, Starkes and Miller at the Road Research Laboratory in Great Britain began detailed at-the-scene studies in 1961(1). In 1964, Mackay formed an interdisciplinary team working closely with Gissane and Bull at the Birmingham Accident Hospital, and throughout the 1960's those two groups conducted a number of specific investigations covering both accident causation and the relationships between vehicle design and injuries(2).

The funding structure operating in the 1960's resulted in such investigations being limited to some 200 to 300 cases per year. As the studies were broad in their approach, encompassing all types of environments, classes of road users and vehicles, and different severities of injury, the sample sizes were correspondingly small for any specific detailed analysis. Thus, those early projects mainly defined a range of topics, gave some insight into the frequencies of various crash characteristics, and the consequences in injury terms, but did not adequately address either the specifics of the detailed relationships between vehicle design and trauma or the sampling problems created by too broad an approach.

Consequently, in the early 1970's, the Accident Research Unit at Birmingham University and also TRRL introduced different procedures. Instead of going to the scene, the involved vehicles were examined retrospectively a few days after the accident. Furthermore, several relatively rigorous sampling procedures were introduced; for instance, limiting the criteria to current model cars, serious and fatal casualties, restraint use, or frontal impacts only.

In the 1970's, there was a general upsurge of interest in in-depth studies in Europe, in part generated by the North Atlantic Treaty Organisation's Committee on the Challenges of Modern Society (NATO-CCMS) programme. Teams began operating in Sweden at the Volvo and Saab corporations, in Germany at the Technical University in Berlin, in France at the Association Peugeot-Renault, and at the Organisme National de Securite Routiere (ONSER) in Lyon, as well as at the Transport and Road Research Laboratory (TRRL) and at Birmingham University in England. In addition, various car manufacturers ran their own in-house studies notably at Ford, Volkswagen, and Daimler-Benz. As part of the NATO-CCMS programme, attempts were made to unify crash investigation procedures but, although a lot of useful interchange took place, local and national practices worked against the introduction of completely uniform practices(3). What did emerge, however, was recognition of the need to agree to uniform definitions of crash characteristics and also the need to have standardised scales for the basic input and output variables of crash injury research.

The fundamental input variable is crash severity, and this has been defined variously in terms of degrees of vehicle damage. In the United States, the TAD scale was adopted by ACIR and then used in a modified form in an early in-depth study in Australia(4). The Society of Automotive Engineers (SAE) then took up the problem, and the Collision Deformation Code was developed. This is now SAE-recommended practice and is used throughout the world for describing vehicle damage. At the same time, the concept of Equivalent Test Speed (ETS) was developed(5). In France, the Peugeot-Renault Association introduced the concept of Delta V, i.e., the velocity change in the crash phase of the impact. This has subsequently been shown to be the most appropriate measure of crash severity and is now widely used(6).

The second fundamental variable required in detailed studies is an agreed method of assessing the output, i.e., injury severity. In the 1960's there were almost as many injury scales as there were crash investigation teams. Through the efforts of the American Association for Automotive Medicine, the Abbreviated Injury Scale (AIS) was evolved. The AIS is now the standard method for injury severity classification and is used in almost all detailed accident studies(7).

The 1980's have seen a decline in crash injury research in Europe, which is probably related to the economic recession. No European country has a systematic, long-term, in-depth programme similar to the U.S. National Accident Sampling System (NASS) and the Fatal Accident Reporting System (FARS). With the benefit of hindsight, the establishment of the NASS system and the continued commitment of resources to maintaining that programme must be ranked as one of the most enlightened and far-sighted acts of any safety research administration. By contrast, the European effort continues on an ad-hoc basis without any long-term structure that would allow the detailed evaluation of the effects of design changes and associated legislation with a satisfactory longitudinal experimental design.

It has become apparent from the various studies performed that there are a number of critical points to be considered in conducting in-depth studies.

First, the dependence of the research group on other organisations is great. Good relationships with police, hospitals, garage staff, and, indeed, the general public are vital, and therefore a diplomatic approach and careful use of the media for positive reinforcement are essential.

Second, training of research staff and establishing study procedures takes much longer than most people would expect. The techniques of photography, the recording of vehicle crush measurements, and the reconstruction of occupant-vehicle interactions are quite complex.

Third, given that the investigator is inspecting the crashed car in person, it is easy to be beguiled into collecting information on the general basis that somehow it will be useful someday.

Fourth, allied to the above, is almost total neglect in the formative stages of project planning of consideration of the need for control data. This often results in the limited usefulness of some of the conclusions from in-depth crash studies.

Fifth, it is normal to underestimate the time and effort to be devoted to analysing the data from an in-depth study. Sponsors often see the end point of a project as a sample of a specified number of cases of a particular collision sample, and arrange funding and targets accordingly. The reality is that for the sensible and thorough analysis of in-depth crash injury findings, the contract length should be doubled to allow for analysis and interpretation of the findings and the presentation of such findings in appropriate reports and publications.

In the following sections, the structure of current British in-depth studies is described. The primary aim of the current studies is the collection of data on injury causation and vehicle crashworthiness. These data are used for different purposes by the members of the sponsoring consortium. The Department of Transport Vehicle Standards and Engineering Division (VSE) requires information on the performance of injury-reducing features of vehicles controlled by legislation and information on the trends occurring to review and update the regulations for the construction and use of cars. This information is used both in a national context and internationally with the EEC and ECE organisations. The Vehicle Inspectorate (VI) monitors the data for possible problems and defects that may lead to changes in future vehicle design or recalls under the U.K. Code of Practice on action concerning vehicle safety defects. The Transport and Road Research Laboratory uses the data

for a variety of studies on human tolerance to injury. The two motor companies, Ford and BL Technology, who provide a service to Austin Rover Group, Freight Rover, Land Rover, Leyland vehicles, and Jaguar cars, require detailed information on the performance of current models in real-world collisions to supplement laboratory tests and for the development of their products.

Organisation of the Study

The sponsoring consortium has contracted the Accident Research Units (ARU) at the Institute for Consumer Ergonomics, Loughborough, and Birmingham University to investigate the causes of injury to occupants of cars involved in accidents. Together with the Department of Transport's vehicle examiners in four traffic areas, data will be collected on approximately 700 accidents each year. The team at Loughborough investigates accidents in Derbyshire, Nottinghamshire, and Leicestershire, and the team at Birmingham investigates accidents in the West Midlands. Two of the Department of Transport traffic area teams work with the ARU's, namely East Midlands with the Loughborough team and West Midlands with the Birmingham team. The Northern traffic area team investigates accidents in Durham, and the Western traffic area team investigates accidents in Avon, Somerset, and parts of Wiltshire. The work of the traffic area teams is coordinated by the ARU at Loughborough.

Disproportional stratified sampling of all crash severities is carried out by the Loughborough and Birmingham teams. The Northern and Western traffic area teams investigate a proportion of the serious and fatal accidents in their areas. The area covered by the teams at Loughborough is predominately rural and contains three major centres of population—Leicester, Derby, and Nottingham. There are 9,093 miles of public road comprising 79 miles of motorway, 417 miles of trunk road, 860 miles of A-class nontruck road, 2,820 miles of B-class road, and 4,917 miles of unclassified road. These roads comprise 5.6 percent of the total road mileage in Britain. In 1983, there were 124 car occupants killed and 5,880 injured. The area covered by the team at Birmingham is essentially an urban area with a small rural area separating Coventry from the rest of the conurbation made up of Wolverhampton, Walsall, West Bromwich, Dudley, Sandwell, Birmingham, and Solihull. There are 3,945 miles of public road comprising 43 miles of motorway, 60 miles of trunk road, 350 miles of A-class nontrunk road, 456 miles of B-class road, and 3,036 miles of unclassified road. These roads comprise 2.4 percent of the total road mileage of Britain. In 1983, there were 47 car occupants killed and 4,336 injured. The populations of the two areas are similar: 2.76 million in the Loughborough team area and 2.67 million in West Midlands. The car ownership rates are also similar: 733 thousand private cars and vans in the area covered by the Loughborough team and 776 thousand in the West Midlands area. The car occupant casualties in the area covered by the Loughborough team comprise 5.3 percent of the national total; those in the West Midlands comprise 3.8 percent. Compared with the figures for Great Britain, the areas covered by the two ARU's comprise 6 percent of the total road mileage.

The study is concerned only with cars up to 5 years old that are damaged sufficiently in the accident to be towed away from the scene. These are "case" vehicles. Accidents are notified to the teams by their local police forces. Accident cases are sampled according to police injury classifications of fatal, serious, slight, and noninjury. The disproportional stratified sampling scheme is structured so that each ARU team investigates approximately 300 accidents each year with a roughly equal split between serious/fatal accidents and slight/noninjury accidents. The two remote traffic area teams also investigate 50 accidents each. The local hospital consultants provide data on injuries sustained by those occupants who are taken to hospitals. The coroners provide injury data on fatally injured occupants. The teams also send questionnaires to the occupants in all cases except specified sensitive cases.

Data Collection and Analysis Procedures

The teams all follow standard procedures and record data in identical forms. Consistency between the teams is most important and is achieved by the use of a manual defining procedures and conventions, by regular team meetings, and by an updating newsletter.

Vehicle data are collected on case vehicles by systematic investigation of vehicle component performance carried out by the teams at recovery garages within a few days of the accident occurrence. The teams work in pairs, one person taking photographs and the other completing the form. Vehicle damage and occupant contact details are recorded on specially designed data collection forms used by all the teams. The forms allow information to be recorded in coded and descriptive formats. Certain coding is carried out at the time of the examination, and other coding is completed after the accident has been reconstructed. All aspects of the vehicle that could affect occupant injury are examined and the performance noted and recorded photographically. These include performance of vehicle structures, safety features such as seatbelts, and other aspects such as steering wheels and columns, seats, doors, and glass. The data collected are factual such as extent of crush, extent of steering column stroke, measurement of plastic transfer on seatbelt webbing, and damage to components. Other data are inferential, such as whether the occupant may have been ejected during

the accident, possible contacts, and whether seatbelts were likely to have been worn in the accident. In these cases, the conclusion is recorded and the evidence on which the conclusion is reached noted on the form. A report is generated for each case vehicle, which can be from 12 to 20 A4 pages in length depending on the complexity of the vehicle damage, with certain pages being completed only if there is damage to the component.

Occupant data are recorded on occupant injury forms, based on reports from the hospital consultants, coroners, and the questionnaires. Injury severity is scored and recorded using the Abbreviated Injury Scale (AIS) and the Treatment Period (TP) and Permanent Impairment (PI) scales of the Comprehensive Research Injury Scale. The occupant kinematics are estimated from the collision circumstances, from the occupant contact data recorded during vehicle examination, and from the occupant's injuries. The causes of the injuries are inferred from these sources. This is normally done by the accident teams in consultation with the medical advisers and those who examined the vehicle.

It is important that data of different types are differentiated. There are factual data comprising measurements, observed damage, injuries, and so on, and there are inferential data comprising conclusions drawn from evidence such as whether a seatbelt was worn or what was the source of an injury. The coded data are transferred to mainframe computers for analysis using the SPSS-X statistical analysis package. Both teams have access to Honeywell computers that use the Multics operating system and can be linked together allowing combined analyses. Each team also has a microcomputer for general office management, for keeping track of each accident case prior to completion, and for indexing basic data on vehicle damage and occupant injury severity.

The Data Base

An accident case comprises a detailed investigation and record of each case vehicle involved in the accident, a brief examination and record of the other vehicles, a detailed record of the injuries sustained by each occupant in the case vehicles, and a summary sheet describing the main points of interest for the accident as a whole. The data are recorded in a number of ways within the accident case record. Photographic records in the form of slides are taken for each vehicle. There are standard photographic shots of the vehicle exterior and interior and also photographs of damage detail and occupant contacts. On the vehicle form, the data are recorded in precoded form; wherever damage or other points of interest have occurred, detailed descriptions are written on the form. Information from other sources, such as the occupant questionnaires or causes of component faults or damage, are postcoded. Figure 1 is a section of the vehicle form and shows precoded, descriptive, and postcoded data.

Data are recorded on the injury forms for each occupant. The data are factual, such as occupant's date of birth; descriptive, where each injury is described in detail; and inferential, such as the probable cause of the injury or the contact observed in the vehicle investigation. In addition, the injuries are scored using the AIS, PI, and TP scales. Figure 2 shows an extract from the occupant injury form where the injuries are described, scored, and coded.

The sources of injury are assigned in discussion with the team's medical adviser and entered on the coding forms. The Maximum Abbreviated Injury Score (MAIS) and the Injury Severity Score (ISS) are also calculated. Figure 3 shows an extract from the Injury Coding sheet, which is used to encapsulate all the injury and correlational injury causation data.

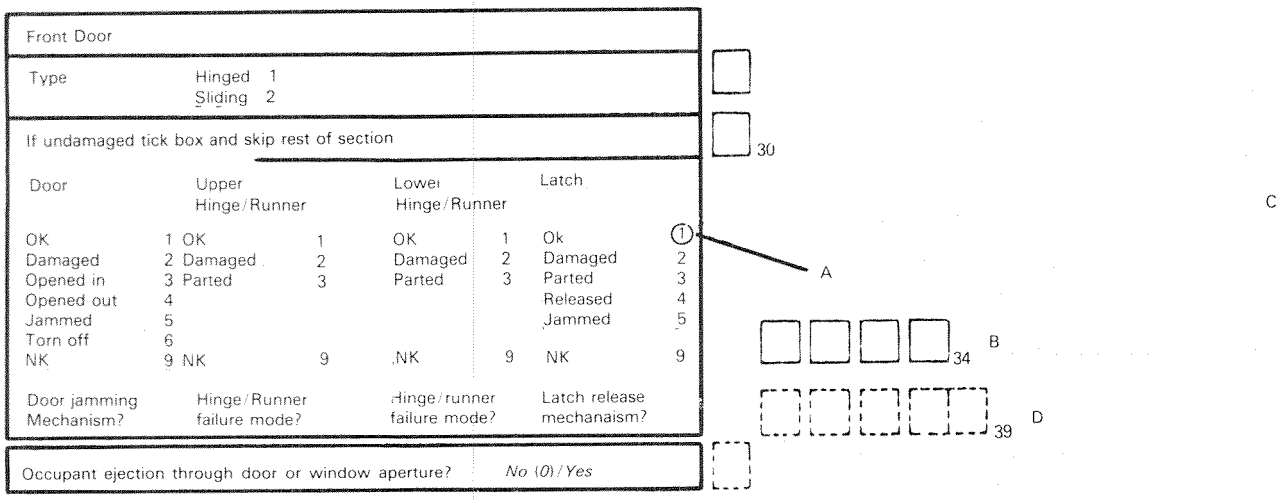

Figure 1. Extract from vehicle form

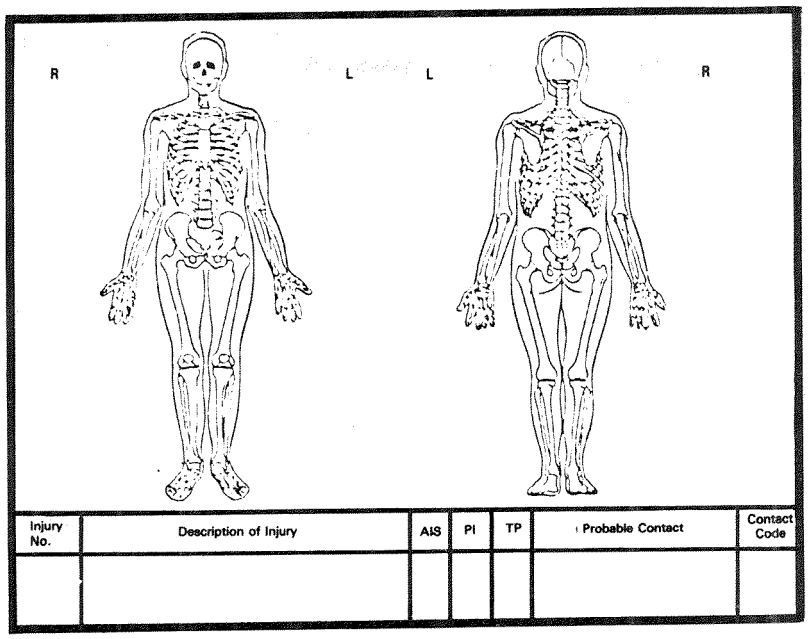

Figure 2. Extract from injury form

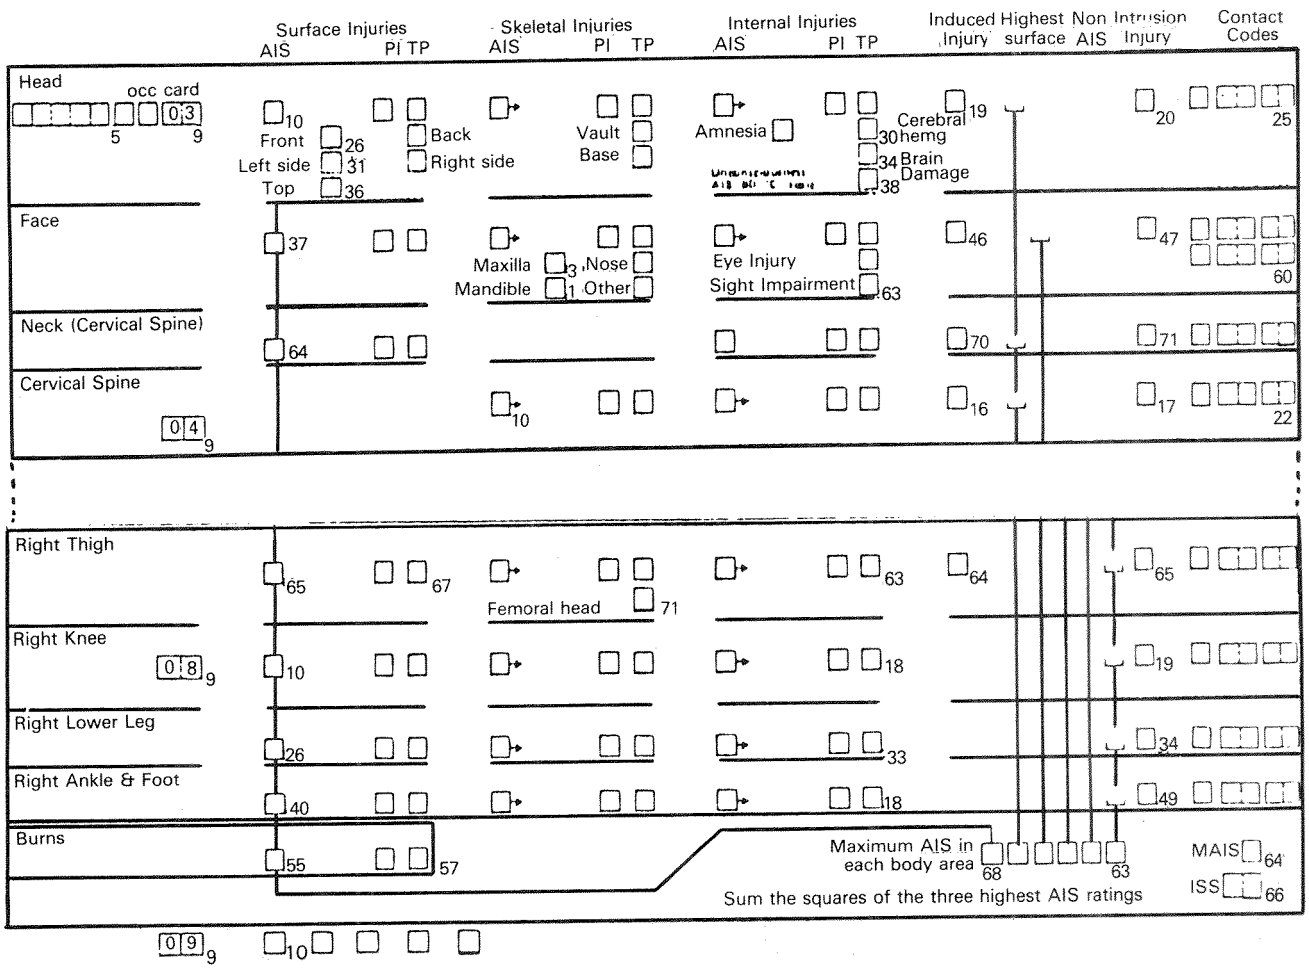

Figure 3. Extract from injury coding form

The data are organised in the computer data base such that all the coded variables are available for each vehicle and each occupant. Certain vehicle variables are also repeated and associated with the injury variables so the data for vehicles and occupants can be analysed together where appropriate.

Preliminary Findings

The study has been underway since 1983. The following preliminary findings are based on data collected by the ARU at the Institute for Consumer Ergonomics at Loughborough and the East Midlands traffic area (EMTA) team during the year 1984.

The accidents are sampled in such a way that the population comprises cars of all makes up to 5 years old involved in an accident in which the car is towed away. From this population, accidents are sampled for investigation in such a way as to include all cases in which an occupant is fatally injured, the majority of cases in which an occupant is seriously injured, and a proportional sample of accidents in which an occupant was slightly injured or not injured at all. To represent the occurrence of accidents generally, weighting factors are applied according to the sampling ratios employed in the accident case selection. Weighted data include injury accidents only, whereas the unweighted data include noninjury accidents that have been investigated.

Accidents

It can be seen from Table 1 that the ARU at Loughborough examined 261 accident cases in the year 1984. These accident cases comprised 297 case vehicles containing 506 occupants. There were on average 1.1 cars investigated per case containing on average two car occupants per case.

Table 1. The size of the data base.

Data Base	Unweighted	Weighted
Total no. of accidents	261	908
Total no. of cars	297	1,058
Total no. of occupants	506	2,558

The distribution of accidents by speed limit in Table 2 is bimodal with 29 percent of the accidents occurring in 30mph speed limits and 23 percent occurring in 60mph speed limits. The former result is not surprising as the greatest density of traffic is found in 30mph urban areas.

Table 2. The accident circumstances

Accident Circumstances		Unweighted freq.	Unweighted %	Weighted freq.	Weighted %
Speed limit mph	30	77	29	272	30
	40	12	5	13	1
	50	4	1	6	1
	60	59	23	250	28
	70	20	8	56	6
	Not known	89	34	312	34
	Total	261	100	908	100
Road class	Motorway	14	5	42	5
	A class	130	50	469	52
	B class	29	11	69	7
	Unclassified	54	21	194	21
	Private road	1	-[1]	2	-
	Not known	33	13	132	14
	Total	261	100	908	100
Time of day (hrs)	00.00-5.59	21	8	38	4
	06.00-11.59	57	22	238	26

	18.00-23.59	90	34	318	35
	Not known	7	3	28	3
	Total	261	100	908	100

[1] Denotes percentage values less than 1.

However, the results showing a quarter of the accidents occurring in 60mph speed limits reflect the essentially rural nature of the Loughborough catchment area with more than twice the miles of road of the Birmingham catchment area. This is emphasised by the fact that half the accidents occurred on A-class roads (50 percent).

The majority of accidents occurred between 12 noon and midnight with 33 percent occurring between noon and 6 p.m. and 34 percent between 6 p.m. and midnight. Only 8 percent occurred in the early hours of the morning.

Table 3, a review of the vehicles that occur most frequently in the sample, shows that the Ford Cortina made up 41 of the 297 vehicles investigated during 1984. This was the most frequently occurring, followed by the Ford Escort Mark 3, of which 24 vehicles were included.

Table 3. The cars in the accident sample.

Make and Model of Vehicle	Unweighted freq.	%	Weighted freq.	%
Ford Cortina	41	13	152	17
Ford Escort 3	24	8	66	7
Vauxhall Cavalier 2	15	5	18	2
Ford Sierra	12	4	10	1
Austin Mini	12	4	33	4
Austin Metro	12	4	31	3
Vauxhall Cavalier 1	8	3	71	8
Ford Fiesta 1	7	2	25	3
BMW (all models)	6	2	11	1
Hillman Avenger 2	5	2	20	2
Vauxhall Astra	5	2	16	2
Audi 80	5	2	7	1
Volvo 240/260	5	2	11	1
Others	140	47	437	48
Total	297	100	908	100

This shows that in a sample of nearly 300 vehicles, very few occur in any reasonable numbers. The composition of the sample reflects the market share of each vehicle as well as the type of roads in the area, possibly indicating that the proportion of business cars in the sample is relatively high, travelling on main roads, with a low average number of occupants. Weighting the data makes a considerable difference in the ranking of vehicle type, causing the Vauxhall Cavalier 1 to appear second in the ranking.

Sixty-five percent of the vehicles involved in accidents in the sample experienced a single impact, as shown in Table 4. Twenty-nine percent experienced two impacts and only 5 percent more than two impacts. This may reflect the traffic density in the Loughborough sample as it is less likely that after an impact a vehicle will go on to strike anything else.

Table 5 shows that in 157 accidents (55 percent), the object struck in the most severe impact was another car. In 47 cases (17 percent), the object struck was an HGV/LGV or PSV, generally of considerably more mass than a car. In 54 cases (19 percent), an object other than another road user or vehicle was struck. These other objects included trees (3 percent), road furniture (4 percent), and a wall. In the second most severe impact,

Table 4. The total number of impacts seen by each case vehicle.

Data missing	9				54		68	

the car was still most likely to strike another car (31 percent).

As indicated in Table 6, it is clear that frontal impacts were most common (63 percent) of the most severe impacts. Impacts on the right side were slightly more common for the second most severe impact. There is, however, very little difference between front and both side impacts for the second more severe impact. The main effect on impact type of weighting the data has been to increase the proportion of rear impacts in the second most severe impact.

As shown in Table 8 the proportion of persons fatally injured in each seating position was approximately the same (6 percent). The proportion of persons seriously injured in each seating position was similar (24 percent). Forty-seven percent of rear-seat passengers were slightly injured. The proportion of front-seat occupants, drivers, and passengers slightly injured was smaller (32 and 38 percent, respectively). This shows that the rear-seat occupants are more likely to receive injuries (77 percent) than the driver (61 percent) or the front-seat passenger (69 percent). The main difference is in the proportions slightly injured.

Occupants

The following tables provide information about the occupants, and the nature and causes of their injuries.

Table 7 shows that of the 506 occupants of vehicles investigated 293 (58 percent) were the drivers of the cars involved, 21 percent were front-seat passengers, and 20 percent were travelling in the rear seats. There are three less drivers than vehicles because some of the vehicles investigated were parked with occupants sitting in them.

Table 7. The seating position of occupants.

Seating position	Unweighted freq.	%	Weighted freq.	%
Drivers	293	58	1,402	55
Front seat passengers	107	21	571	22

Total	27		122		183		174		506

[1] Injury severity in Tables 8 and 9 is based on the severity assigned by the police.

In Table 9, the distribution of injury severity for drivers in different age groups is shown. The drivers in the 1- to 19-year age group appear to be much more likely to be killed in this sample of accidents than drivers of other ages. Taking drivers of 29 years and younger, the table indicates they are more likely to receive injuries of all severities with only 21 percent uninjured. Because of the physical changes to the body associated with ageing, particularly in terms of bone structure, older drivers are generally more likely to be injured than younger drivers in an accident of similar severity. Taking the age group 50 years and over, 65 percent of the drivers received injuries compared with 35 percent of drivers age 30 to 49 years and 79 percent of drivers age 29 years and under. The majority of drivers in the sample (93 percent where the use of seatbelts could be established) were wearing seatbelts.

Causes of Injury

The causes of injury are established from a variety of sources including the evidence of occupant contact marks in the vehicle or elsewhere, from the nature of the injuries, and the likely injury mechanisms. Corroborative evidence may also be obtained from the occupants via the questionnaires.

In Tables 10 and 11, only the weighted data are presented so as to more effectively reflect the injury patterns occurring generally. The weighting takes account of the disproportional sampling procedures, which over-represent the serious and fatal injuries in the population.

Drivers' and Front-seat Passengers' Injuries

The injuries have been divided into minor (AIS 1) and nonminor (AIS 2 to 6) to highlight the differences in causes of injury. In most of the body areas, minor injuries (bruises and lacerations) are caused by objects that will give, such as seatbelt webbing, soft metal facias, and laminated windscreens. The nonminor injuries are caused by more solid objects such as the steering wheel, doors, or another vehicle. These injuries are often caused by an intruding contact—one of the main causes of nonminor leg injuries is an intruding footwell.

Many of the drivers' nonminor skull injuries are coded as noncontact. This is the movement of the brain within the skull due to the deceleration of the head, and is often an AIS 2 injury (loss of memory; a short period of unconciousness) that will result in a 1-night stay in a hospital.

Drivers received minor injuries (AIS 1) from seatbelt webbing and steering wheel and more severe (AIS 2 to 6) injuries from steering wheels, footwell intrusions, and a variety of other sources. Front-seat passengers also received minor injuries from their seatbelt webbing or from the facia. However, their more severe injuries often came from external objects such as the other vehicle, loose objects within the car, or footwell intrusion.

Only occupants known to have been wearing a seatbelt are included in Tables 10 and 11; other occupants were excluded, as the trajectories of unbelted occupants are quite different, resulting in different injury sources.

Vehicles

The vehicles involved in the accidents are examined in detail by the teams, and data on the performance of vehicle components are recorded. The following tables indicate how certain vehicle features performed.

Windscreens

As shown in Table 12, 31 percent of the vehicles in the sample had toughened windscreens and 61 percent had laminated windscreens. In 22 cases, it was not possible to establish the type of windscreen. The proportion of cars with laminated windscreens increases with later models.

Not Broken	51	58	79	45	130
Not Known	-	-	-	-	22
Total	86		178		286
Data missing					11

Laminated windscreens are more likely to be broken than toughened windscreens. The majority of windscreen breaks to both toughened (41 percent) and laminated (56 percent) glass were caused by distortion of the frame. The next most common cause of break to both types of windscreen was an intruding object that was not the other vehicle. The former accounted for 11 percent of toughened screen breakages and 10 percent of laminated screen breakages. The latter accounted for only 9 percent and 6 percent, respectively. In only 2 cases did the occupant cause the windscreen break to toughened glass and in 9 cases for laminated glass. Occupant contacts on windscreens were noted in 27 cases and, in a further 50 cases, occupant contact was suspected but not established. Of these 27 cases, 16 of the contacts were onto a broken screen and 7 onto an unbroken screen. In 4 cases, the state of the windscreen at the time of contact was not known.

Hatchback/Estates

Damage to the tailgate is a fairly frequent occurrence—20 percent of the sample of 149 hatchbacks and estates had some damage to the tailgate. Approximately one-third of those that sustained damage opened in the accident. This can lead to ejection of any unrestrained occupants. There are several different modes of door opening—bodyshell distortion leading to misalignment of latches, latch overload, and component failures. Of these, bodyshell distortion was the most common method, accounting for five of the nine openings. Two rear-seat occupants were suspected of being ejected through an open tailgate. Five rear-seat occupants were ejected through the rear glass area. The rear-seat occupants were not using seatbelts.

Side Doors

Out of 297 vehicles, almost half had damage to the driver's door. Sixty-nine of the 140 damaged doors were jammed, 39 of these by compression of the door aperture. This reflects the predominance of frontal impacts in the sample. Twenty-two drivers were trapped in the vehicle by door jamming. Side doors opening during the accident is less frequent than tailgate opening on hatchbacks and estates, as might be expected, as side doors are fitted with antiburst locks, whereas only a few vehicle models have antiburst locks on tailgates. External crush causing linkage activation was the most common reason for doors opening.

Front passenger doors showed a similar pattern to drivers' doors, though rather more were totally undamaged (64 percent). This is consistent with the fact that more of the frontal impacts were offset toward the right than the left. Again, jamming was fairly frequent, and opening uncommon. Seven front left-seat occupants were trapped by door jamming.

There were 140 cars with rear side doors. More than half the rear doors were damaged, but there was no difference between the proportions damaged on the rear right (34 percent) and the rear left (35 percent) doors. Of those doors that were damaged, 24 percent were jammed by compression, with no difference between left and right sides. Eight occupants in rear seats were trapped by door jamming. Four occupants were ejected through an open side door, and these were all unrestrained rear-seat occupants. A further five occupants were partially ejected through a side window.

Seats

Of all front seats, 64 percent were fixed (i.e., did not tip forward to allow passengers into the rear), 24 percent had hinged backs, and only in 11 percent of cases did the whole seat tip forward (base-hinged). Nine out of 104 of the seat back hinge types and 7 out of 54 of the seat base hinge types failed. The most common cause was misalignment of components for the seat back hinge, and catch overload for the base hinge. If the antitilt lock did fail, there nearly always appeared to be the potential for extra loading being transmitted to the seat occupant.

Four cars had no rear seats, 137 (46 percent) had fixed seats, 102 (35 percent) had a folding single seat, and 52 (18 percent) had divided seats where one section could be folded and the other remain upright. Of the folding seats, there were 24 cases of latches releasing (out of 308 latches). Nearly all of these occurred on the single folding seats—only 5 released on divided folding seats. The explanation may be that the divided seats will distort on their inboard edge, thus dissipating loads, whereas the single folding seat is forced to take most of the weight of any loading on its latches. The most common cause of

latch failure is misalignment of the two parts of the latch (10 cases). There were 6 cases where both seat latches released, effectively leaving no restraint for any loads in the rear of the car. In the cases where the latches released, there appeared to be the potential for loading to be transmitted to any seat occupant in approximately half the cases. However, there were only three occupants in a rear seat when a latch failed—these people all sustained extra loading. None of these occupants were in a seat where both latches failed.

The questionnaires completed by the vehicle occupants provided information on the materials carried in the luggage compartments. Some of the items could seriously increase the loading on the seat backs and the seat occupants. Examples of the loads carried in a luggage compartment are advertising materials in boxes, tools and a tool box, suitcase, spare wheel, computer accessories, and a car gearbox.

Conclusion

The purpose of this paper has been to provide an overview of a major study of the causes of injury to car occupants currently underway in Britain. The establishment of a high-quality, reliable, and strictly sampled data base has been a very extensive exercise. It involves the cooperation of a large number of people outside the Accident Research Units: hospital consultants, coroners, police officers, recovery garage owners, and many more. It is important, therefore, that the data obtained in this study are consistently collected by the accident investigators, that the data from the two units are compatible, and that the computer programs are reliable.

This paper has described the organisation of the study and the ways in which data on vehicles and occupants are collected, recorded, and analysed. The data presented as examples of the preliminary findings are based on a single year, 1984, the first full calender year of the study in which both teams were investigating accidents. The data are presented to indicate the sort of information available from the study and the ways in which it can be used. The variety of vehicle makes and models found in a sample of nearly 300 means that very few vehicles are represented in any quantity. Only one vehicle occurred more frequently than 10 percent. This makes detailed analysis difficult due to the small numbers involved. Most vehicles saw only one impact, and most impacts were frontal and with another car. Rear-seat occupants are more likely to receive injuries than front-seat occupants. The majority of front-seat occupants were using seatbelts (93 percent); the majority of rear-seat occupants were not. The majority of minor injuries (AIS 1) to belted front-seat occupants were bruising from seatbelt webbing or from contact with the steering wheel (drivers). The steering wheel also caused more serious injuries (AIS 2 to 6) to drivers. The more serious injuries to front-seat passengers often came from external objects such as the other vehicle. With regard to vehicle components, damage to the tailgate of hatchbacks and estates was fairly frequent. Approximately one-third of those that sustained damage opened in the accident, usually due to compression of the door aperture. Four occupants were ejected through an open side door, and these were all unrestrained rear-seat occupants. In the future, further detailed analysis will be made on the increasing data base. The general crashworthiness of vehicles and the detailed performance of specific components will be studied. The specific causes of injury will be investigated, and the relative frequencies of different crash types and injuries will be documented. One of the first detailed analyses is the examination of seatbelt effectiveness in reducing injury to front-seat occupants. This is reported by Dr. S.J. Ashton et al., at this Conference.

Acknowledgments

In a study such as this, which relies on the cooperation of many different organisations and individuals, there are many people to acknowledge. The authors would like to thank all those who have made this work possible. In particular, they would like to thank:

1. The sponsoring consortium for their financial support and their representatives for their advice and guidance. They are: Department of Transport VSE and VI, TRRL, Ford, and BL Technology who coordinate Austin Rover Group, Freight Rover, Land Rover, Leyland vehicles, and Jaguar cars.
2. The Chief Constables and their officers in the study areas for their cooperation.
3. The consultants and other staff at all the hospitals in the study areas for their assistance.
4. The coroners in the study areas for their cooperation.
5. The Department of Transport vehicle examiners in the West and East Midlands, Northern and Western traffic areas of the Department of Transport.
6. The staff of the two Accident Research Units:

at ICE, Loughborough	Birmingham University
Geoff Hedges	Stephen Jowett
Ann Marshall	Andy Parkes
Abayomi Otobushin	Michael Twiss
Nigel Robertson	Meryl Knight
Carl Sutton	Wendy Phipps
Mo Symes	Colin Smith

Large Scale Data Collection Systems—The NASS Experience

Franklin G. Richardson and
Frances Bents Costello
National Center for Statistics and Analysis, National Highway Traffic Safety Administration

Abstract

The National Accident Sampling System (NASS) has grown from a pilot data collection system with 10 teams in 1978 to the current system of 50 teams using over 130 accident data researchers in 27 States. At the end of 1984, there were over 45,000 cases in the NASS files with each case including approximately 400 different data elements. This large system with widely separated collection sites requires that each team use specific operational procedures to assure the consistency, uniformity, and reliability of data. The overall goals of NASS are to create and maintain a network of collection teams that use specific operational procedures to assure consistency, validity, and reliability of the resultant data file. Since NASS attempts to serve statistical and clinical needs, both creativity and compromise have been employed in developing the field capabilities and in maintaining the system so that useful data are acquired. It is important for the users of any data file to be aware of the definitions and limitations of the data, but it is especially important in a system such as NASS where such a large amount of data is gathered and the collection occurs at such widely separated locations under varying local conditions and regulations. Current procedures for the selection of cases, collection of data, and quality control are described. Sampling revisions that will be introduced in 1985 to enhance the file usefulness and significant field operational changes are also discussed. The paper concludes with the argument that NASS, or any similar system, must be concerned as much with the qualifications, training, and motivation of field personnel as with statistical design.

Introduction

The National Accident Sampling System (NASS) was established by the U.S. Department of Transportation in 1978. It was designed to produce nationally representative estimates of the highway accident toll to provide a detailed accident data base that could be used to identify significant safety problems, to detect trends, and to evaluate motor vehicle safety countermeasures(1). Beginning with a pilot effort at 10 data collection sites, NASS increased the number of teams annually. By mid-1982, it had reached its current complement of 50 Primary Sampling Units (PSU's) in 27 States that produce data on 12,000 highway accidents each year. At the end of 1984, there were over 45,000 cases on the file. The NASS teams gather about 400 data items on accidents of every type (pedestrian, motorcycle, light truck and van, heavy truck, and passenger car) and on accidents of every severity (nontow property damage only, minor, moderate, and serious injury, and fatal).

The establishment of a multitier data collection and quality review system requires expertise in the subject area of interest; equally important are skills in planning, coordination, task identification, negotiation, and management. The administrative challenges are often greater than the technical difficulties that must be mastered to create and maintain a smoothly operating system. This paper examines some issues that the field operations staff considered in establishing, operating, and maintaining the NASS data collection system. Part of the discussion is specific to the accident investigation field, while much of it can be applied to any data collection effort.

Case Selection Procedures

An important first step in any data gathering scheme is to define what you want to examine. NASS begins by selecting as its universe all accidents that are reported to the police as documented on Police Accident Reports

(PAR's) and are submitted to the individual State traffic records agencies. Immediately this leads to an underrepresentation of very minor accidents that are: (1) never reported to police, or (2) are not subject to inclusion in State files. Statistically, these minor accidents are addressed outside of NASS and are of little general interest to clinical users(2).

Since PAR's from almost all jurisdictions include vehicle type and some measure of injury severity, it is feasible to stratify accidents in NASS with this information. Accidents are classified in a hierarchy of 22 strata that begin with the more rare accident types of pedestrian, motorcycle, and truck accidents and end with automobiles and all others. As a second stratification, the recorded injury severity is adapted from the various police codes. Experience has shown there is some over- or undergrading of injuries in this process, which will be discussed later, but the stratification system generally is useful in allowing statisticians to select a greater proportion of serious accidents. If such weighting schemes were not applied, the bulk of the NASS file would consist of very minor accidents. This would be satisfactory for national estimates but of little use to engineers responsible for improving vehicle crashworthiness and reducing occupant injuries. This hierarchical approach will be modified with the introduction of revised sampling procedures described later.

NASS teams record all accidents reported by designated police jurisdictions, either two or three times each week, and then execute a PSU-unique sampling algorithm that selects the specific cases to be investigated in that PSU for that day. There was uncertainty during the initial planning about the effectiveness of small team sizes and the ability of two or three investigators to manage a variable workload of cases, so each investigator is assigned a fixed caseload of two accidents per week. The fixed workload lends itself well to program planning and management. It creates difficulties for statisticians, however, when, for example, one motorcycle accident holds a case selection weight of 20 while a similar accident in the same site on a different day holds a selection weight of 360. Consistency in case selection is an important operational achievement.

Staff

The next major protocol is concerned with staff selection. In establishing NASS, it was decided data would be collected through contracts with firms that would hire technician-level staff who are trained and directed by NHTSA. Prior to NASS, contracts were awarded to those few organizations that had developed their own style of expertise in accident investigation. The NASS design required almost 200 investigators collecting data in precisely the same way. Significant attention during the pilot study was devoted to determining whether individuals who often had no related experience or expertise in accident research could be trained to become proficient in standardized data gathering methods. Experience has shown that about 6 months of formal training and careful oversight are required to train a novice. Training remains a key element in field operations.

A second level of expertise was established called Zone Centers. The Zone Centers consist of groups of several highly experienced accident researchers who not only assist in developing standardized protocol but provide all technical oversight and quality review to the data collection teams. These mid-level managers have been critical to the success of NASS through their involvement in training PSU investigators and in reviewing, monitoring, and controlling the information that becomes the data files.

Data Collection

Once the sample of police-reported accidents is selected, it becomes necessary to describe the various data gathered from numerous reports and field inspections in a consistent way. NASS uses a set of standard reporting forms that are modified every 2 to 3 years. The 400 data elements are arrayed according to the following scheme:

- Accident
- Pedestrian/Nonmotorist
- Vehicle
- Driver
- Occupant

The Accident Form is used to collect data on the first harmful event, ambient conditions, and case administrative information. The Vehicle Form guides the data collector in gathering specific vehicle information, and one form is completed for each involved vehicle. Separate forms are used for towaway or nontowaway vehicles. Included are vehicle make/model descriptions, some vehicle component conditions (e.g., tire condition), Collision Deformation Classification (CDC)(3), and Truck Deformation Classification (TDC)(4), and such postcrash data as the amount of intrusion, the amount of exterior crush, and steering column performance. Similarly, the Driver Form is used to acquire specific data on the driver's education and training, precrash maneuvers (if any), license status, alcohol involvement, and traffic violations. One form is completed for each involved driver, which permits the coding of any environmental data unique to the involved vehicles (roadway characteristics). The Pedestrian/Nonmotorist Form and the Occupant Form are identical in the nature and extent of injury information recorded, but the Pedestrian Form includes data on location and activity while the Occupant Form has provision for seating location and restraint type and use. NASS also uses special forms for CRASH III(5) reconstructions and schematics of scene data.

To make data collection consistent across all 50 collection sites, extensive documentation has been employed. The five basic data forms are accompanied by

a Coding and Editing Manual that currently includes a total of 780 pages of specific coding instructions. The Collision Deformation Classification (CDC), Abbreviated Injury Scale (AIS)(6), and Injury Severity Score (ISS)(7) systems have been incorporated. This extreme level of specificity is crucial for clinical use of the data. When field personnel enter data onto the Master File, there are 800 automated range and consistency checks applied to every NASS case before the data are accepted. These checks are identical to coding manual instructions and supplement Zone Center review by assuring that incorrect key strokes or out-of-range entries are flagged and corrected.

Other data collection aids are available and used. Most rural PSU's use a scene inspection jig that can be adjusted to simulate the wheelbase of vehicles and can be used to trace postcrash trajectories. In 1984, we also introduced the vehicle contour gauge, which not only facilitates taking crush measurements on passenger cars but also assists case review staff and data users in assessing vehicle damage.

Consistency of technique is further reinforced in NASS through training. In NASS, all investigators undergo up to 10 weeks of intensive training, which includes self-paced audiovisual modules, classroom training, and on-the-job supervision. This is followed by about 6 months of careful oversight by Zone Center staff. Even though we consider NASS to be technician level data, investigators still generally cannot assimilate the wide variety of data taking procedures for many months.

Limitations of Procedures

The use of these standardized procedures has both benefits and costs. They clearly contribute to the uniformity and reliability of data encoding. At the same time, unusual circumstances (which are very common in this field) can be difficult to categorize according to convention. When this occurs, data can be "force fit" into a specific coding attribute or a default to "other" or "unknown" codes can be used. Either way, the clinical user of the file may find it impossible to locate the specific accident circumstance that is of interest if he relies solely on the automated files for his information. Because of this, both automated files and the individual case reports are routinely reproduced and made available to users.

A good example of the difficulties encountered in standardization is the categorization of accidents into strata for case selection. This classification is based on police-reported information, but, unfortunately, the States do not all use a uniform code. Overall, NASS teams class about 28 percent of police-reported injuries as serious or incapacitating. There is a wide variation among States, however. Alabama, where two PSU's operate, instructs the police to class accidents at this severity level if the injured person is "carried from the scene." This means that in any accident when one occupant is transported to a medical facility, regardless of the true severity of the injury, the accident is classified as serious. As a result, 48.6 percent of the accidents in Alabama are initially classified as serious. At the other extreme, Pennsylvania, where six PSU's operate, classes injury severity as major, moderate, or minor, adds the type of apparent injury such as amputation, broken bones, concussion, burns, etc., and from this additional description the field investigator must determine the injury severity. In this State, only 4.1 percent of the accidents are initially classified as resulting in a serious or incapacitating injury. The practical effect is that a large number of cases in Alabama are selected for investigation as serious injury cases when in fact they are not, while in Pennsylvania teams are failing to select as many cases with serious injury because they are grouped together with a large number of truly minor injury cases. Under the present circumstances then, national estimates of injury severity based upon initial classification may be skewed, but individual case files are rich with injury data for the clinical users. Changes in case stratification are being studied that would go beyond the initial police-reported severity in these two States to make the initial injury severity classification. This improvement will serve both statistical and clinical users.

A second problem is the limitation that must be placed on data collection so files can be produced. Because of the sampling scheme employed, an accident is not selected for investigation until it is 3 to 4 days old. Given this late start, it is imperative the researchers locate and measure scene data and vehicle damage as quickly as possible before vehicles are repaired and scene evidence is scattered. These data must be gathered within 2 days of case selection. Likewise, drivers and occupants must be interviewed within 4 days so recollections are altered as little as possible. Researchers must also request and encode medical records, driver and vehicle registration information, and, when possible, execute a CRASH III reconstruction. All the above activities are scheduled to be completed and case data are to be entered onto the microcomputer data entry system within 2 weeks of case selection. Then the cases are to be submitted to the appropriate Zone Center for review no later than 35 days after selection. These deadlines guarantee that the data flow, from collection through quality review and to final file, occurs smoothly and rapidly. This allows the publication of statistical reports within a few months of accident occurrence. These deadlines also result in some loss of data, particularly in fatal accidents. The NASS system underreports fatalities because cases are selected based on police reports and are therefore limited to those fatalities that occur almost immediately after an accident. A small number of longer term fatal injuries are drawn from cases initially listed as involving serious injuries. The Fatal Accident Reporting System (FARS)(8) provides

a precise count of traffic fatalities that occur within 30 days of an accident and is a valuable complement to NASS.

The loss of medical data is accommodated somewhat through the use of an update protocol. Under this scheme, the completed portion of the case investigation must be submitted to the Zone Center according to the 35-day schedule. A notation is made that additional medical data will be forthcoming. The team then has 90 days to obtain copies of hospital emergency room reports and discharge summaries. When received, the medical information is encoded on update forms and submitted to the Zone Center, which appends the original case file, conducts a quality review, and approves the case for inclusion on the Master File.

Scheduling also creates challenges in the collection of data from the vehicle inspection. The interval between accident occurrence and case selection allows 4 days in which vehicles can be towed, transferred, and repaired. For truck tractor-trailer combinations, the vehicles are generally drivable and have left the study area. The data completion rates for truck inspections are often low compared to an overall vehicle inspection rate of about 75 percent.

Protocol Changes

It is important to understand the capabilities of the data collection system and concentrate on those things that are achievable. NASS data collection activities have been limited to those areas that lend themselves to objective measurements. It is impossible to insure consistent data collection methods if the coding is left to an investigator's judgment.

Most NASS data collection at the present time is focused on vehicle crashworthiness, i.e., extent of vehicle damage and resultant injuries. There are major reasons for this. First, NHTSA applies much of its resources to vehicle safety design and countermeasures. Second, the state-of-the-art in accident investigation is most advanced in the areas of damage measurement and reconstruction. Finally, given the importance of standardization and consistency, NASS can most effectively produce documentation of physical, measurable, and verifiable data sources. Several hundred researchers have been successfully trained to measure roadway dimensions and vehicle damage, and to report injury severity in the same consistent manner. Areas such as human factors and accident causation, which rely on extensive data interpretation and judgment by trained experts to reach conclusions that may not be otherwise substantiated, have been avoided.

It is difficult to make valid assessments of pre- or at-crash conditions. For instance, during the extrication of entrapped occupants, towing of the vehicles, or even handling at the crashed vehicle repair or impoundment facility, major modifications can occur to the vehicle crush profile, tire and wheel condition, restraint condition, etc. Because of the difficulties engendered in assessments of this kind, NASS has chosen to focus its resources on those data elements of major concern such as restraint use and vehicle damage. Extensive training is conducted to show how seatbelt webbing can be used to detect belt use and the differences between door beam crash damage and distortion of the door from emergency extrication tools. Some areas such as tire condition and performance would require a substantial commitment to extensive data collection if meaningful conclusions are to be reached. The perceived need for tire data is small at this time, however, so NASS has avoided both a major commitment to collecting tire data and the seduction of doing more limited data collection, which is easy but inconclusive.

In recent years, a beginning has been made in collecting precrash data by coding driver-related factors such as erratic driving or improper, if not illegal, actions. In 1985, the CALAX(9) system, which describes preimpact locations and actions, for one or two vehicles, was incorporated into NASS. These first attempts at encoding accident-related factors are the subject of considerable dispute at the quality review level because there is little substantive information such as measurements or slides that can be used as verification. The activity is useful for analysts who are interested in precrash conditions and is contributing to advancements in field protocol.

Quality Control

Almost 20 percent of NASS resources are devoted to quality control. The technical experts at the four Zone Centers are tasked with responsibility for monitoring the development and performance of PSU staff, serving as accident investigation specialists, conducting periodic visits to all field sites, maintaining and upgrading all supporting documents, training, performing elaborate reviews of case materials, and creating and analyzing an automated file on every aspect of data quality. The NHTSA staff also performs independent spot checks of the analysis file, conducts site visits to PSU and Zone Center installations, and monitors myriad status reports produced by the field. Until very recently, the Zone Centers spent an average of 4 hours reviewing every variable of every case submitted by PSU's. This appears to be too large an effort. When NASS began, there was no comprehensive quality control plan to accompany the data collection scheme. Since NASS was the first to attempt to implement such a specialized major system, there was little direct experience on which to draw. The expertise available was in field investigation, not data management and review. The roles of the Zone Centers have remained critical to NASS success but have shifted greatly with time. Through trial and error, education,

and budget constraints, the approach to file building has changed to one seeking only excellence, not perfection. NHTSA is concentrating on improving the quality of work at the lowest common denominator by selecting and training new investigators more carefully and removing nonperformance from the system more quickly. Case review has been reduced until only a portion of cases completed by competent investigators are examined, freeing Zone Center staff to focus on weak performance areas. Further review of the quality control activities is planned. A group of NASS experts representing statistical design, analysis, and data collection is working with a quality control expert to further streamline the review activities while maintaining the high quality of the data file. This task will take several years to fully implement but is necessary to improve NASS performance as Federal dollars become more limited.

NASS Sampling Revisions

As the NASS system has become stabilized at the 50-team size and the process of data collection and file building has become more routine, attention has turned to ways to modify the system to better meet user needs as to the type and injury severity of accidents sampled. Earlier adjustments to the accident sampling procedure had been made in 1982 to provide an increased number of "heavy truck" accidents, and in 1982 and 1983 the percentage of heavy truck accidents was increased, although many of these were low-injury-severity accidents.

Beginning in 1984, the concern was to increase the proportion of cases with a higher injury severity. This was accomplished primarily by reducing the number of low-injury-severity heavy truck accidents. More recently, work has begun on examination of means to increase the proportion of high-injury-severity cases even further, and to combine this with changes that would improve the accuracy of the national estimates and simplify the case weights. Obviously, the original NASS statistical design approach and the current team locations impose limits on how much change is possible without a significant expenditure of funds. Four team locations, for example, produce police reports for less than 50 serious injury accidents in a year and about one-third of the locations have less than 150 police-reported serious accidents. These sites provide valuable data representative of very rural accidents but present unique problems to the sample and design staff.

Three aspects of this change are being planned. First, a change already implemented is the accomodation of field staff personnel shortages (caused by illness, lack of training, or resignation) by reducing the workload. Whereas previously, if a team was understaffed or undertrained, the number of cases to be investigated was reduced, the number of cases is now maintained but less information is collected on some accidents with less serious injuries. Since teams are understaffed or undertrained about 20 percent of the time, this change has been important in keeping the number of cases up and thus improving the case weighting.

The second major change planned is a change from a "constant caseload assignment" to a "variable caseload assignment." From its inception, NASS has assigned each investigator a fixed number of cases each week—nominally two. By changing to a variable caseload, the ability to sample a greater number of serious cases is increased (more cases will be sampled when serious injury accidents occur) and the variation in case weights will be reduced. Both statisticians and clinical users will benefit. The shift will require more aggressive field management and increased quality control because the workload is largely determined at the PSU level rather than being dictated by sampling protocol.

The third major change is a revision of the Police Report stratification from 24 to 5. Accidents are now stratified on both vehicle type (e.g., motorcycle, heavy truck, pedestrian) and on police-reported injury severity, combined with the reported transportation of injured persons to a medical facility. The revised stratification would be based only on the injury severity and whether any injured persons were transported to a hospital; accident type will not be considered.

The anticipated effect of these changes will be to increase the number of serious injury cases (AIS 3+) that are investigated. It is anticipated that about 3,000 serious injury cases will be acquired annually with this system as compared with the current 1,800 cases at that injury severity.

Remaining Challenges

Experience in building and refining the National Accident Sampling System has proven one thing—it can be done and done very well. The greatest resource and most formidable obstacle is people. From the beginning, NASS concentrated on elaborate statistical design, consistent field protocol, extensive documentation, and creative administrative control. What was largely overlooked was that the backbone of this system would really be a sizable group of reasonably qualified, modestly paid technicians who would become experts in a field with an uncertain career path, little recognition, and even less job security. The NASS investigator turnover rate is about 30 percent each year because of poor initial candidate screening, contractual recompetition, and movement to related career fields. Federal procurement guidelines do not equip NHTSA well in providing incentives, upward mobility, and job security, and yet these gains would provide NASS with a greater proportion of highly experienced researchers while reducing the data and dollars lost to attrition and retraining.

Consideration is being given to alternative ways of awarding contracts for multiple PSU's, extending the interval between contract awards, and promoting highway safety as a career to address this problem.

The solution to these "people" problems may well be the most creative element in NASS and the most valuable contribution to meeting NASS goals.

Five Years of New Car Assessment Program: Balance and Current Conclusions

J. Provensal,
F. Hartemann, and
C. Tarriere
Regie National des Usines Renault

Introduction

Over 6 years have elapsed since the inception of activities devoted to crashworthiness ratings in the United States. A large number of vehicles, covering virtually the entire fleet of representative American vehicles of the early 1980's, have been subjected to tests whose conditions were established concurrently with devising what was destined to become the New Car Assessment Program.

However, as work progressed, a major controversy arose over the validity of methods employed by the National Highway Traffic Safety Administration (NHTSA). This controversy has not ceased. Now that a second type of test—one involving a deformable mobile barrier—seems to be in process of evaluation, it is deemed timely to complete the data acquired so far, summarize the state of progress, and examine—even propose—the orientations anticipated for the future.

Choice of a Rating Method

In 1972, the Motor Vehicle Information and Cost Savings Act assigned to the Department of Transportation the mission of evaluating methods designed to yield a determination of the following vehicle characteristics:

- Damage susceptibility
- Degree of crashworthiness
- Ease of diagnosis and repair

In this text, "crashworthiness" was defined as the protection a passenger vehicle affords its passengers against personal injury or death as a result of a motor vehicle accident(1).

In 1978(2), NHTSA resumed its work devoted to establishing a rating system for application to automobiles. The discussion was already underway on the relative feasibility and advantages of methods of rating based on the following:

- Historical data collected from information on vehicles already in service
- Predictive data collected from evaluation tests and yielded by new vehicles for which there were no available results based on the experience of utilization

This alternative presumes a choice that is not easy to make. In fact, if one does not generally contest an

indicator or a criterion based on the careful processing of statistical data, it can be assumed—in the particular case of automobiles where the rate of launching of new models is high—the time required for establishing such an indicator would make this indicator unusable in actual practice, since the model to which it was to apply would no longer be on the market by the time the indicator was available.

Conversely, a predictive method can supply the market with an indicator available immediately, concurrently with the release of a new model onto the market; however, it is vital to make sure, beforehand, that it is feasible and actually yields valid results corresponding to a vehicle's performance.

This fundamental point had not eluded the attention of NHTSA, which, in 1976, had reduced its research devoted to the development of a predictive method for crashworthiness, deeming the feasibility of such a method was mediocre at that time(2).

After examining various data bases (police reports, accident records compiled by insurance companies, and the accidentological data banks of NHTSA (NCSS, NASS, and FARS), NHTSA concluded that "specific make and model crashworthiness comparisons isolating the effects of the vehicle are not yet feasible from historic data files..."(2), and undertook a testing program aimed at developing a predictive method.

The testing work, based on 1979 model vehicles, consisted of subjecting these vehicles to impact tests under the conditions listed in FMVSS 208, 212, 219, and 301; one major difference was in the choice of impact velocity, which was fixed at 35mph, i.e., 5mi faster than the speed normally used for the aforesaid standards.

It is not without interest to recall and comment on the requirements compiled by NHTSA, which had formed the basis for the choice. These were contained in four points summarized as follows(2):

1. The system must supply the data sufficiently ahead of time before the market release of a given new model.
2. The results yielded by the predictive method must be readily accessible and usable by consumers.
3. The cost of obtaining data must be reasonable.
4. The test procedure must be repeatable and objective, capable of distinguishing significant differences in the safety performance of the cars, and carefully developed after wide review by the scientific and technical community.

This list of requirements shows the omission of a basic point that, in our opinion, should have been listed as the first entry in the conditions to be met by a predictive rating system.

The system of rating must accurately take into account the possible differences in behavior regarding the passive safety of the vehicles, this behavior being evaluated on the basis of historical data collected from, for example, accident investigation reports.

This requirement was in no way contested, either by the individuals who took part in the discussion from its outset(3,4) or by NHTSA itself(2,5). Finally, setting up a predictive rating method and a historical rating method in competition with each other implicitly amounts to acknowledging that the aim is to provide an accurate representation of the vehicles' real performances with regard to passive safety.

After 6 years of tests systematically performed by NHTSA on new models, a certain amount of data has been acquired and a few attempts have been devoted to correlating real-world accident data with the results of the predictive method. This paper summarizes the situation to date.

Global Statistical Approaches

Two global statistical approaches were made prior to NHTSA's deciding on its choice of predictive method(2). In fact, these approaches had been requested by the latter to evaluate the feasibility of a rating by a historical method. In 1980, Friedman(6) concluded, after a study of FARS data, "it is clear from the FARS data results that notable differences in fatality rates exist across make-models groups, while the analysis which controls for the crash severity (ΔV) shows little or no differences." This clearly shows that the differences between vehicles, all impact conditions combined, are due to the influence of the mass of the aforesaid vehicles; once the data are grouped on the basis of equivalent conditions of impact, i.e., of fixed speed variations, the differences shown by the FARS data are insignificant.

Similarly, after examining the data in police files and in FARS and NASS records, Carlson(7) stated: "...we conclude either that the present statistical techniques are not sensitive enough or that in general the overall injury severity differences between makes and models—except those differences associated with vehicle size—are very small. This result should not be ignored by NHTSA as it proceeds with its overall crashworthiness rating development."

The initial evaluations based on accidentological findings were hence negative and, logically, they should have led to the discontinuation of the investigation of a predictive method whose most foreseeable result was the absence of the detection of any difference whatsoever.

Actually, at that point, NHTSA's procedure was the complete reverse: "The principal goal (of the test program) was to determine if automobiles of similar mass exhibited significant performance differences..." and "if the data (of the test program) revealed significant differences in the performance of cars...a good basis to proceed with a permanent program would exist."(2)

The discontinuation, in 1982, of tests performed at 35mph against oblique barriers (30° angle) also illustrated this determination to use only a test that would reveal "significant differences." In fact, examination of the findings yielded after six oblique barrier impact tests performed in 1981 shows that the thoracic criteria (for both passengers and drivers) remained in the range of from 31 to 50g/3ms, and, most importantly, that, for the six vehicles involved, the head criterion remained below 1,032. Therefore, no further action was devoted to this test, preference being given to the tests performed against orthogonal barriers, and even if:

1. The conclusions of these tests were in agreement with the results anticipated obtained on the basis of the initial examinations of the accidentological investigations, i.e., the absence of significant differences between vehicles.
2. It was recognized that the most frequently occurring configuration of frontal impact in real-world accidents is distinctly more to be assimilated with impacts against oblique barriers (involving only part of the vehicle's front surface) than with impacts against orthogonal barriers. This is shown in Figure 1, which represents cases of frontal accidents sustained by Renault 5 cars recorded in the A.P.R. survey to date. References (8) and (9) are also clear in this respect.

In light of the initial investigations and in pace with the accumulation of NCAP data, six reports (10, 11, 12, 13, 14, 15) were published; they endeavor to connect NCAP findings properly so-called with those from the accidentological data banks. With only one exception (Report No.14), these reports concluded there was an absence of correlation between the accidentological results and those of the NCAP. It is not without significance to recall the latest of these reports(15), compiled at NHTSA's request, which clearly summarizes the general opinion: "With respect to the broader question of whether or not the NCAP crash test results are useful as a general measure of crashworthiness for both belted and unbelted drivers and passengers in all types of accidents, it seems quite clearly that they are not. This can be seen perhaps in variable injury distributions across a wide range of HIC scores."

Figure 2 contains diagram 3, based on (15), which summarizes the overall findings based on the analyses performed.

Investigation No. 14, which concludes as to the existence of a correlation between the FARS data and the NCAP findings, is of major interest in that it endeavors to restrict the accidentological sample to only those impacts whose configuration is close to the NCAP testing conditions (orthogonal frontal impact against a fixed barrier). However, a number of comments can be made concerning the methods used and the ensuing conclusions:

1. As the author of the investigation admits, the sample is very small. It is composed of 695 fatal casualties, representing a fraction of the percentage of the victims killed in front-seat positions in frontal impacts in the United States during the reference period. Basically, this ensues from the following:—
   - The rigorousness of the procedure in the selection of cases
   - The fact that the population from which the samples were taken is that of the FARS file, which—as its name indicates—includes only accidents that cause at least one death. Thus it is that, at the beginning of the selection, nearly 63 percent of the cases are eliminated of those that, since they did not involve collisions between vehicles in motion, are unsuitable for the analysis envisaged.

   In view of the foregoing, it is not possible to claim that the samples chosen are representative of the reality of front-frontal collisions. In particular, this sample excludes collisions against fixed rigid obstacles, which are theoretically covered by the NCAP. In addition, it is clear that vehicle/vehicle collisions—even those of vehicles of closely similar mass—have results influenced by the relative aggressiveness of the vehicle, which is an undeniable factor of skew.
2. The subsample pertaining to belted passengers is far too small for the statistical analysis applied thereto to have any value: 95 percent of the drivers in the sample were not belted; the number of belted individuals in the subsample is therefore only about 35. Finally, the level of significance ($p \leq 0{,}05$) (Table 5 of (14)) is not achieved for the SUM and RSUM parameters (indicators constructed on the basis of the NCAP results).

   Under these conditions, the finding of a relation (Figure 1, (14)) between the NCAP results and the probability of the decrease of a belted driver is of no validity whatsoever.
3. In addition, and most importantly, the application of the NCAP results to unbelted passengers (as noted above, the latter constituted virtually the entire sample) is technically inadequate. It suffices to examine the comparative trajectories and kinematics of a belted passenger and of an unbelted passenger in cases of frontal impacts to see they share absolutely no points in common, either as concerns the relative movements of the various parts of the body or, for example, the points of impact against the elements of the passenger compartment. There is no question of deducing from the results measured on a belted dummy the performances concerning unbelted

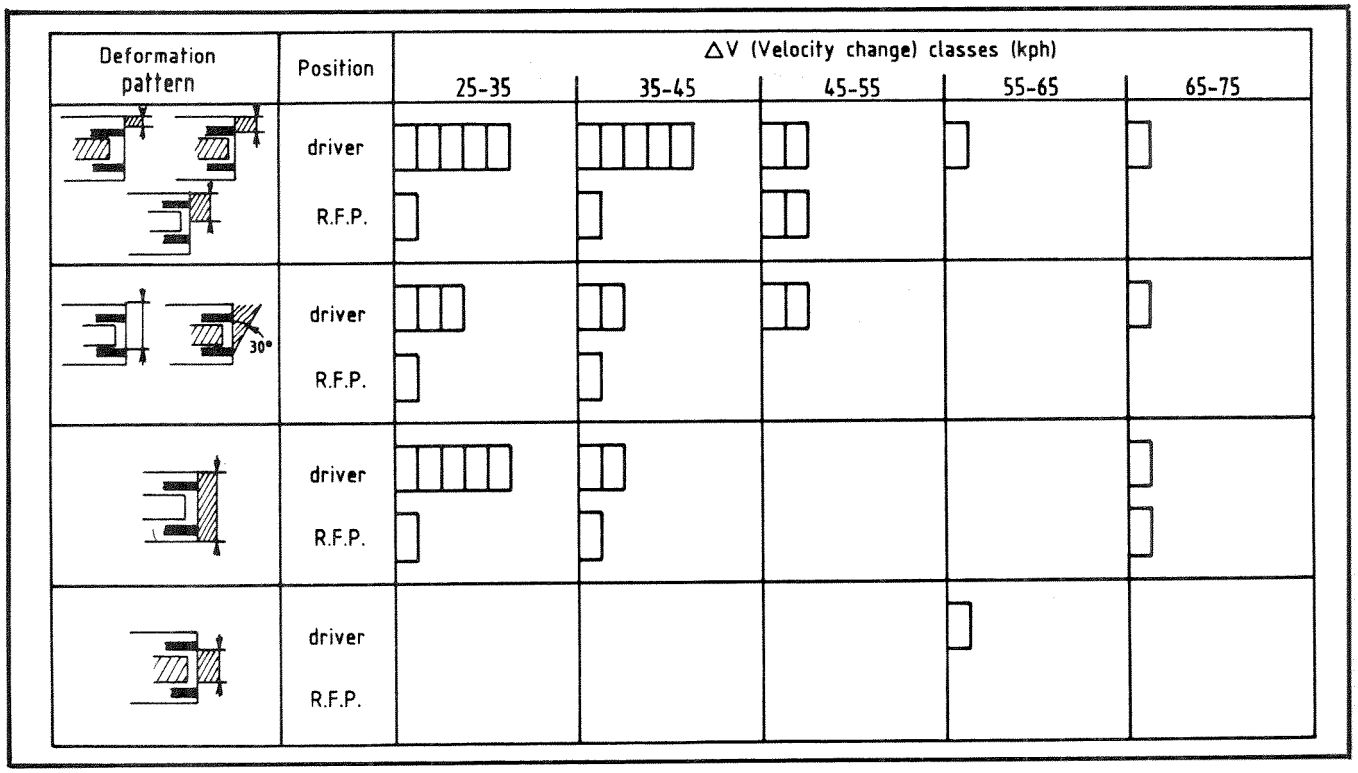

Figure 1. Number of belted occupants (Renault 5) involved in frontal impacts

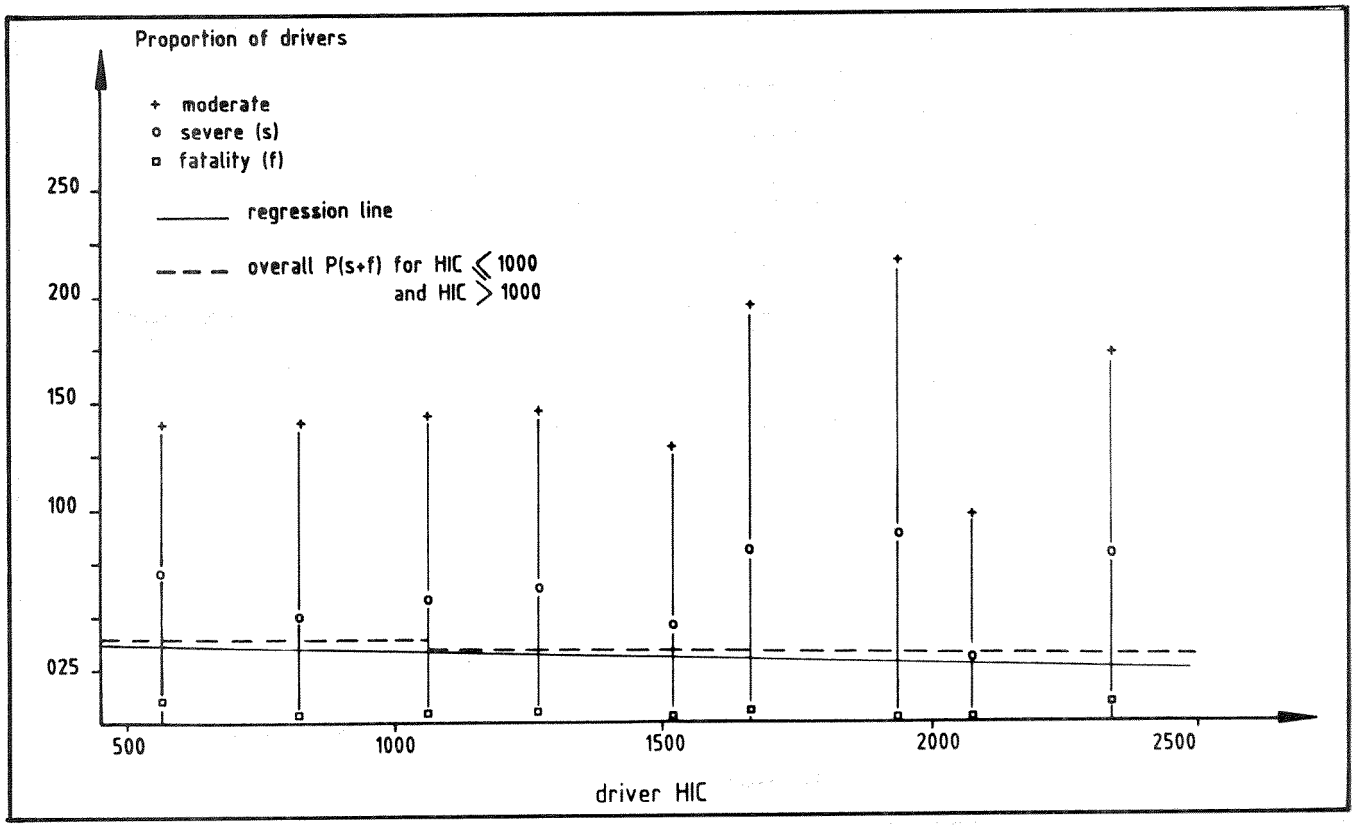

Figure 2. Driver injury distributions by driver HIC(15)

passengers. This fact is unanimously acknowledged both by NHTSA(16)—"The test results are indicative of relative crash protection provided to occupants wearing safety belts"—and by the ITHS itsel(17): "Recently, the Highway Loss Data Institute reported that among 1978 car models, small imports had the worst injury claim frequencies. The DOT results are based on injury severity to belted occupants in 35mph crash tests of 1979-1980 models, while the HLDI data are based on insurance claim frequencies for 1971 and 1978 models whose occupants were, for the most part, unbelted." This being stated, it is always possible to correlate the two factors. However, it emerges (Tables 2, 3, 4 of document 14) that when parameters such as velocities, vehicle-mass ratio, drivers' ages, and the wearing of safety belts have, as expected, a strong influence on the probability of death, with an excellent level of significance (Figure 3), the trend observed with the crashworthiness parameter is more than discrete, with a level of significance that drops below the usually recognized limit ($p \leq 0{,}05$) by a marginal value only $p = 0{,}045$) and in the one case in which HIC and chest deceleration are combined to obtain the term SUM.

4. Finally, examination of the previous publications (10, 11, 12, 13) by Zador(14) enables them to conclude: "An important conclusion that can be

Figure 3. Compared levels of significance for various parameters

drawn from this review is that there is evidence of a trend of decreasing injury risk with better NCAP results."

Zador(14) processes, for example, the data of document 13, grouping them differently to reach this conclusion.

It suffices, as we did in Figure 4, to carry over from document 13 the representative points of the couples (Gillis index, actual fatality rate) to see that it is wishful thinking to try to correlate these two factors. The trend noted by Zador(14), if it exists, has not so far been detectable and therefore cannot be considered as established.

To conclude this discussion of global statistical approaches, let us note that neither the automobile manufacturers nor the automobile users can be satisfied with a coherence that is only partial between the NCAP results and the real-world accident behaviors. If an indicator is set up, it must accurately reflect the real-world characteristics that are to be quantified.

Investigation of Certain Occurrences of Real-World Accidents

In the face of the failure of the global statistical methods, which for the time being do not allow us to reject the null hypothesis (no relation between NCAP results and real-world performances), we are led to adopt a different approach, i.e., a detailed case-by-case investigation of real-world collisions that are closely similar to NCAP impacts. Clearly, such a procedure inevitably brings about a loss of the concept of the statistical significance of the possible conclusions to be drawn from such an approach: It is difficult to generalize them.

Figure 4 lists the vehicles and occupants, both belted and unbelted, involved in collisions featuring conditions closely similar to those of the NCAP-type impacts. These vehicles were selected from the APR accidentological files, which now contain more than 6,000 thoroughly analyzed cases.

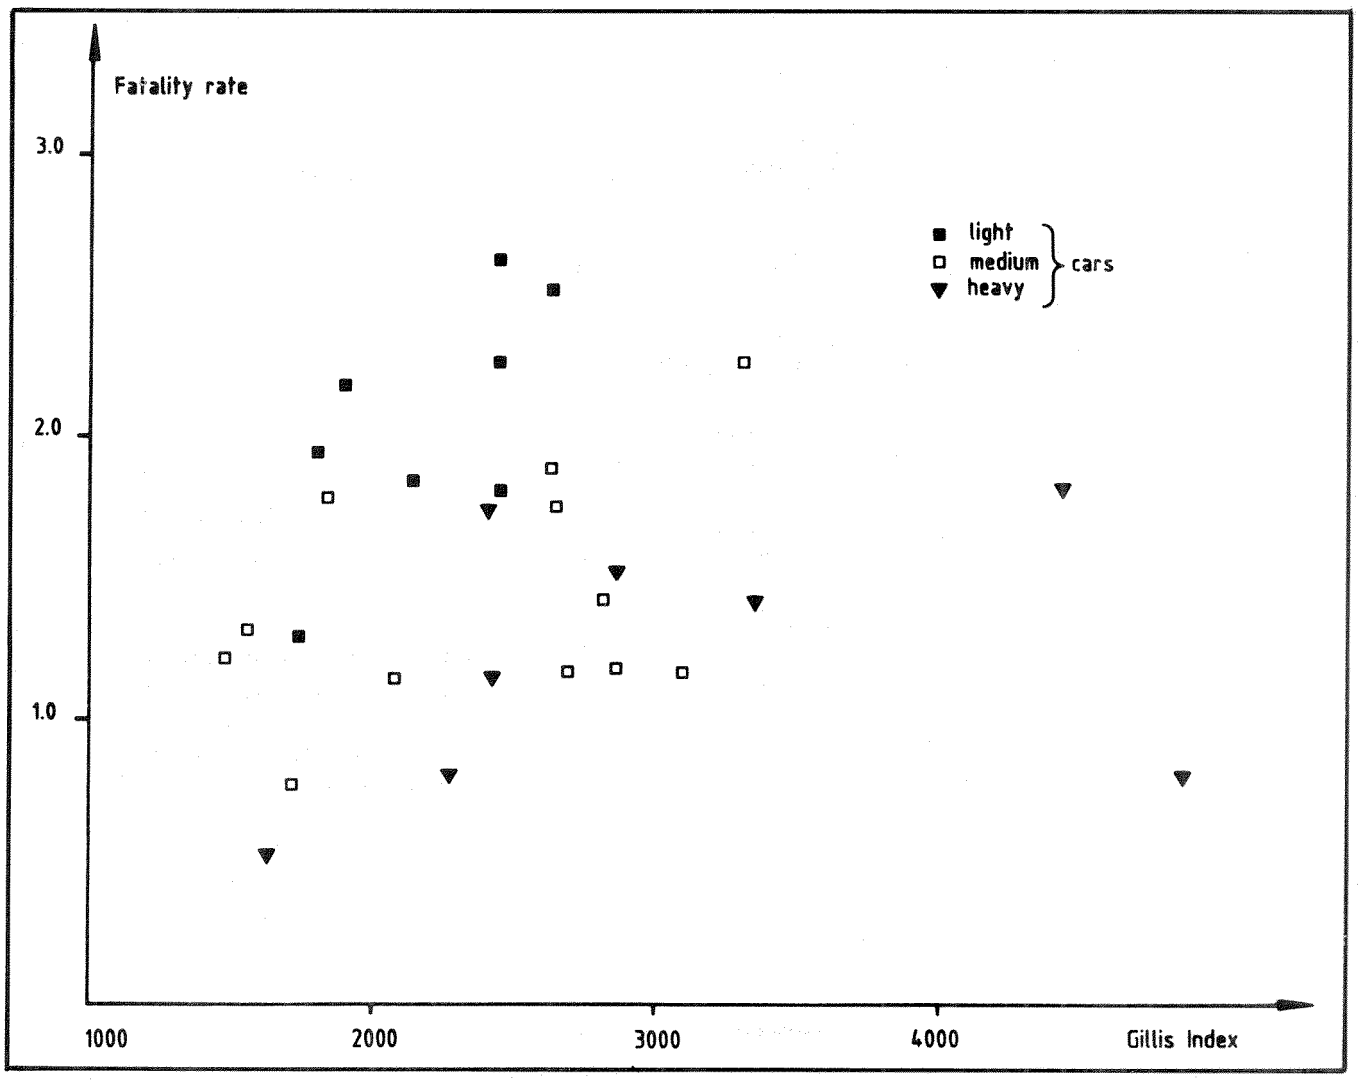

Figure 4. Fatality rate versus Gillis index(13)

The criteria of the choices were based on the following considerations:

- Extent of deformation of the vehicle's front surface. (This surface must have been involved in its entirety, and the intrusion points must have been distributed: appearance of deformation comparable to that of an impact against an orthogonal barrier.)
- Estimated value of the velocity change undergone at the time collision occurred ($\Delta V \geq 56$km/h)
- Estimated value of the vehicles' average deceleration ($\bar{\gamma} \geq 15$g).

Figure 5 compares the points representative of the real-world collisions selected (21 vehicles) with those of NCAP tests (fixed orthogonal barrier) at velocities ranging from 50 to 65km/h.

			TOTAL ↓
Nb of Vehicles	8	13	21

DRIVER	8	13	21
R.F.P.	6	6	12
TOTAL →	14	19	33

Figure 5. APR sample of occupants involved in severe frontal collisions

The degree of injury sustained by the 33 occupants in the sample is indicated in Figure 6. It is clear that these severe collisions involve a high rate of fatal casualties and serious injuries. Only 3 out of 14 belted occupants involved sustained moderate injuries, of a level lower than OAIS 3, with all the unbelted victims incurring injury levels far beyond this limit. Despite the smallness of the sample (due to the infrequent occurrence of this kind of collision identifiable with impacts against fixed orthogonal barriers), the effectiveness of the safety belt once again emerges.

Present-day vehicles offer a possibility of survival under these impact conditions, which are severe. In certain cases, unbelted occupants (with the age factor playing a preponderant role) sustained injuries of a level lower than the fatal level. However, beyond a certain severity ($\Delta V > 65$km/h, $\bar{\gamma} = 15$g), the 5 unbelted individuals in our sample met death; this was the case for only 2 belted subjects involved in collisions of similar violence.

Among the 14 belted occupants in our sample, 3 of the fatal casualties were not autopsied, so we have no record of the state of their injuries. A summary of the injuries sustained by the 11 other occupants is shown in Figure 7.

This latter figure, although based on a very small sample, shows that if the injuries to the body areas concerned by Regulation 208, and, consequently, by the NCAP (the head, chest, and lower limbs), recur with great frequency to the 11 belted occupants for whom we have records, two of the body areas not governed by this regulation,i.e., the pelvis and the abdomen, are also extensively involved. This is not surprising in view of the severity of the collisions investigated. It is therefore insufficient to attempt, in impacts of this same type, to describe, as does the NCAP, the protection afforded by the vehicle and its retention system while failing to investigate the fate of all the body parts and areas. In the final analysis, this can lead only to a result devoid of validity.

Before ending this analysis, we will devote special attention to two cases taken from the sample previously described, which are interesting in that they are comparable to tests performed by NCAP, the results of which are in our possession. The first case involved a Renault 5 and the second a Renault 18. A brief description of the accidents, an assessment of their severity, and the state of the injuries sustained by the occupants compared with the NCAP results are provided in Figures 8 and 9, respectively.

Although these results cannot be judged as statistically significant, the total incoherence between the NCAP values and the injuries actually sustained by the occupants do not incline us to optimism concerning the predictive character of the NCAP results. Yet the two cases investigated are similar in terms of configuration of collision to the tests performed within the NCAP.

Comparison Tests Performed With Human Subjects

Finally, it appeared interesting to use a third way for assessing the performances of NCAP's predictive method since, at present, the statistical approaches (whether global or focused on real-world accidents whose configurations are similar to those of the NCAP impacts) make it possible to reach only a negative conclusion with regard to the correlation between real results and predicted results.

We therefore decided to reproduce, at our testing site, only experimental collisions against fixed, rigid orthogonal obstacles at a velocity of 50km/h (35mph), the Part 572 dummies replaced by human subjects. These subjects, placed in vehicles that had been assigned different classifications in the NCAP tests, were to make it possible to confirm or infirm the classification emanating from the crashworthiness rating procedure.

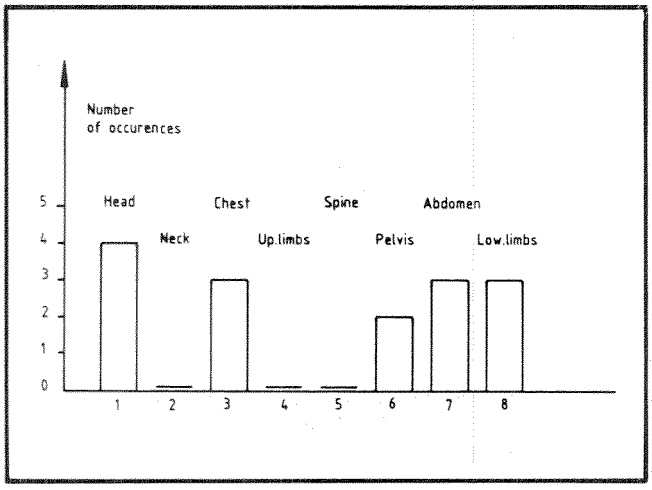

Figure 8. Number of severe injuries (AIS ≥ 3) observed on eight body segments (11 belted occupants)

Choice of Vehicles

The choice of vehicles was made on the basis of a single a priori consideration, that of the desire to have two cars that had yielded distinctly different results with regard to the HIC and chest deceleration in the NCAP tests. The only other selection criterion was the availability of these cars. It was necessary to get cars strictly similar to those used in the crashworthiness rating tests.

Figure 10 shows the table listing, for each of the A and B vehicles, the areas in which the NCAP results are located (HIC and chest deceleration).

Testing Procedure

The cadavers[1] were prepared and equipped with instruments in accordance with methods described in earlier reports (18, 19, 20, 21, 22):

- Pressurization of the vascular system
- Correct placing of the intrathoracic viscera
- Fitting of instruments to the head and spinal column

The purpose of the tests implied that the zones of the heads of the dummies and cadavers involved in the impacts should be the same, and that the localizations of these impacts—for example, against the steering wheel—should also be closely similar. These requirements were met through adjustments of the positions of the seats in their tracks on the basis of the anthropometry of the cadavers used (described in Figure 11).

After the tests, the cadavers were x-rayed and then autopsied. The heads, necks, and spinal columns were removed for a closer analysis of injuries that might possibly have occurred (notably, brain lesions).

Ribs were also collected for the purpose of characterizing the overall bone resistance of the thorax.

Findings

The findings are summarized and compared with the NCAP values in Figure 12.

In vehicle A, the central cushion of the steering wheel failed to provide sufficient protection for the face of the driver. In addition, there is doubt regarding the brain. In fact, the failure of the injection does not permit a conclusion as to the possible occurrence of microscopic injuries. However, no large macroscopic lesion was found.

The passenger sustained chest fractures (11 rib fractures and 1 sternal fracture, without the occurrence of flail chest or visceral lesions). These were moderate injuries classified at level 2 in the AIS scale. They were particularly moderated in view of the poor condition of the subject's bone structure (BCF = -0,54)(22).

In summary, it may be concluded there was adequate protection of the occupants in vehicle A under these impact conditions, except for protection of the driver's face.

In vehicle B, a rather late chest retention brought about impact of the cadaver's head (lower jaw) and neck against the center of the steering wheel and caused the injuries associated therewith, which were severe. It also permitted impact of the passenger's forehead against the dashboard. The chest injuries were quite severe for both occupants (AIS 4). Submarining occurred for both cadavers, with that of the passenger bringing about abdominal injury. Although the trajectories and the zones impacted of the various body areas were similar in the tests performed with cadavers and those performed with dummies, the latter tests completely failed to show the actual results from vehicle B in this specific type of collision.

Comment

Although the findings are presented only on the basis of a single test involving cadavers, obviously ruling out any statistical interpretation, the conclusions are clear. In this particular case (which was a case chosen at random only on the basis of the criterion of a difference with regard to the NCAP findings), the result obtained via the predictive rating method is manifestly reversed. At worst, and to take into account the unsuccessful injection of the brain mass, which prevented detection of the possible occurrence of microscopic injuries, we might deem as equivalent the findings for the drivers (fatal casualties in both cases), whereas the NCAP ratings classified "B" as better than "A" for the drivers, and the findings for the

[1] The cadavers were those of individuals who had bequeathed their bodies.

passengers as different ("A" > "B"), whereas NCAP predicted them as equivalent. However, this failure was obtained under circumstances that were the most favorable for the demonstration of the validity of NCAP, i.e., strict abidance by the conditions of the crashworthiness rating impact.

Conclusion

In this report, we have summarized certain research work that, since the onset of the New Car Assessment Program in 1979, has been geared to finding confirmation of the merits of the vehicle ratings ensuing from the application of the NCAP.

The analyses reveal the following:

1. It is vain to hope that the predictive method currently being implemented in NCAP can accurately represent the passive safety performances of vehicles in all types of accidents.
2. The general statistical studies that endeavor to correlate the predicted results with the real-world vehicle results do not at the present time make it possible to establish this correlation. This is likewise true for the studies that limit the samples investigated only in the cases of configurations similar to those performed within the framework of the NCAP.
3. There are clear technical reasons that account for this lack of correlation between the historical results, and the predictive results; we consider two of these reasons to be especially important:
   - The failure to take into account all the body areas that can be involved during the NCAP-type collisions, which are severe
   - The absence of representativeness of the Part 572 dummy, which does not allow any valid evaluation of the passenger protection performance of a given vehicle

   To date, there is nothing to support declarations of the following kind:
   - "NHTSA concludes that, generally, the car performing well (in the NCAP test) should be the vehicle of choice(2)."
   - "If a vehicle restraint system performs well in the NCAP tests, it is likely to perform well in a variety of accidents on public roads(23)."
   - "Changes made in restraints and vehicle crash characteristics as a result of weaknesses shown in NCAP tests have almost certainly improved their crash safety(23)."

   On the contrary, at the present time the following conclusion must be drawn: "We do not have any engineering reason to conclude that a 35mph barrier test is a reasonable predictor of car safety in the real world."

   In the last analysis, the above-quoted conclusion is in no way surprising. It ensures—quite logically—from the list of requirements that governed the compilation of NCAP: the search—we might almost say at any cost—for a difference whose reality still remains to be proven in relation to the real-world accidents, which are and will remain, inescapably, the reference.

In light of the foregoing, the following emerge as both vital and urgent necessities:

- Pinpointing the possible real differences between vehicles
- Identifying the causes of these differences
- After that—and only after that—devising a predictive method that will be able to take these differences into account both effectually and accurately

Moreover, it is entirely possible that such an approach would lead to one or the other of the following conclusions:

- The differences are not significant: uselessness of a rating program.
- The differences do actually exist, but no predictive method is feasible.

Conversely, if the program were pursued along its current lines, it is probable the interest of the clients—and of the automobile manufacturers—in the aforesaid program would eventually vanish completely, if only as the result of their perusal of the precautions for the use of the rating that it has been necessary to include and that, in certain cases, goes so far as to point out "there is no guarantee that a car that passed the test will adequately protect you in an accident(24)"

An Aid for the Assessment of Biomechanical Values With High Scatter and Uncertain Limit Values

Dr. Walter Schmid
Daimler-Benz AG, Sindelfingen

Abstract

In the case of characteristic quantities with an unusually high scatter and remarkably high uncertainties in establishing limit values, it is often very problematic to determine a particular value as the development target. This value must keep a defined safety margin to a limit value that is probably set down by regulations. But often a certain safety margin to the requirements of reality has already been observed when establishing limit values. In the case of the values referred to here, this double safety might—on the one hand—lead to development targets that are technically not feasible or only at unacceptable expenditure. On the other hand, this might compel actual safety reserves that no sensible person would ever demand.

For this reason, the example of HIC, the head injury criterion, is used to demonstrate the possibility of finding development targets and limits for specifications and regulations without being forced to keep unrealistic safety margins. It becomes obvious that in the example of HIC, a limit of 1,500 is much more realistic than, for example, a limit of 1,000.

Introduction

The endeavor to make their vehicles as safe as possible during traffic accidents presents vehicle manufacturers with the still unsolved problem of how to measure safety with few accident tests. For this purpose, the mechanical stress on the human body is determined with the help of dummies.

It is attempted in other specific tests on the human body to deduce from the mechanical stress whether this stress will lead to injuries. If so, it should be possible to determine the degree of seriousness of such injuries.

Unfortunately, deterministic considerations are often made during such attempts, although it is generally

known today that a connection between mechanical stress and injury of human body depends on many statistically distributed influences and can thus be established only in the sense of statistical statements.

On the other hand, it is not usual to fix certain factors, e.g., vehicle characteristics, in regulations and guidelines on the basis of statistical information. Rather, the intention is to set up limit values, whereby it is possible to ascertain in as few tests as possible whether values lie below these limits.

Such limit values can, however, be deduced from statistical statements. It became obvious that it is necessary to define a development target first before the limit value suitable for the individual problem can be given. The application of the method proposed is demonstrated by the example of the head injury criterion.

A Method To Determine Problem-Specific Limit Values

When investigating the interdependency between a mechanical stress and an injury of the human body, it became apparent very quickly there is no clear-cut limit stress, in the sense that stresses below the limit would never and those above the limit would always lead to injuries.

Statistically distributed dimensions, physical properties, age, and condition of the human body (e.g., muscles flexed or not), as well as the scatter of important parameters in the test procedure, can be taken as the reason why statements on the probability of injury with a given mechanical stress in biomechanical systems are the right problem-specific standards.

At first sight, it seems easy to define limit values by seeking mechanical stresses that insure the probability of injury remains below a given value (e.g., 10 percent). But if such limit values were adopted in legal regulations or guidelines, one would be compelled to seek development targets at an appropriate distance, because this is the only way—as a result of the measurement scatter occurring during the test—to make the risk of failing the test go down to an acceptable level.

This method required a double safety margin—that for establishing the limit value and that for the development targets. In reality (on the road), the probability of injury is no longer 10 percent, as assumed in the regulations, but considerably lower.

The uncertainties in establishing the limit values and the measurement scatter for biomechanical quantities are unusually high. In addition to giving unrealistic information about the real probability of injury, the method—first limit value, then development target—would lead to conditions for the design of a vehicle that are at present neither feasible nor economically reasonable.

For this reason, the right way is to define the development targets first, taking into consideration the uncertainty of the biomechanical interdependencies and the measurement inaccuracy, and afterward determine limit values, which should be the only factors for checking whether or not the development targets have been achieved.

Development Target

In Figure 1, the probability of injury is plotted versus a mechanical stress parameter selected at will.

The larger the mechanical stress (MS), the higher the probability of injury of the human body. Usually this curve has the shape of a cumulative frequency curve.

The lower the influence of statistically distributed parameters, the steeper the curve. It can be regarded as the cumulative frequency curve of a normal (bell-shaped) distribution ($\overline{MS}$, S_{MS}), particularly if the influence parameters are normally distributed.

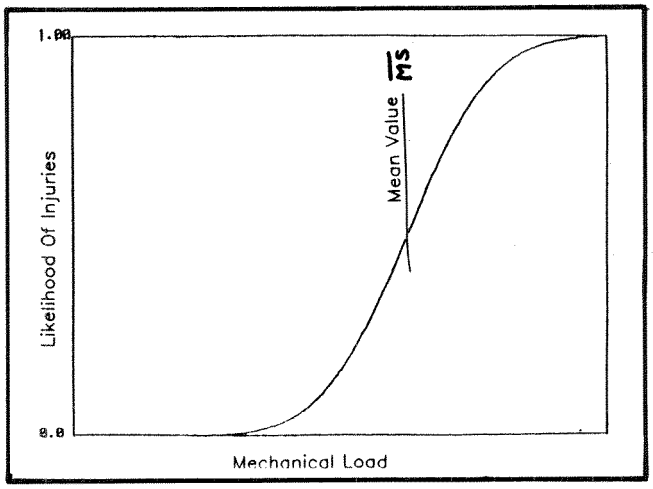

Figure 1. Interdependence between the probability of injury and a mechanical stress

Figure 2 shows the distribution of the measurement results, which, as a rule, are normally distributed as well ($\overline{M}$, S_M).

S_M comprises both the scatter of the vehicle characteristic varying from vehicle to vehicle and the scatter of the measurement results caused by measurement uncertainty.

In addition, the scatters S_M and S_{MS} depend upon the error probability, i.e., upon the size of the sample.

The probability of injury (P_V) in a vehicle is calculated from the product of the curve in Figure 1 and the curve in Figure 2 (Equation 1).

To insure that the probability of injury (P_V) in a vehicle is kept below a value to be specified (e.g., 10 percent), the development target ($\overline{M}$) should keep a specific distance (m) from the average ($\overline{MS}$) of the curve in Figure 1 (Figure 3).

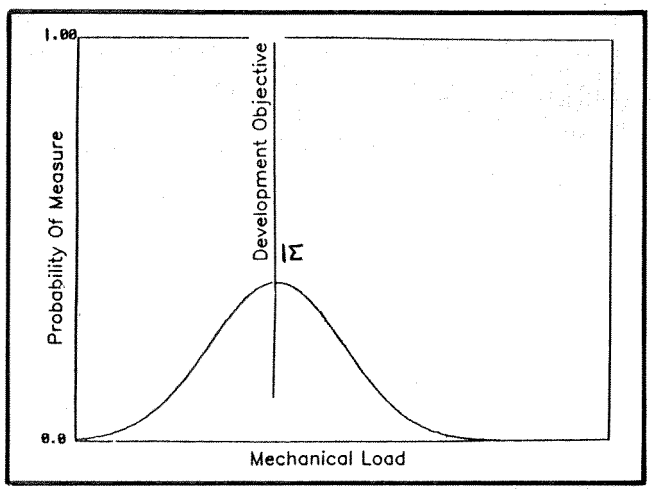

Figure 2. Scatter of the measuring results

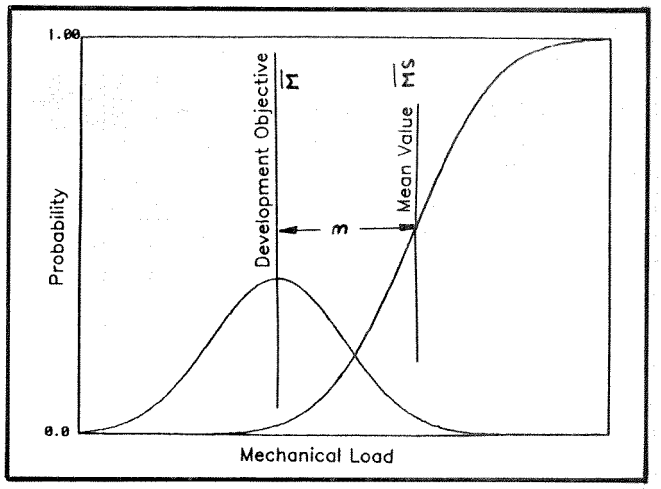

Figure 3. Determination of a development target

In general, this makes it possible to define a development target in accordance with the following proposition:

Proposition 1:"An article should be made so as to insure with a probability of more than (1-P) % that a desired property is actually provided. For this decision the error probability should be lower than α%."

Concerning safety on the road (1-P) = 90% and α = 5% are the usual values.

Limit Value

As by now the development target has been well defined and determined, a limit value to be set in regulations and guidelines need only allow for the probability with which an article (the vehicle) may fail a test.

The limit value is defined:

Proposition 2:"The limit value is to be determined so that an article whose development target is well defined and complied with will pass a test with a probability of (1-Q) %. For this decision the error probability should be lower than α% as well."

The probability mentioned here depends on the scatter occurring when measuring different samples of an article. This means that it comprises changes of the properties and the measurement uncertainty.

$$(1)\quad P_V(m) = \frac{1}{2\pi\, S_M \cdot S_{MS}} \int_{-\infty}^{\infty} e^{\frac{-1}{2}\frac{(MS-\overline{M})^2}{S_M}} \cdot \left[\int_{\infty}^{MS} e^{\frac{-1}{2}\frac{(u-\overline{MS})^2}{S_{MS}}}\, du \right] dMS$$

where $m = \overline{MS} - \overline{M}$

The Head Injury Criterion (HIC)

The method proposed for fixing the development targets and the limit values to be deduced shall now be explained by the example of the HIC.

The results of a large number of experimental investigations are shown in (2). For these investigations, cerebral injuries, given in AIS (Abbreviated Injury Scale), were compared with the "causing" HIC values (Figure 4). If the axes are exchanged, and the relationship AIS = f (HIC) determined with the help of a modern, non-parametric, statistical analysis method(3,4,5), it is possible to determine the probability with which the seriousness of the injury equals or exceeds 3 (AIS 3+) as a function of HIC. For the HIC (Figure 5), we obtain the values $\overline{MS} = \overline{HIC} = 1750$, the mean value, and $S_{MS} = S_{HIC} = 450$, the scatter value.

On the basis of the acceptable probability of injury (e.g., 10 percent), we obtain the development target for the HIC value. Additionally, this development target depends on the "measurement scatter" S_M. For this reason, Figure 6 shows the development targets for the HIC value for various probabilities of injury (1, 5, 10, 20, 30, 40, and 50 percent) plotted versus the ratio of the measurement scatter S_M and the scatter S_{MS}. As the vehicle characteristics themselves scatter, and because additional inaccuracies occur during measuring, the limit value should keep a certain margin to the development target in specifications and regulations, and this the more, the higher the scatter S_M. Moreover, this margin depends on the probability with which a test is to be passed. Figure 7 shows the test limits for different probabilities of erroneous rejections. The development target is chosen for a 10 percent likelihood of injuries AIS 3+. The HIC value has a standard deviation S_M = 225 (~20.5%), so that with S_{MS} = 450 the ratio S_M/S_{MS} = 0.5. If, for example, the limit is fixed at 1,500 for the HIC values, the probability of failing a test is still as high as 4

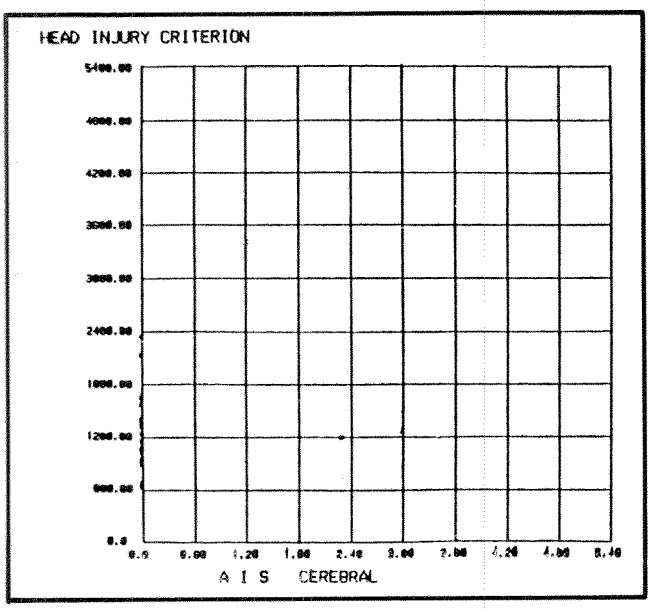

Figure 4. Biomechanical measurement results(2)

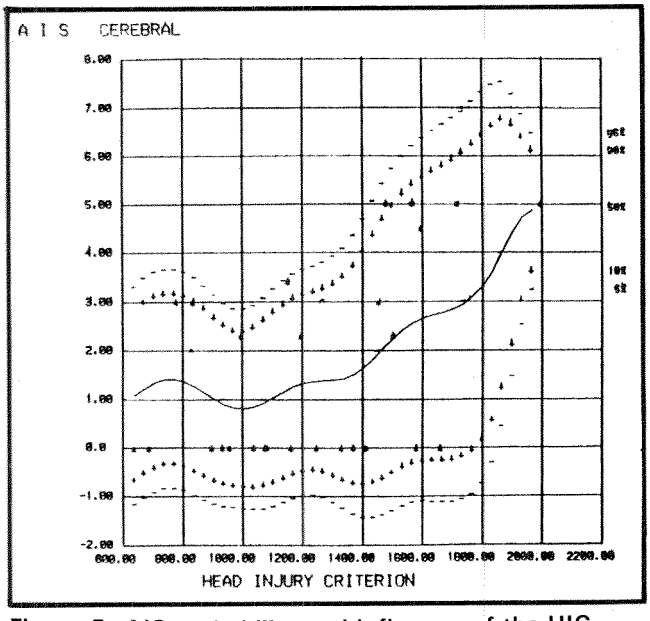

Figure 5. AIS probability and influence of the HIC

percent. The development target has been chosen correctly in relation to the problem, and the vehicle population represented by the vehicle under test was designed correctly with regard to the development target.

In addition, this example shows that the limit value 1,000 would be extremely unrealistic for the HIC whereas the value HIC_{limit} = 1,500 would be well defined.

Test Results and Real Accidents

Is the HIC value a quantity that gives information about the risk of injury in real road traffic? The vehicle

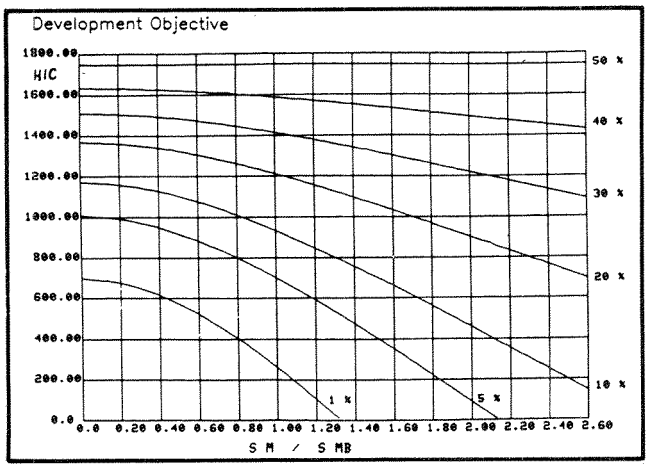

Figure 6. The development target HIC

developer must ask this fundamentally significant question in view of the high development costs caused by lowering the limit of the HIC value with given test conditions.

In the test program, New Car Assessment Program (NCAP), carried out by the National Highway Traffic Safety Administration (NHTSA), vehicles are driven into a rigid barrier at 35mph, and the HIC, the chest acceleration, and the femur load are measured on dummies(6).

The real accident is recorded in large-scale statistics of the vehicle insurers and published for the various vehicle models, e.g., in (7), in the form of information about the relative frequency of accidents involving injuries.

Figure 8 shows that the HIC seems not to be a sensitive standard for measuring safety on the road. This may be due to:

- The test method used in the NCAP is not problem-relevant.
- The test parameters in the NCAP are incorrectly chosen (e.g., v_0 = 35mph is too high(8,9).
- Head injuries are not the characteristic feature in road traffic.

Car Size and Safety: Results From Analyzing U.S. Accident Data

Leonard Evans
Transportation Research Department, General Motors Research Laboratories

Abstract

The results of studies performed by the General Motors Research Laboratories to investigate the relationship between car size (indicated by car mass) and safety are presented. Most of the studies reviewed rely heavily on one data set that has uniquely useful features. This is the Fatal Accident Reporting System (FARS) data set maintained by the National Highway Traffic Safety Administration (NHTSA), which is part of the U.S. Department of Transportation. This file contains detailed information on every fatal traffic crash occurring in the United States since 1975. The studies find that given a single-car crash, the unbelted driver of a 900kg car is about 2.6 times as likely to be killed as is the unbelted driver of an 1,800kg car. The relative disadvantage of the smaller car is essentially the same when the corresponding comparison is made for belted drivers. For two-car crashes, it is found that the driver of a 900kg car crashing into another 900kg car is about 2.0 times as likely to be seriously or fatally injured as is the driver of an 1,800kg car crashing into another 1,800kg car. The above-mentioned results refer to what happens if a crash occurs. Relations between car size and accident involvement rates will also be discussed.

Introduction

This paper summarizes a number of studies performed by General Motors Research Laboratories to investigate relationships between car size and safety. The main thrust will be on the probability of driver death (or injury) given that a crash has occurred, as a function of the car size.

In all cases, we characterize car size by the physical variable mass as measured by the curb mass of the car. We then determine relation between probable driver death (or injury) and car mass. Such relations do not imply that car mass, as such, is the causative factor. Clearly, a wide variety of vehicular characteristics are strongly correlated with car mass (e.g., wheelbase, track, size in general, hood length, trunk size, engine displacement, etc.).

Most of the studies reviewed rely heavily on one data set that has uniquely useful features. This is the Fatal Accident Reporting System (FARS) data set maintained by the National Highway Traffic Safety Administration (NHTSA), which is part of the U.S. Department of Transportation. This data set contains detailed information on every fatal traffic crash in the United States since January 1, 1975. Thus, unlike most traffic crash data sets, it is not a sample but a census. Much of the focus of this paper is on fatal crashes because the uncertainties surrounding such crashes, especially as recorded in FARS, are so much less than those associated with other levels of injury. Some of the studies to be reviewed use other data sources, which will be described in the appropriate sections.

In this paper, the main findings from previously published studies are summarized. For full details, including raw data, specific derivations of results from raw data, references to other work, and detailed discussion of underlying assumptions, the reader is referred to the original paper cited. The topics discussed in this paper are—

Crashes involving one car
- Driver fatality likelihood versus car mass
- Belted compared to unbelted fatality risk versus car mass

Crashes involving two cars
- Effect of mass of each car on driver fatality likelihood
  - — Crashes in all directions

  - — Head-on crashes only
- Effect of mass on driver fatality likelihood when cars of similar mass crash into each other
  - — Crashes in all directions
  - — Head-on crashes only

Method

Exposure

A problem common to essentially all investigations using field accident data is that of exposure, or the opportunity to be involved in a crash(6). Although the FARS data give detailed information on the characteristics of the drivers and vehicles involved in particular types of crashes, information of the type often used to estimate exposure (for example, distance of travel, number of registered cars) is not available internal to the FARS file. Although such information might be available from an independent source, there are pitfalls associated with bringing together data sets with dissimilar origins and definitions(8).

Exposure for most of the studies reviewed here that use the FARS data will be estimated using the exposure approach introduced by (6), and more simply described in (8).

For simplicity, let us consider that we wish to estimate as a function of car mass the likelihood a driver is killed, given his car strikes a tree. The FARS data do not provide any information on the number of crashes with trees in general, because only crashes in which a car occupant is killed are coded. In the exposure approach(6), we, in essence, assume that the number of crashes with trees (most of which are nonfatal) is proportional to the number of crashes with pedestrians, and the number of crashes with pedestrians is in turn proportional to the number of crashes with pedestrians in which the pedestrian is killed, this latter quantity being coded in the FARS data because of the pedestrian fatality. This involves assuming that, given a car-pedestrian crash, the likelihood the pedestrian is killed is independent of the car mass. This is reasonable on physical grounds. Even the lightest car is generally much heavier than the heaviest pedestrian, so the pedestrian kinematics after the crash are essentially independent of car mass. That is, the car's speed is not appreciably altered by the pedestrian impact. Note that other factors being the same, the larger car, being wider, is more likely to strike a pedestrian. This does not bias the exposure measure because the larger car is equally more likely to strike the tree.

The results of many studies(1) do not refute the assumption that in car-pedestrian crashes, the probability of a pedestrian fatality is independent of car mass(6). There is at most a weak hint that the larger car is more likely to kill the pedestrian, given a crash.

In the exposure approach, it is also assumed the relative dependence on car mass of the likelihood of encountering a pedestrian is the same as the relative dependence on car mass of the likelihood of encountering a tree. Examining variations by time of day and by urban versus rural classification showed no large departures from this assumption(6).

Thus, in the exposure approach, the number of car drivers killed in some group of cars divided by the number of pedestrians killed in crashes involving cars from the same group is proportional to the likelihood of a driver fatality, given a crash. That is, to within a scaling factor, the probability of driver fatality, given a crash, is estimated by the number of drivers killed divided by the number of pedestrians killed.

The degree to which results derived using this exposure approach are independent of driver behavior, and agree with results from other methods, will substantiate its appropriateness. Other exposure estimates used in this paper will be discussed in the appropriate sections.

Analytical Relations

In most of the studies, relative driver fatality (or injury rate), y, and mass, m, are fitted using a least squares procedure to:

$$\ln y = A + bm \qquad (1)$$

The data are plotted in the figures in a linear rather than logarithmic form, so Equation 1 may be conceptualized more conveniently as:

$$\text{where:} \quad y = a \exp(bm), \quad a = \exp(A) \qquad (2)$$

The logarithmic relation (Equation 1 or Equation 2) was chosen in preference to a linear relationship between y and m for two reasons. First, the logarithmic relation generally provides a better fit to the data. Second, the logarithmic relation is a simpler and more effective way to compare relative rates for cars of different masses. Such comparison involves only the slope parameter, b. Hence the relative influence of car mass is immediately given by this one parameter. The other parameter, a, is merely a scaling factor that cancels when rates for cars of different masses are compared.

Rather than using the analytical relationship between rate y and car mass m (Equation 1 or Equation 2), it is often even simpler to focus on a comparison of rates for two cars of specific masses—one a small car and the other a large car. The specific illustrated masses we choose are 900kg and 1,800kg. Thus, we compare the rate for a 900kg car with the rate for an 1,800kg car, which, from Equation 2, is given by

$$y(m = 900\text{kg}) / y(m = 1{,}800\text{kg}) = \exp(900\, b) \qquad (3)$$

where b is in kg^{-1}. The simplicity of Equation 3, involving only b and the difference between the illustrative masses chosen, underlines the advantage of the logarithmic relation.

Results

Crashes Involving One Car

Driver Fatality Likelihood Versus Car Mass

The relationship between driver fatality likelihood and car mass was addressed by (6) applying the previously described pedestrian fatality exposure approach. All fatally injured drivers, independent of whether they were coded as using a restraint system, were included. As only a few percent of such drivers are coded as using any restraint system, the results apply essentially to a population of unrestrained drivers. Later we discuss the corresponding relationship for restrained drivers.

The ratio of drivers killed in single-car crashes to pedestrians killed is shown versus car mass in Figure 1; all crashes involved cars whose drivers were ages 16 to 24 years. This ability to focus on specific subsets (e.g., drivers of given age) is an important advantage of the pedestrian exposure approach over most traditional exposure approaches.

The data in Figure 1 show a clear reduction in fatality likelihood, given a crash, with increasing car mass.

Figures 2 and 3 show information similar to that in Figure 1, but for driver ages 25 to 34 and ≥35 years, respectively. Despite the large differences in accident involvement rate for drivers of different ages, observe that the ratios plotted in Figures 1 through 3 are essentially the same for each of the age groups. This supports the claim that the ratio is reflecting physical properties of the vehicle, essentially independent of driver behavior effects.

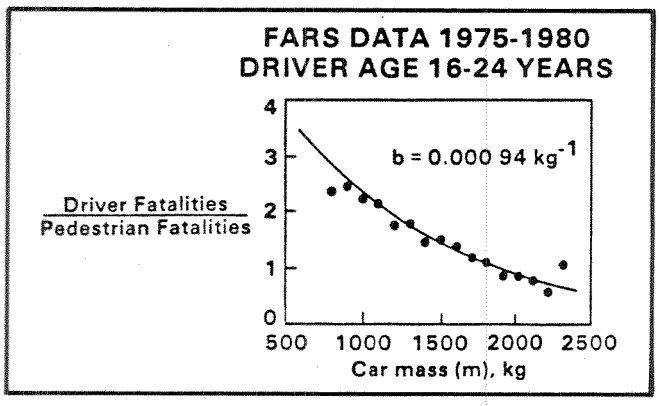

Figure 1. Ratio of drivers killed in single-car crashes involving no other vehicles to number of pedestrians killed in crashes involving cars of the same mass, versus car mass (driver age 16-24 years)

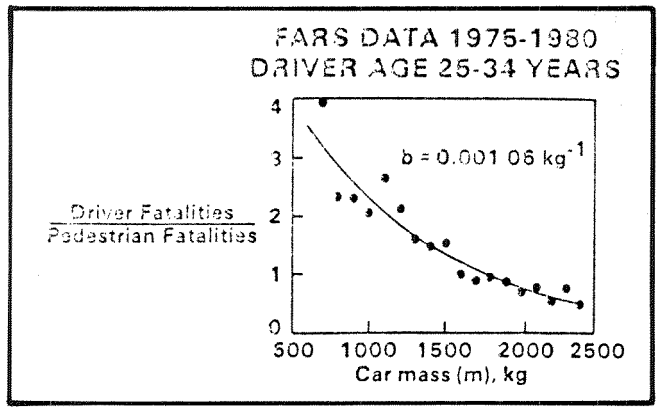

Figure 2. Ratio of drivers killed in single-car crashes involving no other vehicles to number of pedestrians killed in crashes involving cars of the same mass, versus car mass (driver age 25-34 years)

In addition to using pedestrian fatalities to estimate exposure, Evans also used motorcycle fatalities based on a parallel rationale(6). Furthermore, crashes in which car drivers were killed as a consequence of a crash with a truck are examined as another type of single-car crash. Thus, Evans(6) examined 12 relations (two types of driver fatalities × two types of exposure fatalities × three age categories) of which Figures 1 through 3 represent three. The results for all 12 cases are summarized as:

$$y(m) \propto \exp(-0.001\ 06m) \qquad (4)$$

where y is the relative likelihood of a driver fatality, given a crash, and m is the car mass in kg.

In terms of the specific example discussed earlier, Equation 4 implies that the driver in a 900kg car is 2.6 times as likely to be killed in a single-car crash as is the driver in an 1,800kg car.

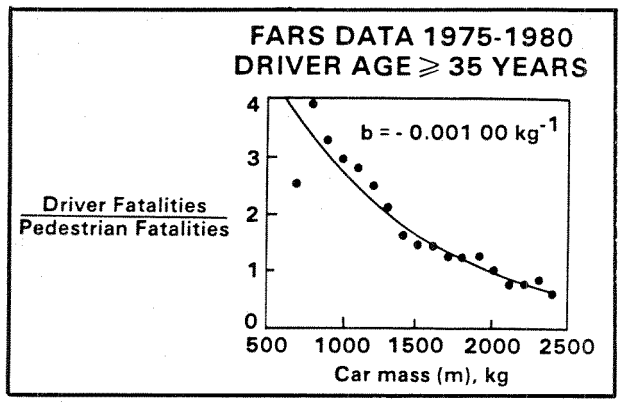

Figure 3. Ratio of drivers killed in single-car crashes involving no other vehicles to number of pedestrians killed in crashes involving cars of the same mass, versus car mass (driver age 35 years)

Belted Driver Compared to Unbelted Driver Fatality Risk Versus Car Mass

To determine the car mass relationship for belted drivers, a similar analysis was applied(9) to that small subset (less than 3 percent) of drivers coded in FARS as using some type of safety belt (lap, shoulder, or lap plus shoulder). Here the sample size is too small to disaggregate by driver age. To further increase the sample size, the numerator was taken to be the sum of all drivers killed in crashes involving one car (single-car crashes plus car drivers killed in crashes with trucks) divided by all nonoccupants killed (pedestrians plus motorcyclists).

This composite ratio of drivers killed per nonoccupant killed is shown versus car mass in Figure 4.

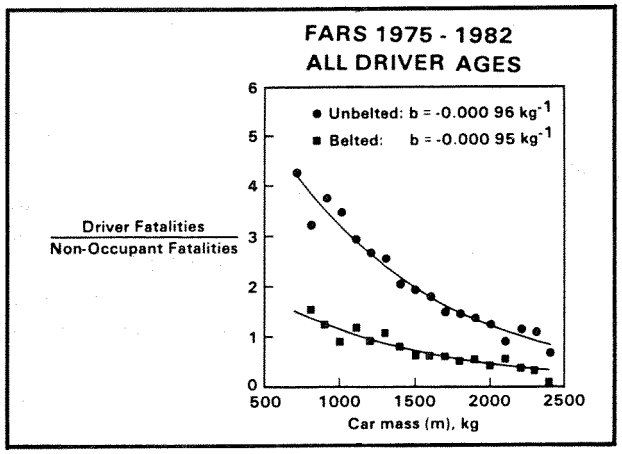

Figure 4. Ratio of car drivers killed in crashes involving only one car to nonoccupants (pedestrians and motorcyclists) killed involving cars in the same mass range

The data shown here should not be used to estimate safety belt effectiveness in preventing fatalities because of likely systematic bias in restraint use indications. Belt use indicated for fatally injured drivers is probably unbiased. However, for crashes in which nonoccupants are killed, the driver usually survives uninjured. The safety belt use information provided to the investigating officer is therefore, to a considerable extent, self-reported. Self-reporting, interview-type surveys invariably indicate belt use rates that exceed observed actual use rates by factors of two or more (compare, for example, the survey results of (14) or (13) with consistently observed U.S. use rates of 11 to 14 percent. Although the circumstances of such surveys have little in common with those at the scene of a crash in which a pedestrian or motorcyclist is killed, they nonetheless point out the possibility of a bias toward the more socially acceptable response; namely, to indicate a restraint system was used. Accordingly, the data should not be used to estimate safety belt effectiveness in preventing driver fatalities, given a crash. Any bias toward overestimating belt use for the crashes in which nonoccupants were killed will not affect the relations with car mass provided such bias is not also a function of car mass; we assume any such bias to be independent of car mass.

The curves shown in Figure 4 are:

$$y_{unbelted}(m) \propto \exp(-0.000\ 96m) \quad (5)$$

$$y_{belted}(m) \propto \exp(-0.000\ 94m) \quad (6)$$

Clearly, from Equations 5 and 6 there is no material difference in the relative effect of car mass for the belted and unbelted cases.

In terms of the example using specific car masses, we find the belted driver of a 900kg car is 2.3 times as likely to be killed in a crash as is the belted driver of an 1,800kg car.

From Equation 5, an unbelted driver in a 900kg car is 2.4 times as likely to be killed in a crash as is an unbelted driver in an 1,800kg car. Note this is not identical to the 2.6 ratio reported earlier because Equation 5 is not identical to Equation 4. The calculation that produced Equation 5 differs from that which produced Equation 4 by including unbelted drivers only rather than all drivers; by using 1975-1982 data rather than 1975-1980 data; by using a composite ratio rather than an average of individual ratios; by combining all ages rather than disaggregating into three driver age groups. These and other differences reflect either improvements over the earlier work or aggregation performed to increase the population size to obtain sufficient data for the belted case.

Thus, in conclusion, we find that in a single-car crash, a driver of a 900kg car is about 2.4 times as likely to be killed as is the driver of an 1,800kg car. This result is essentially the same for belted or unbelted drivers.

Crashes Involving Two Cars

Here we wish to examine how the mass of each car involved in a two-car crash affects the relative likelihood that the driver is killed. As the data must be disaggregated twice by car mass, coarser divisions than used in the single-car case are required. Accordingly, a number of analyses based on the six mass categories displayed in Table 1 have been performed.

Relative Driver Fatality Likelihood When Cars of Different Mass Crash Into Each Other

All Impact Directions—The data from FARS 1975 through 1980, given in (12) and based on (5), are reproduced in Table 1.

Each entry in the table shows the number of drivers in cars in the m_i mass category killed as a result of crashes with cars in the m_j category. For example, 35 drivers of

Table 1. Number of driver fatalities in cars of mass m_i in collisions with cars of mass m_j, all impact points

			Car j						
	Mass, kg		m_1	m_2	m_3	m_4	m_5	m_6	Total
Car i	500- 900	m_1	34	79	156	352	582	578	1,781
	900-1,100	m_2	33	86	165	396	679	693	2,052
	1,100-1,300	m_3	36	74	171	443	684	698	2,106
	1,300-1,500	m_4	47	79	226	604	1,088	1,132	3,176
	1,500-1,800	m_5	34	95	189	558	1,071	1,253	3,200
	1,800-2,400	m_6	35	70	139	415	753	878	2,290
	Total		219	483	1,046	2,768	4,857	5,232	1,4605

m_6 cars were killed as a consequence of crashes with m_1 cars. In these same crashes involving m_1 and m_6 cars, 578 drivers of m_1 cars were killed. Thus, we can infer immediately that in crashes involving m_1 and m_6 cars, for every driver killed in m_6 cars, there are 578/35 = 16.5 drivers killed in m_i cars. Note this result is exposure independent. If there were more crashes involving m_1 and m_6 cars, this would affect the quantity of data but not the 16.5 result in any obvious way.

The relative risk to the drivers in cars in any pair of masses may be compared in a similar exposure-free way. One may readily note, for example, how rapidly the ratio of drivers killed in the lighter car compared to in the heavier car increases as the mass disparity increases. Cerrelli presents data in a similar format to Table 1, but including a wider range of vehicles, from minicompact cars to heavy trucks; for the case of these vehicles crashing into each other, the driver fatality risk in the minicompact car was 36 times what it was in the heavy truck(4).

Estimates for arbitrary masses are best made by interpolation. For example, the data indicate that when 900kg and 1,800kg cars crash into each other, the driver in the 900kg car is about 13 times as likely to be killed as is the driver of the 1,800kg car. This is larger than the 8 times ratio, which was based on substantially fewer data, reported by Evans(5).

To proceed beyond pair-wise comparisons requires some estimate of exposure. The pedestrian exposure approach was used(12) to transform the data in Table 1 into that of Table 2. Each number in Table 1 was divided by the product of the number of pedestrians killed in crashes involving cars of mass m_i and the number of pedestrians killed in crashes involving cars of mass m_j. For convenience, all values were rescaled so the nominally safest case, a driver in a car in the heaviest mass category (m_6) crashing into a car in the lightest mass category (m_1) was assigned the value 1.00. Each value in that a driver in a car of mass m_i is killed in a crash with a car of mass m_j. This table is interpreted as the result sought. Efforts to summarize the information in bivariate analytical form were unsuccessful, so, again, estimates for arbitrary masses are best made by interpolation.

Head-on Crashes Only—Here the analysis is essentially as above, except the data are for head-on crashes, defined as follows. The head-on data are based on the variable "principal impact point," the position on the vehicle of the impact that produced the greatest personal injury or property damage. This variable is coded in 12 "clock points." Direction of impact force as such is not coded in FARS data. For FARS data, we define a head-on crash as one in which both cars are coded as having principal point of damage at the 12 o'clock position. That is, if either car is coded as, for example, left front (clock point 11), this crash is not included. Hence the data come as close as possible to representing head-on crashes, based on FARS data.

Table 3 shows the raw fatality data for the head-on case, which is to be compared to the all-directions case shown in Table 1. From these tables, we see that about 40 percent of all fatal two-car crashes are head-on crashes. Head-on crashes compose a much smaller percentage of two-car crashes with less severe injuries.

The data in Table 3 are converted into relative fatality rates using the pedestrian exposure method to generate Table 4. Again, it is rescaled so the bottom left value has the value of 1.00.

Generally, the car mass effect tends to be somewhat larger, though not consistently so, for the head-on than for the all-directions case. For example, the data indicate that when a 900kg car and an 1,800kg car crash head-on, the driver of the 900kg car is about 14 times as likely to be killed as is the driver of the 1,800kg car.

Cars of Similar Mass Crashing Into Each Other.

One type of a two-car crash of particular interest is when the two cars are of similar mass. In such crashes, the

Table 3. Number of driver fatalities in cars of mass m_i in collisions with cars of mass m_j, principal impact point "12 o'clock" for both cars.

			Car j						
	Mass, kg		m_1	m_2	m_3	m_4	m_5	m_6	Total
Car i	500- 900	m_1	14	38	68	136	218	207	681
	900-1,100	m_2	13	43	68	186	264	274	848
	1,100-1,300	m_3	17	34	65	168	253	268	805
	1,300-1,500	m_4	17	29	92	252	407	445	1,242
	1,500-1,800	m_5	10	44	73	222	450	573	1,372
	1,800-2,400	m_6	10	31	50	152	326	367	936
	Total		81	219	416	1,116	1,918	2,134	5,884

dynamical forces on each car are similar. Indeed, for the head-on case, such crashes are in some respects similar to barrier crashes.

All Impact Directions—The relative risk of fatality when a car in the m_i mass category crashes into another car in the same mass category is given in the highlighted diagonal elements in Table 3. These are shown plotted in Figure 5. The values, y, have been rescaled as follows. The data highlighted in the diagonal elements were fitted to Equation 1 using weighted least squares(12), and the value for M = 1,800kg assigned the rescaled value 1.00. Here we use M to denote the common mass of the two cars that crashed into each other, in contrast to m, the mass of one car.

The other two curves in Figure 5 show estimates of the probability of driver serious injury or fatality when cars of similar mass crash into each other based on two State data sources, New York(15) and North Carolina(2). The rates here are number of drivers injured divided by the number of crashes, rescaled in the same way so the value at M = 1,800kg corresponds to y = 1.

The results in Figure 5 are summarized in Table 5 in terms of the comparison between 900kg and 1,800kg cars.

Note the relatively good agreement (see Figure 5, Table 5) between the FARS results based on the pedestrian exposure approach and the State results calculated as drivers injured per crash. This agreement provides support that the pedestrian exposure approach is reasonable.

In summary, we find that a driver in a 900kg car crashing into another 900kg car is about 2.3 times as likely to be seriously injured or killed as is a driver in an 1,800kg car crashing into another 1,800kg car when all directions of impact are considered together.

Head-on Crashes Only—Here the analysis is as before, except that the starting point is the highlighted diagonal data in Table 3, which is used to generate the relative fatality data in Table 4. These data are shown plotted, after rescaling as before, in Figure 6, together with head-on only data for the States of New York and North Carolina.

Results from the data plotted in Figure 6 are summarized in Table 6 in terms of comparing a 900kg car

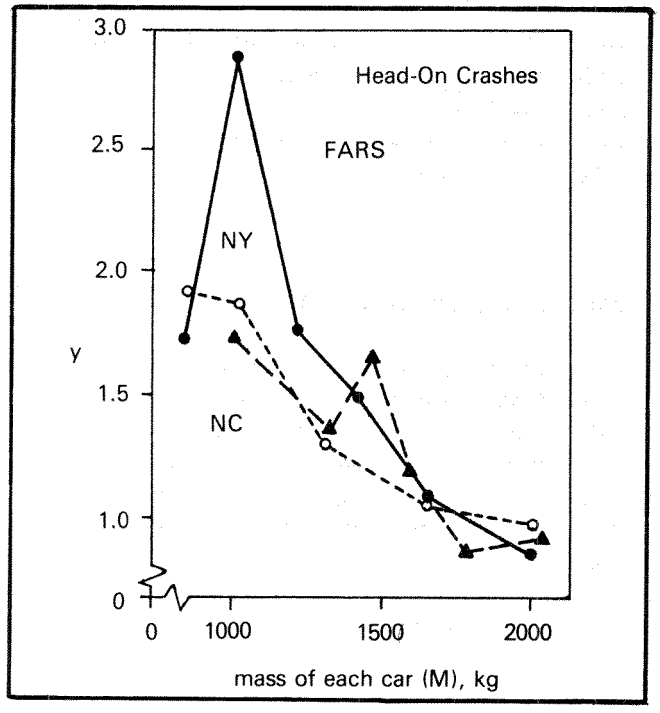

Figure 6. Relative likelihood, y, of driver injury (serious or fatal) when a car of mass M crashes into another car of similar mass (values relative to a value one for two 1,800kg cars crashing head-on into each other)

Table 4. Relative likelihood of driver fatality in car mass m_i involved in a 2-car crash with car mass m_j, principal impact point "12 o'clock" for both cars

Mass, kg		Car j					
		m_1	m_2	m_3	m_4	m_5	m_6
Car i 500- 900	m_1	10.14	20.41	23.12	21.70	22.10	20.70
900-1,100	m_2	6.98	17.12	17.14	22.00	19.84	20.31
1,100-1,300	m_3	5.78	8.57	10.37	12.58	12.03	12.58
1,300-1,500	m_4	2.71	3.43	6.89	8.85	9.09	9.80
1,500-1,800	m_5	1.01	3.31	3.47	4.96	6.38	8.02
1,800-2,400	m_6	1.00	2.30	2.35	3.35	4.56	5.07

Table 5. Summary of the ratios of driver injury (serious or fatal) when two 900kg cars crash into each other (all directions) to that when two 1,800kg cars crash into each other.

Data	Driver Injury	y(M=900kg) / y(M=1,800kg)
FARS	fatal	2.27
NY	serious or fatal	2.35
NC	serious or fatal	2.16
	mean	2.26
	standard deviation	0.10

Table 6. Summary of the ratios of driver injury (serious or fatal) when two 900kg cars crash head-on into each other to that when two 1,800kg cars crash into each other.

Data	Driver Injury	y(M=900kg) / y(M=1,800kg)
FARS	fatal	2.42
NY	serious or fatal	1.68
NC	serious or fatal	2.02
	mean	2.04
	standard deviation	0.37

crashing head-on into a 900kg car to an 1,800kg car crashing head-on into an 1,800kg car. In summary, it is found the likelihood of driver serious injury or fatality is about twice as great when two 900kg cars crash head-on as when two 1,800kg cars crash head-on.

Summary and Discussion

The results presented are summarized in Table 7. These reports support the overall conclusion that given a crash, the driver in a smaller car has a substantially higher probability of serious injury or fatality. In no case of comparing 900kg to 1,800kg cars was the disadvantage to the driver of the lighter car less than a factor of two.

The main focus of this paper has been on how car size affects the probability of driver death or injury, given a crash occurs. Although the effects found are of substantial magnitude, they are smaller than many influences due to driver behavior. For example, younger drivers have fatality rates that exceed those for older drivers by factors of four or five(3,16). Part of the physical disadvantage of the smaller car is mitigated by lower accident involvement rates being associated with smaller cars(8,7,9). Indeed, although when a 900kg car crashes into a 900kg car, the probability of driver serious injury (or fatality) is twice as great as when an 1,800kg car crashes into an 1,800kg car, the actual number of drivers seriously injured or killed in the small-small crashes is, paradoxically, less than for the large-large crashes when normalized for numbers of cars and driver age(10). This is one of a number of examples of "human behavior feedback"(11). Such feedback need not necessarily reduce the effectiveness of safety engineering improvements; these are indications(11) that in some specific cases, such feedback may further enhance such improvements. However, as stressed in (11), the question of how users react to safety engineering changes should always be addressed in any consideration of the potential net effects of such changes.

In overall conclusion, it is found that given a crash occurs, drivers of smaller cars are substantially more likely to be killed than are drivers of larger cars. For the example given of comparing driver fatality likelihood in a 900kg car to that in an 1,800kg car, in none of the crash types discussed in the paper was the disadvantage to the driver of the 900kg car less than a factor of two.

Rating System for Serious Consequences (RSC) Due to Traffic Accidents—Risk of Death or Permanent Disability

Hans Gustafsson
Folksam Research and Development Division, Stockholm, Sweden

Åke Nygren and
Claes Tingvall
Folksam Research and Development Division, Karolinska Hospital, Department of ENT, Stockholm, Sweden

Abstract

Injury rating is an important issue in the field of traffic safety. The injury pattern can be obtained either from the scene of the accident, including all severity grades, or from the frequency of those fatally injured. Less attention has been paid to the long-term consequences of an injury. Furthermore, the existing rating system is based on the medical status at the scene of the accident or immediately after and judges only the risk of death.

Nygren(6) showed that for many body regions the AIS values did not reflect the outcome of a trauma expressed in permanent medical disability.

In this study, 339,675 accidents with private cars were analyzed with respect to injuries to car occupants. In these accidents, 14,361 persons were injured. The risk of permanent disability due to different injuries is derived and linked to AIS values to different body regions.

A rating system for injuries based on the risk of death or permanent disability is proposed. The rating system called RSC, risk of serious consequences, used ISS and AIS for different body regions. RSC was used to describe differences in injuries to belted and unbelted car occupants.

Background

Much attention has been paid to the problem of injury rating, especially in the field of traffic accidents. Today the AIS (Abbreviated Injury Scale) is used all over the world and accepted as a sufficient tool for injury rating. There is a great number of empirical materials coded according to the AIS.

Several methods have been used to judge multiple injuries coded in the AIS such as OAIS and MAIS. The most widely used technique today seems to be the ISS (Injury Severity Score) where the highest AIS values for three body regions are squared and summed(1).

AIS and ISS, as well as other expressions of multiple injuries, have been treated with questionable statistical methods(2), although this is not very surprising as many normal and well-known statistical quantitative methods are not possible to use when analyzing AIS values. This is mainly due to the fact that AIS values as well as ISS values are not equidistant and the scale is qualitative.

Bull(3) and Baker(1,4) showed there is a high correlation between ISS and risk of death. Somers(2,5) has also shown this connection but proposed another score

system, PODS, with a mathematical expression for risk of death for a given combination of AIS values.

Bull(3) made an analysis of the relationship between ISS and permanent disability where he found rather good correlation.

Nygren(6) showed that injuries with low severity according to AIS (AIS 1 and 2) with no interaction of other injuries often lead to permanent disability. These results indicate that neither ISS nor AIS, not linked to body region, can fully explain the risk of permanent disability. This is not surprising as AIS and its outlines are not primarily derived to serve purposes other than estimating threat of death.

On the other hand, there is a certain need to be able to describe risks of disabling injuries and long-term consequences as such consequences are expensive to society and important to reduce.

Since many materials are coded in the AIS and most accident researchers are familiar with the AIS and its outlines, one should be cautious in proposing a new rating system. A better way to proceed is probably to derive new methods based on the AIS and ISS.

In this paper, a new way of using the AIS is presented, aimed at giving a tool for estimating the risk of medical disability. A new score is also presented where two highly unexpected consequences of traffic accidents are mixed together, namely fatalities and medical disability. The score is called RSC, risk of serious consequences.

The proposal to use the AIS, in this case linked to body region, to predict the risk of medical disability is also meant to be a system where the individual patient is not followed up but only observed immediately after the accident.

Material

A material consisting of 5,871 car occupants injured during the period July 1, 1976, to December 31, 1978, has been used to produce risks of permanent disability. All injuries have been coded according to the AIS.

The accidents in which the injuries occurred were reported to the Folksam Insurance Company, and a further description of the material was presented by Nygren(6). A small loss of data, consisting mainly of minor injuries, was shown to exist, but this was considered to affect the result only marginally. The same material was used to demonstrate the RSC. In this article, the difference between belted and unbelted occupants in accidents was shown.

Figures for death risks given by the ISS were taken from Bull(3) and Baker(4).

The definition of medical disability was described by Nygren(6) and is used by Swedish insurance companies. The basis for the medical disability should be an objective judgment based on functional loss and pain. No attention should be paid to occupation or other individual parameters. Most disability cases have fixed values or latitudes. The advantage of the Swedish system is not the scaling in itself, but the fact that cases of medical disability are judged by a committee consisting of members of all insurance companies. This guarantees a certain level of consistency.

Method

The risk of death or permanent disability is:

$$P(FUD) = P(F) + (I-P(F)) * P(D) \quad (1)$$

Expressed in this way, the probability also includes the risk of being both dead and medically disabled, although this is, of course, impossible in real life.

As the probability is not separated, this is of no practical meaning. If the probability of being medically disabled is based only on survival, separation is still possible if the expected number of deaths is calculated first and then the number of those surviving with medical disability.

The way used to express the probability of death or medical disability(1) in a way gives understanding of the above-mentioned idea.

The probability of death can be derived in two different ways from AIS data, either by empirical figures or by some sort of mathematical expression. Somers(2,5) proposed PODS, probability of death score, based on the AIS. Bull(3) and Baker(4) showed the correlation between the ISS and death. In this paper, empirical death risks have been used but mathematical expressions could be used as well. Data were taken from Bull(3) and Baker(4). The death risk was separated for different ISS intervals, and these figures are given in Table 1.

The risk of medical disablement for surviving injured car occupants has been separated in risks to different body regions for different AIS values.

The figures given in Table 2 are originally shown by Nygren(6). The figures here are slightly modified.

Table 1. Risk of death correlated to the ISS

ISS-intervals	Risk of death ($0 \leq r_f \leq 1$)
1- 3	0.00
4- 8	0.001
9-14	0.005
15-19	0.04
20-24	0.08
25-29	0.16
30-34	0.26
35-39	0.37
40-44	0.50
45-49	0.65
50-54	0.85
>54	1.00

Table 2. Risk of permanent disability for different body regions and AIS for those surviving

External	0.0001	0.05	0.05	0.05	n.a

* 0.10 if rear-end collision
0.04 if other direction

The risk of being injured or medically disabled can be expressed as(2):

$$P(FUD) = P(F) + [(1 - P(F)) * (1 - \prod_{i} P(D_i^c))] \quad (2)$$

or expressed as a risk with empirical values:

$$RSC = r_f + [(1 - r_f) * (1 - \prod_{i} (1 - r_{id}))] \quad (3)$$

where r_{id} is the risk of medical disability for different body regions.

The expression $\pi (1-r_{id})$ is the risk of not having at least one medical disability for a specific body region. The risk, called RSC, is calculated for every single individual. The RSC value for a single injured person is treated as a single observation with fixed risk figures for death and disability.

The risk of death or medical disability for a certain group is called MRSC (Mean Risk of Serious Consequences). MRSC can be calculated because RSC values are equidistant. RSC and MRSC can also be treated with common statistical techniques.

The risk of death sometimes fails to be calculated by ISS. This occurs when there is only one very high AIS value (5 or 6). AIS 6 is by definition a fatal injury with rf = 1 though in studies of the interrelation between ISS and risk of death, ISS = 36 (from AIS = 6) only has $r_f \approx 0.4$. This problem is also present for AIS code 5. Baker(1) showed that an AIS = 5 together with a second low AIS code to another body area led to a mortality rate of more than 50 percent. In RSC, 50 percent is used as the lowest fatality risk for AIS = 5.

Example

Three persons had injuries as listed in the table below.

Injured person 1	Injured person 2	Injured person 3
AIS 3, Skull/brain AIS 2, lower extr.	AIS 1, neck (rear-end) AIS 2, upper extr.	AIS 4, chest AIS 3, abdomen
ISS = 13	ISS = 5	ISS = 25
Risk of death $r_f = 0.005$	$r_f = 0.001$	$r_f == 0.16$
Risk of permanent disability [1 - ($\prod$ (1 - r_{id})] (if surviving)		
$r_d = 0.278$	$r_d = 0.132$	$r_d = 0.030$
Σ RSC = 0.598 MRSC = 0.199		

Results

RSC was tested on accident material to describe the differences between belted and unbelted car occupants. Table 3 shows the distribution of injured persons in ISS groups for belted and unbelted front-seat occupants.

Table 3 shows clearly the positive effects due to seatbelt use. However, these values are not possible to translate into understandable figures on followings of seatbelt use apart from the number of fatalities. Let MRSC denote the estimation of MRSC in a sample.

Table 4 shows the difference between belted and unbelted expressed by MRSC for the same material as in Table 3.

Table 4 demonstrates clearly the difference between belted and unbelted car occupants when MRSC is used. The mean risk of serious consequences is reduced by 69 percent for drivers and by 60 percent for front-seat passengers when seatbelts are used compared to not-used. Apart from this effect, there is a reduction of the number of injured of about 30 to 40 percent(6), so the real effect on MRSC is larger.

If MRSC in big samples can be assumed to be asymptotically normally distributed, simple calculations can be used to give confidence limits for estimations of MRSC.

Discussion

This paper describes a technique to estimate the serious outcome of road traffic accidents. There is need for such techniques, especially when dealing with permanent medical disability. However, there are many questions that must be discussed before a technique based on the present suggestion can be accepted as a general tool for description of injury severity. In this paper, there is only one definition of permanent medical disability used. Of course, there are other definitions, as well as several other techniques, to describe the outcome of an injury.

Thorson(8) used a subjective but individually judged scale for the long-term consequences of injuries. In some respects, such a scale takes into account the social consequences due to a trauma, but since it is individually graded the demands for high-quality data require a long period of collecting data, etc. Thorson did not compare AIS values with the outcome.

Others have studied the relation between ISS and the risk of permanent disability(3).

Table 4. MRSC (mean risk of serious consequences) for injured, belted, and unbelted front seat occupants

	MRSC
Drivers	
Belted	0.079
Unbelted	0.257
Front seat occupants	
Belted	0.078
Unbelted	0.196

In this paper, it is proposed there should be a scale used on a common basis where there is no information required for the injured person other than AIS values for different body regions. A discussion should, therefore, also concentrate on such a scaling system. There are mainly three areas that are interesting:

1. Limits and criteria for medical disability or impairment
2. Age and sex factors influencing long-term consequences
3. Body areas and AIS

The limit for medical disability is subjective and can be set from 1 to 100 percent. In this paper, 10 percent was used due to technical and subjective reasons. The technical reasons are that only cases with at least 10 percent medical disability are judged systematically by a certain group of experts.

A subjective reason to use 10 percent as a limit is, among other things, that disability over this level is a long-term consequence of an accident that is unacceptable to most people. Other limits must, of course, be discussed. To use the disability level (1 to 100 percent) for weighing the seriousness of the outcome is on the other hand a method that can be questioned since the precision in the decision of different levels is subjective in many cases.

Table 3. Distribution of ISS among car occupants >15-years-old with and without seatbelt use (%)

	ISS 1-3	ISS 4-10	ISS 11-	Killed	N
Drivers					
Belted	61.7	29.1	5.7	3.4	3,173
Unbelted	33.3	30.8	14.8	21.1	522
Front seat passengers					
Belted	57.3	31.8	7.8	3.2	1,509
Unbelted	40.6	34.3	14.2	11.0	254

Age and sex have an influence on the risk of being both killed(3,4) and disabled(6). In some cases, it is necessary to take age and sex into consideration. The present material was not big enough to produce figures for subsets of injured.

AIS to body regions was used to generate disability risk figures. AIS to single body regions is the lowest level that can be reached in most accident materials. Nygren(6) showed that a higher level (e.g., AIS irrespective of body region or ISS) would be incorrect. Still, it is necessary to study the sufficiency of the level. For some AIS levels to certain body areas, e.g., lower extremities, it is still an open question if such a region should be divided into joint injuries and other injuries.

The relation between ISS and risk of death has been shown by several authors(3,4). Other techniques have been proposed to predict fatalities(2,5). In this paper, empirical values were used, but other techniques can be used as well with no other modification of RSC.

The figures used in this paper were taken from injured car occupants. It is important to have figures also for other road traffic categories.

Conclusion

By using ISS as a tool for describing death risks and AIS values to different body regions to calculate the risk of medical disability, it should be possible to use a technique to give figures on the risk of death or permanent disability by using only AIS data on a sufficient level. The relation between AIS and risk of permanent disability can be established by following injured persons over a period until the objective medical disability level is fixed.

Today there is no adequate system to judge serious consequences due to traffic accidents on a common basis, though there is a strong demand for such a system. ISS, as well as AIS not separated to body regions, cannot describe the risk of medical disability. RSC can describe both death risk and the risk of long-term consequences at the same time and can be used on most accident materials collected all over the world. It is, however, very important to discuss mainly the definition and limits for medical disability.

MRSC, used on seatbelt effectiveness, shows that the risk of death or medical disability is reduced (among injured car occupants) by 60 to 70 percent. The reduction is higher when injury frequency reducing factors are included.

Seatbelt Research and Legislation in The Netherlands

L.T.B. van Kampen
Institute for Road Safety Research SWOV, The Netherlands

Abstract

SWOV is the coordinating institute for scientific research on traffic safety in the Netherlands. A new international approach is being prepared for integrated road safety plans both in the field of the policymakers (on all levels) and in the field of research. This approach becomes necessary to further improve the safety of traffic on a large scale. Research projects such as detailed accident studies and seatbelt surveys have been carried out by SWOV and the results reported to the government and used to develop seatbelt legislation in the Netherlands. The layout of current seatbelt legislation and the compliance details are discussed.

Legislative developments are to be expected with respect to seatbelts on back seats. A comprehensive

report of SWOV on the pro's and contra's of new measures in this field has been published.

Mathematical crash models are being developed and used and may well be applied to predict changes in the population at risk with regard to injury severity levels. This will create a priority scale for proposed new measures.

Introduction

For more than 20 years, the Institute for Road Safety Research SWOV has been the coordinating institute for scientific research on traffic safety in the Netherlands. Though some 90 percent of its activities are carried out on behalf of or by order of the traffic safety departments of the Ministry of Transport, SWOV is an independent institute with regard to the scientific aspects of its work and publication of its reports.

The research program of SWOV is revised annually in consultation with the Ministry of Transport.

Typical research activities of SWOV are (Figure 1)—

- Design of new research projects with emphasis on the methodological aspects, such as accident studies, evaluation studies, surveys, etc.
- Carrying out research projects or supervising studies designed by SWOV and carried out by other institutes
- Analysis of traffic safety developments
- Acquisition of relevant data from external data sources and positively influencing their quality
- Acquisition of relevant literature, reports, articles, etc., and maintaining a national library and documentation data bank on traffic safety (IRRD)

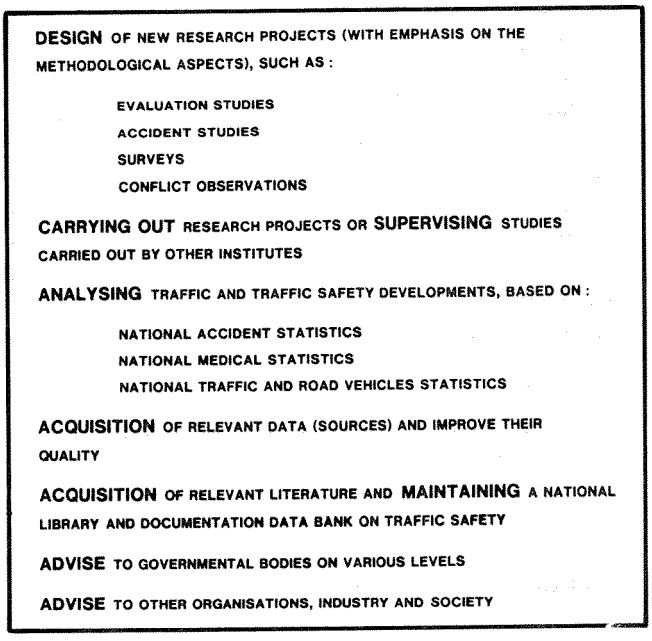

Figure 1. Typical examples of SWOV research activities

The knowledge acquired from the research activities is reported mainly to the government, either in written reports or as advice in various working and policy groups. This way, the investment of taxpayers is returned with profit for society. The results are then used by the authorities to develop and implement new legal measures to further reduce traffic unsafety.

Integrated Road Safety Programs

SWOV took a leading part in the OECD-S1 High Level Group on "Concepts and Methodologies for Integrated Road Safety Programmes" during 1983 and 1984.
