The final report on this international research project gives conclusions and recommendations for further development of the dynamic systems approach as a tool toward far better integrated and cost-effective national and international policy and research programs. These are very much needed to (further) reduce the still too heavy toll of road casualties: fatalities, injured, and disabled(6).

As part of this program, SWOV developed the so-called "phase-model of the transport and traffic (unsafety) process" (Figure 2).

On the level of the individual road user, the model shows the various sequential steps starting from travel need, through the different phases, to the ultimate outcome of an accident. It shows at what phases in the traffic process disturbances may occur, leading to failures and, if not controlled, inevitably to the next phase where again failure may occur. It illustrates that no accident ever is the result of just one separate item, but always has a multicausal character.

At the moment, SWOV applies the theories by trying to integrate all types of research into an overall design of traffic safety research. This implicates that the outcome of studies should be checked against this integrated design and that proposed measures are also viewed in that much broader perspective.

With regard to seatbelts in cars, this means all different aspects of that problem have to be considered before a final conclusion or final measure can be derived. All interactions should be considered among those different aspects. To mention a few in the seatbelt area—

- Technical factors (such as design and testing of seatbelts and anchorage points)
- Biomechanical factors (such as effectiveness of seatbelts in crashes, measured in real accidents and simulated in crash tests and mathematical models)
- Behavioral factors (such as attitudes of road users toward the problem and actual use established by surveys; influence by campaigns)

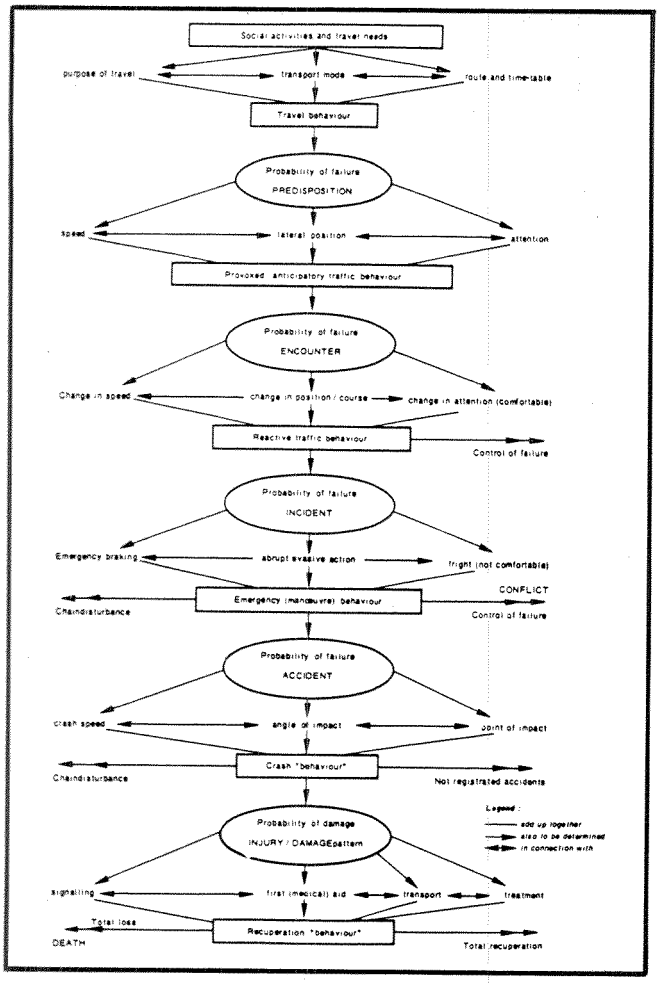

Figure 2. Phase-model of the transport and traffic (unsafety) process

- Legislation (design and implementation of legal measures)
- Law and enforcement (police motivation)

In all those fields, SWOV has to acquire scientific knowledge to maintain its coordinating functions. On the other hand, it can be understood that the efforts and cooperation of those many other institutes and organizations, authorities, and industry in the Netherlands working on specific fields of the problem are needed to influence traffic safety successfully.

Seatbelt Research

Before introducing the actual situation on seatbelt legislation and use in the Netherlands, this paper will give a summary of some research projects and their results that have influenced the development of those legislative measures.

SWOV research, of course, takes into account what other research on a specific subject area has already been carried out by other institutes in the world and what results can be used therefrom.

In 1969, when SWOV started with its first extensive accident study (aimed at seatbelt effectiveness), it certainly took into account what had already been done in other countries, such as Sweden (the Volvo-Bohlin study) and the United States. Results there were very promising. Since the Dutch traffic situation (road types, vehicle mix, etc.) differed considerably from other countries, it was decided to carry out a similar study in the Netherlands. This was a typical crash phase-oriented project, aiming at a representative sample of many thousands of cars in crashes from all over the Netherlands.

Without going into detail on that study, it brought enormous amounts of data on cars and car damage, on accidents, and on the occupants and their injuries. Self-evident, this material was processed and analyzed by means of the computer. Sophisticated analysis by multivariate techniques was applied. Results were given in the report called "Lap belts and three point belts"(7). This report gave other researchers something to think or to laugh about, since SWOV found no statistical difference in effectiveness between the two types. We are speaking about the years 1969 and 1970 when only a small part of the cars were supplied with belts and the overall use was less than 5 percent! It is therefore reasonable to suppose that the sample could not discriminate fully between the different types of belt. However, there was and still is more than enough scientific evidence that lapbelts do prevent fatalities and injuries by preventing ejection and reducing contact with the car interior, though in a different way than 3-point belts, leading to different injury patterns(2).

In the second SWOV accident study, carried out during 1976 and 1977, this result was confirmed, but now SWOV was also able to show that 3-point belts (with or without an automatic locking system) have a statistically significant greater effectiveness than lapbelts, both giving above 50 percent fatality-reducing capability. Practically, the matter is not very interesting now since it was internationally decided to apply only 3-point (automatic) seatbelts on front and back seats, except on middle seats where lapbelts are allowed under certain conditions.

Convincing and statistically significant results from that second SWOV accident study (which aimed more broadly at injury-causing parameters in car crashes) showed again the great benefits of seatbelts for both drivers and front-seat passengers (at least 60 percent less chance of being killed). Taking into account also the injury-reducing potential of seatbelts, SWOV used these results to show what would happen in the Netherlands if seatbelts were suddenly not used anymore (Figure 3).

With regard to victims in car crashes, this would—

- Almost double the number of fatalities
- Increase the hospitalized by some 30 percent
- Increase the less severely injured by some 20 percent

- Decrease the number of uninjured by some 10 percent

Although the absolute numbers of road casualties in the Netherlands may be low in comparison to other countries, the relative effect of this thought is terrifying. Important both for SWOV and for policymakers are the results of the annual seatbelt surveys. Since 1969, SWOV has carried out an annual nationwide survey into the availability and use of seatbelts in cars.

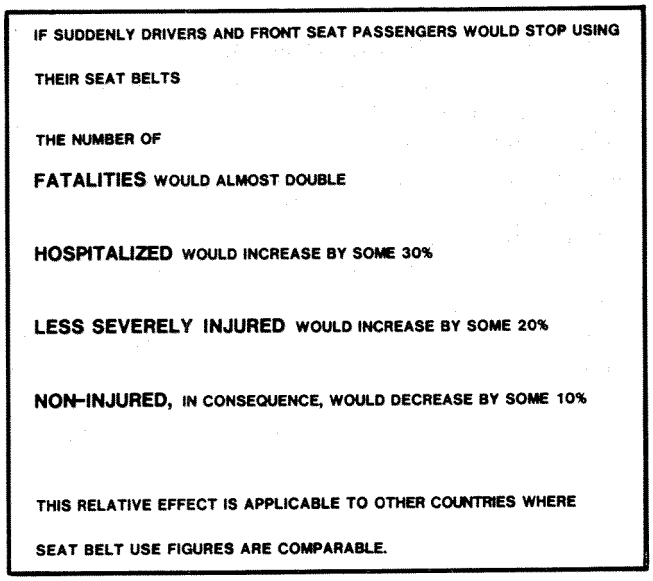

Figure 3. Illustration of seatbelt effectiveness in The Netherlands

In the first 10 years, SWOV used petrol stations for this purpose, where additional questions could be asked of drivers while there. Before the 3-point automatic belt became more or less a standard provision in cars, SWOV measured the slack in static seatbelts used at that particular moment. The average slack was very high, but this did not seem to prevent seatbelts from having a great effect as documented in the accident studies. Of course, the general recommendation to the public was to use the seatbelt properly without any slack.

After 1979, SWOV changed methods and the surveys were then carried out at traffic signals, where cars had to stop in the normal traffic situation and seatbelt use could be observed directly and beyond doubt. A few questions were asked just to have a final look at the seatbelt and its use.

The results of the surveys point out that the most important factors influencing the use of seatbelts by drivers and seat occupants are the length of the trip and whether use is compulsory or not. It was found that use inside city limits (shorter trips) was always considerably lower than that outside city limits. To determine this, trip length was asked. Another result was that women used seatbelts more often than men, and there was some age influence, though not systematically.

Before 1975, use levels were a maximal 35 percent; after 1975, use stabilized around 70 percent outside and 50 percent inside city limits (Figure 4). From June 1, 1975, occupants of front seats had to use their seatbelts, and it is undeniable this had a great influence on actual use as shown in the figure (see also next paragraph).

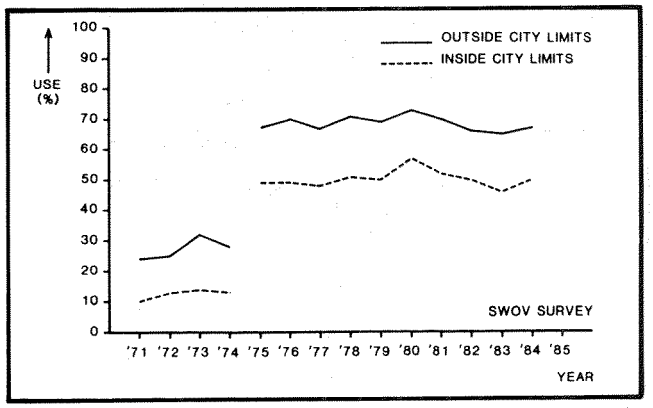

Figure 4. Use of seatbelts by drivers of cars in The Netherlands, from 1971

Legislative Situation on Seatbelts in The Netherlands and Its Relation to Research Results

On January 1, 1971, anchorage points and seatbelts became compulsory in new passenger cars, on both front-seat outboard positions. Exceptions were made for open cars and for all cars older than 1971. All existing types of seatbelts (3-point, lap, and diagonal) were allowed. Nationally, 3-point belts and lapbelts still are allowed.

After that period, a governmental working group in which SWOV had advisory capacity prepared compulsory use, taking into account results of the first SWOV accident study and other relevant research. There was a strong international movement toward compulsory use in Europe and outside Europe (Australia), so the political situation was clearly in favor of the measure.

Many technical and legal problems were solved in the group and the outcome was that on June 1, 1975, use of seatbelts became compulsory, both outside and inside city limits. Main items of the seatbelt law are:

Use is compulsory—

- For front-seat outboard occupants (driver and front-seat passenger)
- In cars from 1971 (not in older cars)
- For occupants over 1.5m length
- For occupants over 12 years of age (passenger)

Exceptions were made—

- For the driver in case of backward driving
- For the driver in case of short trips (delivery)
- For taxi drivers if passengers were transported

- For children under 12 (they should be seated in the back) unless they were over 4 years and could be properly restrained

Individual exemptions are possible on certain specific medical grounds only, considered by a special committee and approved by the Secretary of Transportation (see also Figure 5).

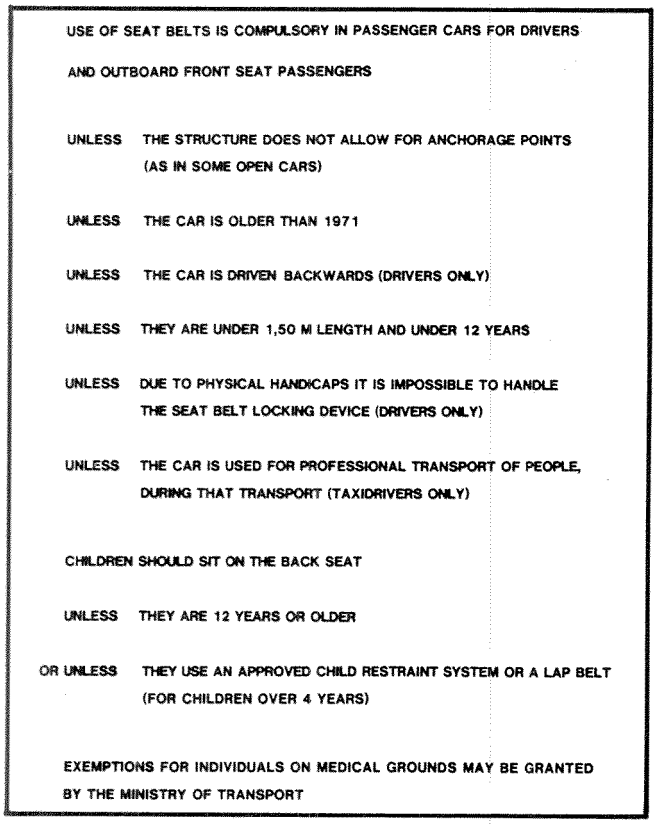

Figure 5. Details of seatbelt use legislation in The Netherlands, 1975 to 1977

The situation with regard to children was reviewed in 1977. Since then, children of all ages were allowed on front seats if use could be made of special and appropriate child restraint systems. Children over 4 years were allowed to use lapbelts on front seats. The reasoning behind this specific measure was that it was considered far better that children were restrained on front seats than unrestrained on back seats.

Since then, the seatbelt and child restraint industry developed various good child restraint systems for use on front seats as well as back seats. The latest developments in this field are two types of rear-facing infant restraint systems (for babies under 1 year) having approval of TNO-Delft and, therefore, they are legally allowed on front seats.

Approval under ECE 44 is still not possible since that particular age group is not present in the regulation. Changes are being prepared under leadership of the Netherlands. Both approved systems are restrained by means of available adult seatbelts.

There is some discussion about the fact that children over 4 years are allowed to be seated on front seats in lapbelts. Since in most cars only automatic 3-point belts are available, this seatbelt is sometimes used as a lapbelt by directing the shoulder strap behind the body or even behind the back of the front chair. By some experts, this is considered dangerous, since straps are located in the wrong direction and separation may occur in the edges of metal parts on the upper B-pillar or on the locking device.

Seatbelts on Back Seats of Cars

There is at the moment in Europe some international movement toward compulsory use of seatbelts on back seats. In most new cars, seatbelts are already available as a standard provision on two or three back-seat positions. A few countries already have made this use compulsory.

In the Netherlands, the Ministry of Transport asked SWOV to appraise the different aspects of seatbelts on back seats in order to prepare new legislation. SWOV reported on this subject in 1982(9), and the Ministry of Transport has announced that, as a first step, compulsory availability of seatbelts will be prepared.

In the SWOV report, the many aspects of the problem were singled out and assessed, leading to conclusions and recommendations on the different legislative options (no special measure; compulsory availability only; compulsory availability and use). Some aspects were—

- Effectiveness in crashes
- Type of seatbelt
- Anchorage points
- Definition of seating position
- Use of back seat for different purposes
- Use of back seat by different age groups (emphasis on children)
- Relation with existing seatbelt legislation on front seats
- Psychological aspects with respect to compulsory use
- Seatbelt campaigns

Starting points were the results of the previous SWOV accident studies with respect to effectiveness of seatbelts, occupancy of back seat, age distribution of back-seat passengers, etc. Additional information on the actual situation with regard to seatbelts and child restraint system availability and use was separately gathered by means of regular inquiries from a representative sample of Dutch households in 1983.

At that moment, seatbelts on back seats were available in 20 percent of all cars in the Netherlands. This percentage was 40 percent in cars of households with children under 4 years. Child restraint systems were available and used in about 15 percent of all cars. This percentage was also much higher in cars of households with small children(5).

Effectiveness of seatbelts in back seats had to be derived from front-seat effectiveness, since use of seatbelts on back seats is still very low, and accident studies, whatever their sample, will not produce any significant result due to lack of data.

It was reasoned in the report that the effectiveness of seatbelts on back seats would be less than on front seats, due to better protection capability of the back-seat environment in most collision modes. On the other hand, seatbelts would protect fully against ejection, although the data of the last SWOV accident study show that ejection from back seats occurs somewhat less often than ejection from front seats under comparable conditions. It was concluded that, given the Dutch accident situation, seatbelts on back seats, if used to the same degree as on front seats, would probably prevent less than 50 fatalities and, of course, reduce the injury severity of several hundreds of injured occupants to lower levels.

Typical aspects of the Dutch back-seat problem are (see also Figure 6)—

- Total occupancy is about 15 percent of all car occupants.
- 50 percent of back-seat occupants are under 15 years of age.
- Seating positions are not well defined, especially if children are present; this is primarily a legal aspect.
- If more than two or three passengers occupy the back seat, there will be confusion with regard to available seatbelts.

In view of the age distribution, SWOV concluded that very special attention in the legislative field as well as in the technical field should be given to the seating and restraining of children. Priority should be given to the implementation of ECE 44, the international regulation on child restraint systems, to prevent that new measures on back seats would interfere with the proper restraining of children according to this regulation.

SWOV expressed preference for the use of regular adult seatbelts for child restraint devices, as allowed in ECE 44. Since various good child restraint designs are already available using adult seatbelts, there seems no reason to seek other solutions. However, seatbelt legislation on back seats should also not prevent use of child restraints (already available) that need special straps, since it is unlikely that other use is made of seating positions where such special straps are fastened.

Final conclusions in the SWOV report were that compulsory use (and availability) of seatbelts on back seats would need many more exemptions and exceptions than the front-seat legislation has now, and would have to be designed very carefully to prevent misuse and interactions with those groups already using restraint systems (i.e., small children). Even if the government would decide to make only availability compulsory, some of those problems, and others with regard to seating position, should be solved first. It was felt, therefore, by SWOV that voluntary use was the best possible way, supported if feasible by well-designed and properly aimed campaigns.

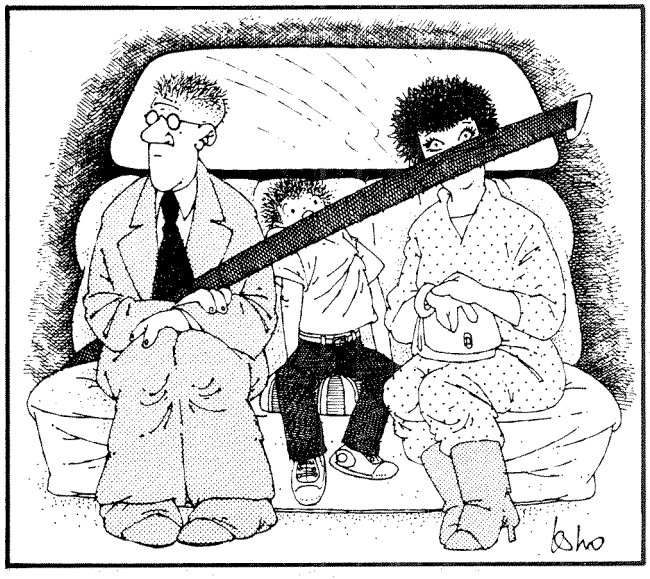

Figure 6.

Campaigns and Special Enforcement Programs

During part of 1984 and 1985, a national seatbelt campaign was carried out by the Dutch Organisation for Traffic Safety (VVN) using various ways of influencing car occupants, especially on short trips where use figures are low. The campaign was considered relevant, since use figures appeared to be decreasing.

As part of the current National Traffic Safety Plan from the Ministry of Transport, SWOV helped design a special seatbelt enforcement program, to be applied in one particular area of the Netherlands (Friesland), while another specific part was used as a control area. Police cooperation was the essential part of this enforcement program aimed at dramatically improving seatbelt use. Before-studies (survey) were organized by SWOV in 1984, and the special program was applied in September/October 1984. The first series of after-surveys have been performed, and others will follow this year. At first sight, a very substantial rise in use figures, far above the average national level of use, has been established, probably proving that special enforcement programs, combining campaigns with police enforcement activities, are successful. The long-term effects of this type of measure, however, have still to be assessed.

Mathematical Models and Seatbelts

As are many other institutes, SWOV is busily engaged in the field of mathematical modeling of road vehicles and their occupants in crashes. Together with others,

SWOV developed models such as MADYMO (with TNO) and VEDYAC (with S.P.A.T., Italy). VEDYAC is a very refined and flexible model simulating many types of vehicles moving in and interacting with all different kinds of environment (such as the road itself and roadside obstacles; also other vehicles, pedestrians, etc.)(3). The car occupant may be simulated either with or without seatbelt. (See Figure 7 for some plot-output examples.)

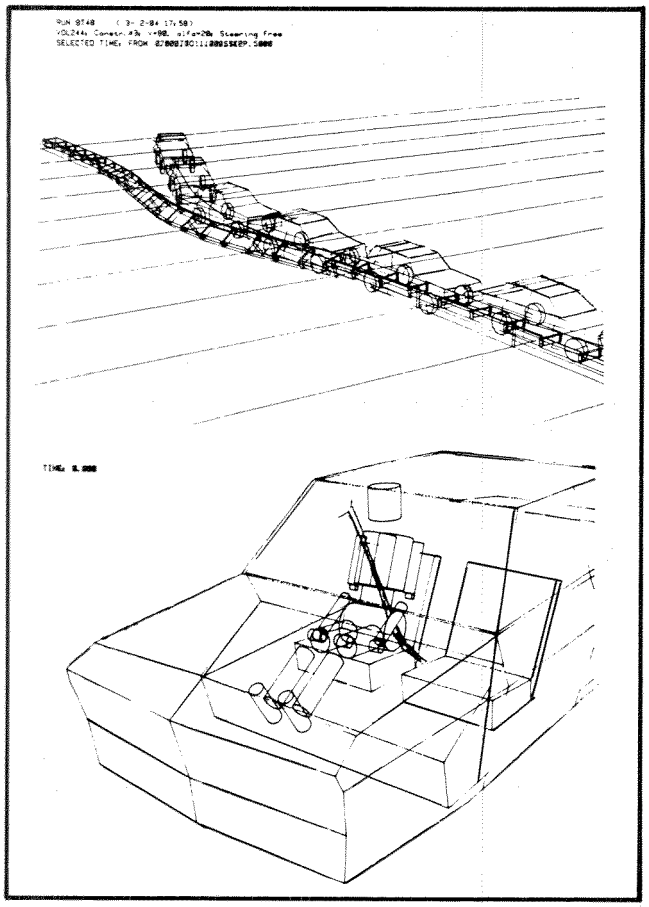

Figure 7. Examples of plot-output from VEDYAC

Quite another interesting development is that SWOV is working on chaining these models with another model representing the traffic population at risk (for instance, car occupants using belts). In such a chained model, proposed changes in policy, legislation, design, etc. (for instance, specific changes to the seatbelt stiffness, steering column, car design, or road obstacle design, etc.) may be applied by changing relevant parameters. The consequences on the population at risk may be predicted in terms of changes in injury pattern and injury severity levels. Such results may have (and should have) considerable influence on, for instance, priorities given by policymakers to different proposed new measures in the field of traffic safety. In view of the various and numerous data needed to carry out this research successfully and put it into practice, there is still much to be done(4).

Other Seatbelt Topics

To complete the list of relevant research, another SWOV report may be mentioned. Reacting on a specific industrial product, developed by a Dutch inventor, SWOV made an appraisal of the possible advantages and disadvantages of an automatic opening system for use in seatbelt locking devices—the Lassche system.

Here again, SWOV based its opinion primarily on accident data concerning the technical condition of seatbelts and locking device after accidents, data on the occurrence of fire, and cars getting into (deep) water. Also the problem of occupants being unconscious or unable to help themselves out of a car is discussed.

It was concluded that the device would not improve traffic safety figures on any great scale, but was undeniably useful for those fearing to be locked in by their seatbelts after collisions (which, in fact, does not often occur judging by the average good technical state of the seatbelts after collisions). There has been some international pressure to allow this and other devices to become legally acceptable by changing ECE Regulation 16 and the comparable Directive of the EC. The present situation is not clear.

Another more practical device, allowed under international and national legislation, is the adjustable upper anchorage point of the seatbelt on the B-pillar. Some car manufacturers already sell such systems as a standard provision. Though no research results are known to SWOV, this seems to be a proper solution for the adaption of the seatbelt to different postures and seating positions of the occupants.

On the other hand, SWOV would like to emphasize that an even more proper approach of the seatbelt case, especially on front seats, is an integral approach. In such an approach, the seatbelt system would be considered part of the total seat structure and fastened directly to it, as is already the case in some vehicles. At the same time, this integral approach should be expanded to the car as a whole, regarding the seating system as part of the car structure and designing and testing both toward optimization of the restraining function for different collision modes. Of course, this thought is not really new, and the drawback may occur when seatbelts are not used. Car safety designers, therefore, also have to allow for unprotected occupants. The point of a fully automatic restraint system such as airbags then comes into focus, and the world is still waiting for solid real-world accident studies on this subject.

Conclusion

Mention must be made again of those other institutes, organizations, industries, etc., working in the field of traffic safety in the Netherlands on various different aspects of this enormous problem for society. Without their efforts, the problem cannot be solved.

Abstract

Some of the factors influencing the introduction of mandatory seatbelt use in Great Britain are outlined. The effectiveness of seatbelts is considered. Pre- and postlaw seatbelt use rates are described. The reductions in front-seat car occupant casualties following the introduction of the law are reported, and it is noted the actual reduction in fatalities is in line with the expected reduction.

The results of the time series analyses of all road accident casualties are presented. These analyses indicate, with the data currently available, the changes in the numbers of other road users injured and killed cannot be attributed to the effects of the seatbelt legislation but are in line with normal seasonal and annual fluctuations.

A brief review is made of studies relevant to the debate on risk compensation, and it is concluded that available evidence indicates that risk compensation probably does not occur when drivers are compelled to wear seatbelts.

Some preliminary results of a study examining changes in injury frequency following the mandatory seatbelt use law are presented. Data from current in-depth studies of accidents are used to describe patterns of injury to restrained occupants. Consideration is given to some of the factors associated with accidents in which restrained occupants are fatally injured, and it is shown that the main characteristic of such accidents is they are high-energy accidents with gross intrusion into the occupant's seating position.

Factors limiting seatbelt performance are discussed, and some possible future developments in occupant protection are described.

Introduction

The Legislation

Although the mandatory use of seatbelts by car occupants was first recommended by crash injury research experts in the late 1960's, it was not until the success of Australian legislation, enacted in 1970, that serious attempts were made to enact such a law in Britain. The first Parliamentary Bill, introduced in 1973, was soundly defeated. Repeated attempts were made over the next 10 years, with the legislation almost being agreed in 1978, only failing to reach the statute book because of the dissolution of Parliament. During the passage of the 1981 Transport Bill through Parliament, a clause on seatbelts was inserted into the bill at committee stage. Members of Parliament were allowed to vote according to their own beliefs as it was recognised by the Government that there were strong feelings both for and against the mandatory use of seatbelts. Prior to the vote, there was considerable public debate about this issue and in this debate professional and specialist organisations, such as the police, the medical community, and in particular the British Medical Association, the Automobile Association, the Royal Society for the Prevention of Accidents, the Society of Motor Manufacturers and Traders, which represent the car industry, together with a number of professional engineering societies and a few individual academics with specialised expertise in transport safety, were almost unanimous in support of the mandatory use of seatbelts by the front-seat occupants of cars.

A further factor was that the general public was generally in favour of mandatory seatbelt use. The public forms its opinions by what it sees on television, hears on radio, and reads in the papers, and one of the key factors in forming public opinion was a television documentary on road accidents entitled The Greatest Epidemic of Our Time. That programme, which was screened twice, once on each of the BBC channels, at prime time, with the last screening shortly before one of the votes in Parliament, had an important role in educating the public about the road accident problem.

The vote was in favour of the mandatory use of seatbelts, and as a result the use of seatbelts by front-seat occupants of cars and light vans has been compulsory since January 31, 1983.

Seatbelt Effectiveness

There are a number of methods of determining seatbelt effectiveness; effectiveness being defined as the reduction in casualties when seatbelt use goes from 0 to 100 percent. One method is to look at a sample of crashes in which seatbelts have not been worn and to predict what would have happened had seatbelts been worn. A second method is to calculate the probability of injury as a function of crash severity and then to compare the probability of injury for restrained and unrestrained occupants at equivalent crash severities. A third method is to look in aggregate at the changes in frequency of different severities of injury as a result of a change in seatbelt use rates, usually as a result of legislation being introduced.

Accident studies have shown that seatbelt effectiveness is a function of collision type, the benefits being greatest in frontal impacts and rollovers and least in rear impacts and for struck side occupants in side impacts. Additionally, crash severity has been shown to have a significant influence on effectiveness. If the accident is of such severity that there is gross intrusion into the passenger compartment of the car, there is often insufficient space for the restraint system to work correctly and thus prevent high-energy occupant contacts with the interior.

Estimates of effectiveness vary greatly between different studies due to differences in samples considered. For instance, Huelke(1) reported that in frontal collisions, 77 percent of the fatalities would have been prevented had the occupants been restrained. However, in a later study, which considered only rural high-speed crashes, Huelke reported an effectiveness of only 32 percent in preventing occupant fatalities(2).

In a study on seatbelt effectiveness carried out in 1963 at the then Road Research Laboratory, Lister et al., reported an injury reduction of about 50 percent(3).
In 1976, from a study of 255 unrestrained car occupant fatalities in Great Britain, Griffiths reported that approximately 41 percent of the fatalities would not have occurred if all the front-seat occupants had been restrained(4).

Bohlin in 1967(5) reported that in two models of Volvo cars, the effectiveness of seatbelts in preventing nonfatal injuries varied from 57 to 63 percent at lower speeds and from 48 to 54 percent at higher speeds, while for the fatalities the seatbelt offered full protection up to 60mph. Although the total sample was large, over 28,780, a large proportion of the accidents occurred at relatively low speeds. The observation about effectiveness for fatalities was based on a very small sample, there being only three restrained occupant fatalities in the sample.

Hobbs and Mills, using data from a British study of towaway accidents(6), reported that seatbelt effectiveness is strongly related to the velocity change in the accident and to the severity of the injuries being considered. They found the effectiveness of seatbelts in preventing nonminor injuries (AIS $>$ 1) in frontal impacts varied from 76 percent when there was a 10mph velocity change, through 42 percent for a 20mph velocity change and 11 percent for a 30mph velocity change, to only 1 percent for a 40mph velocity change. This corresponds to an overall effectiveness of about 65 percent.

Trinca and Dooley(7) reported that 4 years after the introduction in 1970 of mandatory seatbelt use in Victoria, Australia, the first legislature to require the mandatory use of seatbelts, there had been a 37 percent reduction in occupant fatalities and a 41 percent reduction in occupant injuries based on predicted values trend line analysis. Prior to the introduction of the legislation, seatbelt use was around 25 percent, although not all cars had seatbelts fitted.

Mandatory seatbelt use by some or all of the occupants of cars is now required in approximately 33 jurisdictions throughout the world, and, although the effects of such laws are still being debated, the general result of the introduction of such laws has been an increase in the use of seatbelts and a decrease in the number of car occupants seriously injured or killed.

Seatbelt Use Rates

Prelaw Use Rates

In Great Britain, the compulsory fitting of seatbelts for the driver and outboard front-seat passenger has been required since 1967 with retrofit to 1965 model year cars. Consequently, by 1975 virtually all cars had lap and diagonal seatbelts fitted to the front outboard seats and overall use rates were about 30 percent, although there were substantial variations in use by road type. Observations conducted in and around Birmingham in 1975 showed that use rates varied substantially by environment, ranging from below 25 percent in the city centre to over 50 percent on motorways (Table 1)(8).

Table 1. Driver seatbelt use: Great Britain 1975

LOCATION	SAMPLE SIZE	USE RATE
City Centre	5,951	21.9%
Rural 'A' Road	5,742	30.1%
Motorway	7,040	56.7%

Other counts conducted between 1975 and 1981 indicated that overall use rates were essentially static at about 30 percent in spite of Government-sponsored advertising campaigns. Differences in use rates by environment were still evident in counts conducted in June 1982, shortly before the introduction of the law (Table 2)(9). These counts indicated that the average use rate shortly before the introduction of the law was 29 percent in built-up areas, 40 percent in non-built-up areas, and 52 percent on motorways, and the overall use rate was 37 percent.

As the date for the introduction of the law approached, there was a rise in belt use rates, particularly in urban areas, as people anticipated the legal requirement(10).

Table 2. Pre- and post-law driver daytime seatbelt use by road type: Great Britain

	Pre-law (June 1982)	Post-law (June 1983)
Motorways	52%	97%
Built-up roads		
Trunk roads	32%	97%
Principal roads	32%	95%
Secondary roads	26%	95%
Minor roads	27%	92%
Non-built-up roads		
Trunk roads	49%	95%
Principal roads	37%	94%
Secondary roads	47%	98%
Minor roads	34%	92%

Postlaw Use Rates

With the enactment of the law, there was a spectacular increase in seatbelt use to around 95 percent, and use rates have stayed around this level. Figure 1 adapted from official Department of Transport publications(11,12) shows the change in seatbelt use rates with time. There are, however, still slight variations in use by road type, use rates tending to be slightly lower on minor roads than on other roads (Table 2).

Predicted Influence on Casualties

Two parameters are often referred to when discussing the effects that seatbelts have on occupant casualties; these parameters being seatbelt effectiveness and reduction in casualties. These two parameters are not the same, and confusion between them has occasionally led to misunderstanding in the expected decrease in casualities following the introduction of a mandatory seatbelt use law. It should be noted the reduction in casualties will be less than seatbelt effectiveness except in the special case when seatbelt use goes from 0 to 100 percent. The relationship between seatbelt use rates, seatbelt effectiveness, and the reduction in casualties is considered in Appendix 1.

The average seatbelt use rate in Great Britain in 1982 was 37 percent, while in 1983, after the introduction of the law, the average use rate was about 95 percent. Griffiths(4) showed that approximately 41 percent of unrestrained front-seat occupant deaths could be prevented if all front-seat occupants were restrained. The expected reduction in front-seat occupant fatalities with the above use and effectiveness rates is 28 percent. In deriving estimates for pre- and postlaw belt use rate, it is necessary to take into account that occupant fatalities are more frequent on rural roads than on urban roads, and on rural roads prelaw belt use rates were higher than on urban roads. The effect of this is to reduce the expected fatality reduction to about 25 percent (Table 3).

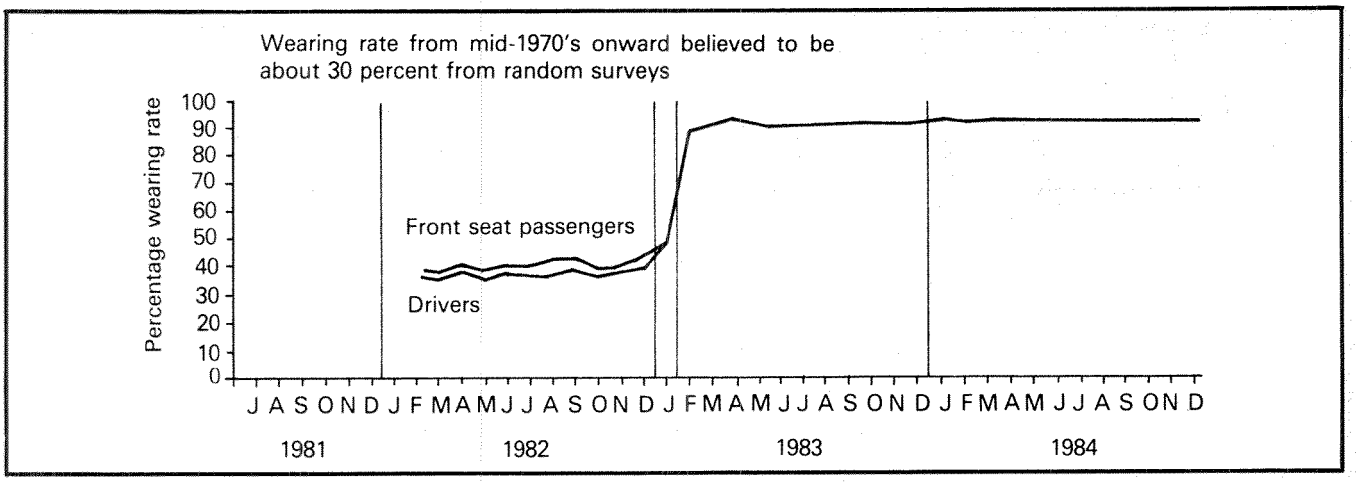

Figure 1. Car and light van front-seat occupant seatbelt use rates

Table 3. Expected reduction in front seat occupant fatalities for differing pre- and post-law seatbelt use rates

Pre-law Belt Use Rate	Post-law Belt Use		
	85%	90%	95%
35%	23.9%	26.3%	28.7%
40%	22.0%	24.5%	27.0%
45%	20.1%	22.6%	25.1%

Actual Influence on Casualties

Figure 2, based on figures in official Department of Transport publications(11,12), shows the monthly totals for front- and rear-seat car and van occupants, and also for other road users, seriously injured or killed in road accidents. Casualties with slight injuries have been excluded as their inclusion produces problems due to underreporting, particularly of bicycle accidents. It is clear from Figure 2 that a significant drop in front-seat car and van occupant casualties occurred coincident with the introduction of the seatbelt law.

Car and Light Van Drivers and Front-Seat Passengers

In describing the effects of mandatory seatbelt use laws, comparisons have often been made between the numbers of casualties in similar periods before and after the introduction of the law.

For example, early in 1984 it was provisionally reported that, in the period February to December 1983, there had been, for car and light van front-seat occupants, 475 (23 percent) fewer persons killed and 6,947 (26 percent) fewer persons seriously injured than in the corresponding 11-month period in 1982(11). Early in 1985, it was provisionally reported that, in the period February 1983 to December 1984, there had been, for car and light van front-seat occupants, 691 (17 percent) fewer persons killed and 12,153 (22 percent) fewer persons seriously injured than in the corresponding 23-month period February 1981 to December 1982(12). Superficially, the difference between these two sets of figures appears to suggest that the mandatory seatbelt use law is becoming less effective with time. This is not, in fact, the case; the difference between the figures for the two periods being due to an underlying upward trend in the number of casualties.

Consider for illustrative purposes the number of drivers and front-seat passengers killed each year between 1981 and 1984 (Table 4).

In 1983, there were 20 percent fewer fatalities compared with 1982; in 1983 and 1984 taken together, there were 15 percent fewer fatalities than in 1981 and 1982 taken together. There was, however, an increase of approximately 7 percent in fatalities between 1981 and 1982 and an increase of approximately 6 percent between 1983 and 1984. This suggests there might have been an underlying upward trend in car and light van front-seat occupant fatalities between 1981 and 1984. Assuming for purposes of this discussion that the annual upward trend was 6.5 percent, i.e., approximately equal to the annual increase from 1981 to 1982 and from 1983 to 1984, then had the seatbelt law not been introduced there would have been approximately 2,380 fatalities in 1983 and 2,530 fatalities in 1984, and the reduction in fatalities as a result of the introduction of the law would have been about 24 percent. This figure (24 percent) is greater than those obtained from simple year-on-year comparisons (20 percent and 15 percent).

The above illustrates that simple before-and-after comparisons can be misleading if there is an underlying trend. A further difficulty in making comparisons between yearly totals comes from the random year-to-year variations in the data. Time series analysis, however, can be used to separate the effects due to different factors.

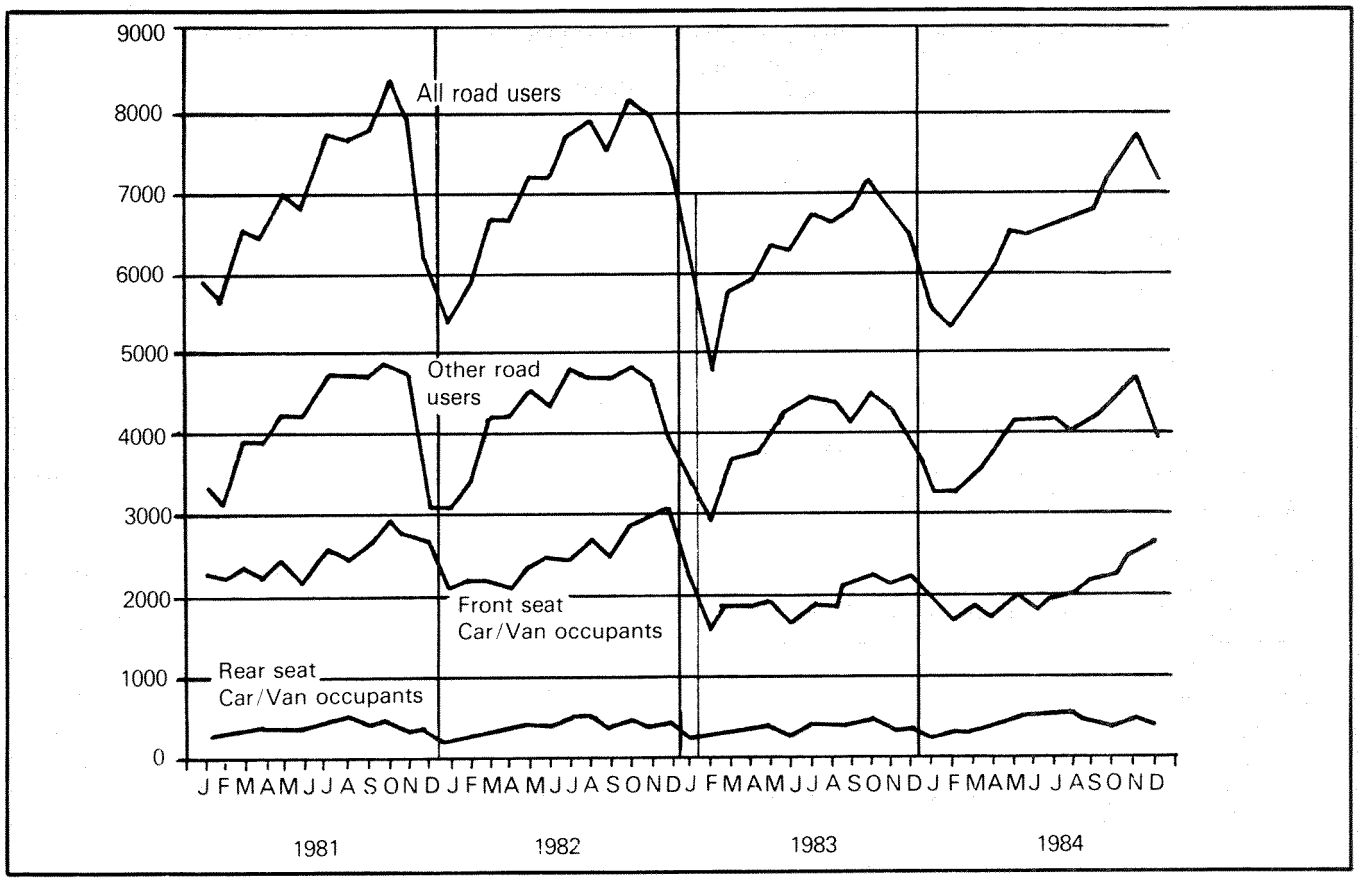

Figure 2. Fatal and serious casualties by month

Table 4. Car front seat occupant casualties: 1981 - 1984

Year	Slight	Serious	Fatal
1981	99,847	28,839	2,112
1982	103,738	28,993	2,260
1983	89,375	22,142	1,799
1984	97,178	23,347	1,901

Scott and Willis(9) have performed time series analyses in which monthly casualty data were fitted to a model that, among other features, allowed for changes in traffic. The model was of the form:

$$C = V^{v}.\exp(k + t.T + x.d_x + e)$$

where:

- C = the number of casualties
- V = the traffic volume for the vehicle type
- T = time in months since December 1978
- d_x = a dummy variable representing the presence or absence of the seatbelt legislation (i.e., $d_x = 0$ in the before period and $d_x = 1$ in the after period)

The parameters "v", "k", "t", "x", and "e" were estimated by the analysis; "x" measuring the change attributable to the seatbelt law. Some of the results of the analyses are given in Table 5.

The results of these time series analyses show that, overall, the reductions in serious and fatal casualties coincident with the introduction of mandatory seatbelt use were about 20 to 25 percent for drivers and about 30 percent for front-seat passengers. It was noted there has been a greater reduction in casualties in built-up areas than in non-built-up areas. This is most probably due to seatbelt use rates being lower in built-up areas than in non-built-up areas prior to the law, there being a greater potential for injury reduction in built-up areas, but may also be partly due to differences in crash severity between the two areas.

In numerical terms, approximately 7,000 fewer people have been killed or seriously injured and approximately 13,000 fewer people have been slightly injured while vehicle occupants as a result of the introduction of the mandatory seatbelt use law.

An examination of the casualty reductions by time of day showed that for car drivers only there was a greater reduction in casualties in the 2200h to 0400h time period than at other times of the day. While this may possibly be due to a greater percentage change in seatbelt use rates at night, it may also be partly due to a change in police procedures for testing drunken drivers that took place in 1983; this change possibly influencing nighttime accident rates.

Table 5. Reductions in car driver and front seat passenger casualties coincident with the introduction of mandatory seatbelt use: estimated from 1979 - 1983 data

		Built-up Areas		Non-built-up Areas		Overall	
	Change	Percent Limits	90% Confidence Change	Percent Limits	90% Confidence Change	Percent Limits	90% Confidence
Driver	Fatal	19%	3% - 32%	25%	16% - 33%	25%	18% - 31%
	Serious	25%	21% - 29%	18%	14% - 22%	21%	17% - 25%
	Slight	12%	7% - 17%	9%	4% - 14%	11%	7% - 15%
Passenger	Fatal	26%	9% - 40%	32%	22% - 41%	29%	20% - 38%
	Serious	33%	27% - 38%	27%	22% - 32%	30%	26% - 33%
	Slight	21%	15% - 27%	15%	9% - 20%	19%	15% - 24%

Car and Light Van Rear-Seat Occupants

Table 6 gives the number of rear-seat occupant casualties for the 4 years 1981 to 1984. It can be seen from these data there has been a general upward trend in the number of rear-seat casualties since 1982. A time series analysis using 1979 to 1983 data indicates there was an increase in the number of fatalities and slightly injured casualties and a decrease in the number of seriously injured casualties coincident with the introduction of mandatory seatbelt use. However, the wide variation in the 90 percent confidence limits stemming from the small numbers involved results in the changes being within the range of normal yearly variations. There is thus no statistically discernible indication that the seatbelt law has had an effect on car and light van rear-seat occupant casualties (Table 7)(9).

Table 6. Car rear seat occupant casualties: 1981 - 1984

Year	Slight	Serious	Fatal
1981	18,127	4,308	304
1982	18,663	4,409	297
1983	19,300	4,282	321
1984	21,084	4,690	372

Other Road Users

It has been suggested that the introduction of a mandatory seatbelt use law may encourage drivers to drive in a more dangerous way(13). This hypothesis, the "Risk Compensation" hypothesis, is discussed in more detail later in this paper. If that were the case, then an increase in the number of injured other road users, i.e., persons struck by cars, such as pedestrians, cyclists, and motorcyclists, would be expected.

To examine whether this has occurred, Scott and Willis(9) performed time series analyses for pedal cyclists, pedestrians, and motorcyclists struck by cars and light vans and by buses, coaches, and heavy goods vehicles; the latter group being considered as the number of unprotected road users struck by these vehicles form controls as the drivers of such vehicles would be unaffected by the seatbelt legislation. The model used for the unprotected road users was a modified form of that used for car occupants in which the respective traffic volumes of both parties were included and took the form:

Table 7. Changes in car rear seat occupant casualties coincident with the introduction of mandatory seatbelt use: estimated from 1979 - 1983 data

	Percent Change	90% Confidence Limits
Fatal	+14%	- 7% - +38%
Serious	- 5%	-11% - + 2%
Slight	+ 2%	- 3% - + 7%

$$C = V1^{v1}.V2^{v2}.\exp(k + t.T + x.d_x + e)$$

where:

- C = the number of casualties
- V1 = the traffic volume for the unprotected road user under investigation
- V2 = the traffic volume for the other vehicle, i.e., cars and light vans or buses, coaches, and heavy goods vehicles
- T = time in months since December 1978
- d_x = a dummy variable representing the presence or absence of the seatbelt legislation (i.e., $d_x = 0$ in the before period and $d_x = 1$ in the after period)

The parameters "v1", "v2", "k", "t", "x", and "e" are estimated by the analysis; "x" measures the change attributable to the seatbelt law.

In performing the time series analyses, only casualties in built-up areas were considered as pedestrian and cyclist accidents are essentially an urban problem. Table 8 details the change in the number of casualties that occurred coincident with the introduction of mandatory seatbelt use, together with the underlying in the number

Table 8. Changes in unprotected road user casualties in built-up areas: estimated from 1979 - 1983 data

		Possible seatbelt effect		Underlying annual trend	
		Percent Change	90% Confidence Limits	Percent Change	90% Confidence Limits

of casualties, for three different road user groups—pedestrians, pedal cyclists, and motorcyclists—struck by vehicles in which drivers have to wear seatbelts, i.e., cars and light vans, and vehicles in which drivers do not have seatbelts fitted, i.e., PSV's and HGV's.

The use of PSV's and HGV's as a control group may not be entirely correct as it is likely that drivers of PSV's and HGV's also drive cars. It cannot, therefore, be stated that accidents involving PSV's and HGV's are unaffected by the seatbelt law.

The casualty series for pedestrians and motorcyclists involved in accidents with PSV's or HGV's shows downward trends, while that for pedestrians and motorcyclists struck by cars or vans shows virtually no trend. Pedal cyclist collisions with cars or vans and with PSV's or HGV's show upward trends; the upward trend for pedal cycle-car/van collisions being stronger than that for pedal cycle-PSV/HGV collisions.

The results of the analyses indicate there was a reduction in the number of motorcyclist casualties struck by both cars or vans and PSV's or HGV's coincident with the introduction of the seatbelt legislation. This reduction is likely to be due mainly to a change in the use of motorcycles following a lowering of the size of motorcycles that learners are permitted to ride; the change in the regulations taking place on February 1, 1983, i.e., almost coincidently with the seatbelt legislation.

For pedestrians, it was found there had been a slight increase in the number of casualties involved in collisions with both cars or light vans and with PSV's or HGV's. However, although the increase in the number of car or light van collisions was slightly greater than the number of PSV or HGV collisions, there was considerable overlap in the 90 percent confidence limits.

The changes in the number of pedal cyclists injured were in opposite directions for the two vehicle groups, there being an increase in the number of pedal cyclists struck by cars or light vans and a decrease in the number struck by PSV's or HGV's. Again, there was considerable overlap in the 90 percent confidence limits.

Scott and Willis(9) reported that although their analyses showed a slight increase in the number of pedestrian and pedal cycle casualties coincident with the introduction of the mandatory seatbelt use law, the changes were statistically insignificant. It was, therefore, concluded that the casualty figures did not support the hypothesis that risk compensation had occurred as a result of drivers being compelled to wear seatbelts but did not permit the suggestion to be entirely refuted.

Further time series analyses, which include 1984 casualty data, are proposed, the results of which will lead to a more accurate assessment of the effects of the mandatory seatbelt use law.

Pedal Cyclists

The greatest changes in the other road user casualties occurred with pedal cyclists. These will therefore be considered in more detail. In conducting their analysis, Scott and Willis grouped together all ages of pedal cyclists and all types of roads in built-up areas. An examination of the ages of pedal cyclists killed or seriously injured in 1982 and 1983 by type of striking vehicle shows considerable differences with age (Table 9). While overall there was a 10 percent increase in pedal cyclists struck by cars or vans compared to a decrease of 7 percent for those struck by PSV's or HGV's, the difference was greatest for children, i.e., those less than 14 years old,

Table 9. Fatal and serious pedal cycle casualties in two-party collisions: Great Britain, Feb. to Dec. 1982 and 1983

	Cyclists hit by cars or light vans			Cyclists hit by PSV's or HGV's		
	1982	1983	% Change	1982	1983	% Change
0 - 14 years	1,384	1,592	+15%	109	87	-20%
15-29 years	1,315	1,428	+9%	124	133	+7%
30 years and over	1,006	1,069	+6%	135	123	-9%
All ages (inc. NK)	3,716	4,104	+10%	368	344	-7%

there being a 15 percent increase in child cyclists struck by cars or vans and a 20 percent decrease in child cyclists struck by PSV's or HGV's. This difference was statistically significant; the changes for the other age groups were not statistically significant. This suggests that whatever occurred between 1982 and 1983 was predominantly due to a change in collisions between child pedal cyclists and cars or light vans. While this could be due to a change in the way cars and light vans were being driven, it could also be due to a change in the way pedal cycles were being used.

Concurrent with this rise in casualties was a change in the use of bicycles by young people: the BMX bicycle becoming popular among children at that time. The use of such bicycles is likely to be greatest in residential areas, and thus it would be expected that the increase in pedal cycle casualties would be greatest in such areas. This, in fact, was the case (Table 10).

Consideration of the location of pedal cycle accidents in built-up areas indicates that the majority occur in residential areas; just over half of all fatal and serious pedal cycle casualties in built-up areas occur on C roads and unclassified roads. Traffic on such roads consists predominantly of cars and light vans; the ratio of cars and light vans to PSV's and HGV's is approximately 22:1 on C and unclassified roads in built-up areas, whereas on other roads in built-up areas it is approximately 14:1.

Thus, an increased use of pedal cycles on C and unclassified roads would be expected to lead to a greater increase in car and van to pedal cycle collisions compared to PSV and HGV to pedal cycle collisions, all other things being equal. There was additionally a reduction of 11 percent in car or light van traffic, and a reduction of 20 percent of PSV and HGV traffic, on C and unclassified roads in built-up areas between 1982 and 1983. These changes in traffic would have the additional effect of reducing the number of pedal cycle to PSV/HGV accidents compared to pedal cycle to car/light van accidents. As this is what actually occurred, support is given to the hypothesis that the increase in the number of collisions between cars or light vans and pedal cycles is mainly due to a change in the use of pedal cycles in residential areas by young people.

Risk Compensation

Adams(13) has suggested that when mandatory seatbelt use is introduced, the actual reductions in fatalities are less than the expected reductions due to an increase in accidents as a result of people driving more dangerously when compelled to wear seatbelts. He has also suggested that, due to the increased risk-taking by drivers compelled to wear seatbelts, other road users, i.e., pedestrians, cyclists, and motorcyclists, are put at greater risk. This hypothesis is an example of the risk compensation theory put forward by Peltzman in the mid-70's(14).

Peltzman hypothesized the introduction of safety devices into cars results in drivers increasing their level of

Table 10. Fatal and serious pedal cycle casualties by location of accident: Great Britain, 1982 and 1983

	1982		1983		Change 1982 - 1983	
	N	%	N	%	N	%
Motorways	3	0.0%	3	0.0%	0	0.0%
Built-up roads						
A roads	1,908	29.2%	2,072	29.8%	+164	+ 8.6%
B roads	656	10.0%	648	9.3%	- 8	- 1.2%
Other roads	2,638	40.3%	2,898	41.8%	+260	+ 9.8%
Non-built-up roads						
A roads	676	10.3%	708	10.2%	+ 32	+ 4.7%
B roads	188	2.9%	187	2.7%	- 1	- 0.5%
Other roads	474	7.2%	423	6.1%	- 51	-10.7%
	6,543	100.0%	6,936	100.0%	+393	+ 6.0%

driving intensity, which, in turn, leads to an increase in the rate at which they will be involved in accidents. He argued, using time series regression analysis of traffic fatalities and injury statistics, that the vehicle safety regulations introduced into America in the 1960's had no net benefits. According to Peltzman, seatbelts, energy-absorbing steering columns, and other safety features do work, but the introduction of such measures compromises their injury-mitigating potential.

Peltzman's work, however, has been strongly criticized by Robertson(15) and by Joksch(16,17). Robertson noted that Peltzman took no account of increased motorcycle usage in the 1970's, although this was probably mainly responsible for the increase in nonvehicle occupant casualties during that period. Joksch reconstructed Peltzman's time series equations and found they were either unstable or had a high degree of time dependency, thus making them unsuitable for prediction.

Limited support for a risk compensation theory comes from a study conducted by Rumar(18) in Sweden. Rumar and his colleagues looked at the speeds at which drivers travelled around icy bends and compared the speeds of vehicles with and without studded tyres. It was found the drivers in cars with studded tyres travelled at a higher speed. There would thus appear to be some evidence for risk compensation. However, a comparison between vehicle travelling speeds and the critical speed for the bend, taking into account the tyre road friction, indicated that drivers of vehicles with studded tyres had a greater margin of safety than drivers of vehicles without studded tyres. Evans and Herman(19) found, in test track experiments, that drivers of vehicles with high acceleration capabilities accepted smaller gaps when crossing a traffic stream. However, it was also found the reduction in accepted gap was less than the increase in safety margin provided by the increase acceleration capabilities of the car. The Transport and Road Research Laboratory has reported that resurfacing of roads results in higher travel speeds(20)

There is thus some evidence that risk compensation occurs when there is direct feedback to the driver as a result of improved performance, ride, or handling of the vehicle.

Support for the risk compensation theory applying to a mandatory seatbelt use situation appears to come from Conybeare(21) in Australia. Like Peltzman, he used a regression model to predict expected casualties and reported that, while deaths and injuries to car occupants decreased after the introduction of compulsory seatbelt use laws, deaths and injuries to nonoccupants increased above predicted values. However, the criticisms applied to Peltzman's models may also apply to Conybeare's model.

A number of studies have examined driver behaviour as a function of seatbelt use. These studies, in the main, have been conducted in environments where seatbelt use has been voluntary. Von Busack(22) compared following headways between users and nonusers of seatbelts on a Detroit freeway and found that nonusers tended to follow other vehicles closer than did users. Deutsch(23) observed driver behaviour at intersections and found that nonusers of seatbelts jumped red lights more frequently than users. Mackay(24) reported on the speeds that drivers traverse sharp curves and noted that the mean speed for restrained drivers was slightly faster than the mean speed for unrestrained drivers. However, it was also noted that vehicle age and seatbelt use and vehicle age and vehicle speed were correlated: the newer the vehicle, the faster the curve speed and the higher the belt use. Ashton(10) reported on the difference in gap acceptance between restrained and unrestrained drivers turning right from a main road into a minor road. They found that unrestrained drivers accepted shorter gaps than restrained drivers.

There is thus strong evidence that users of seatbelts drive less dangerously than nonusers when seatbelt use is voluntary.

Evans(25) compared following headways in high-flow freeway traffic in Michigan, U.S.A., where seatbelt use is voluntary, with following headways on similar roads in Ontario, Canada, where seatbelt use is mandatory. It was found, in both areas, the percentage of drivers travelling at short headways was lower for drivers using seatbelts. It was therefore concluded that belt use laws did not appear to influence drivers to drive at closer and thus riskier headways.

There have been only two studies that have directly examined driver behaviour before and after the introduction of a mandatory seatbelt use law, one in this country(26,27) and one in Newfoundland(27,28). In the Newfoundland study, four measures of driving behaviour were studied, these being travel speed, response to amber at signalized intersections, gap acceptance when turning left in front of oncoming traffic, and following headways. It was reported that there was only one statistically significant change in driver behaviour and that was a reduction in travelling speed on four-lane roads in the period after the use of seatbelts became mandatory. The other changes in behaviour, which were all nonsignificant, were split evenly between increased and decreased risk-taking. In the British study, there were only two significant changes in driver behaviour, these being a significant reduction in speeds on bends and a significant increase in the speeds at which women travelled on straight two-lane single carriageways. There were no significant changes in the speeds at which males travelled on two-lane single carriageways or in the speeds on dual carriageways or in following headways.

Thus, the available evidence from studies of driver behaviour indicates that risk compensation probably does not occur as a result of drivers being compelled to wear seatbelts.

Influence on Patterns of Injury

Preliminary results from a study of the change in injury patterns as a result of the mandatory seatbelt use have been presented by Rutherford(29). In the first 6 months after the introduction of the law, there was, at the 15 hospitals included in the study, a 20 percent reduction in casualties attending hospital and a 35 percent reduction in admissions (Table 11). It was reported that for most body regions, there had been a decrease in the incidence of injury although for some regions—for instance, the neck—there had been an increase in reported injuries (Table 12).

Other hospital-based studies have reported similar findings. Christian(30), comparing 12-month periods before and after the introduction of the seatbelt use law, reported a 54 percent reduction in front-seat occupants killed or seriously injured (ISS > 12). Front-seat occupants requiring admission declined by 42 percent, while deaths fell by 27 percent.

Table 11. Casualties treated at a sample of hospitals

	Pre-law Feb-Jul 1982	Post-law Feb-Jul 1983	% Change
Not Admitted	18	11	-39%
Admitted - Survived	568	367	-35%
Admitted - Died	2,062	1,699	-16%

Internal Chest Injuries	42	12	-71%
Neck Sprain	427	517	+21%

Results From Current In-Depth Accident Studies

The Data

In-depth studies of the causes of injuries to car occupants are currently being conducted by the Accident Research Units of the Department of Transportation and Highway Engineering at the University of Birmingham and the Institute for Consumer Ergonomics, Loughborough. A detailed description of the general methodology has been published elsewhere(31). Both groups investigate accidents in which cars less than 5 years old are towed away, using disproportionate stratified sampling schemes based on injury severity.

In this paper, weighted data are presented from a preliminary analysis of a sample of injury accidents that occurred in 1984 in Derbyshire, Leicestershire, Nottinghamshire, and Durham. In this area, a total of 240 accidents involving 275 cars less than 5 years old were investigated, and in these vehicles there were 539 occupants. Weighting the data to allow for the differing percentages of accidents of each injury severity investigated provided a weighted data base of 2,804 occupants. Unless otherwise stated, all quoted results are based on an analysis of the weighted data. It should be noted there may be small differences between the totals of the various tables. This arises from rounding errors in the calculation procedures used to produce the weighted totals.

Drivers accounted for 50 percent of the occupants, front-seat passengers for 23 percent, and rear-seat passengers for 27 percent (Table 13). The relatively high proportion of rear-seat occupants probably stems from the increased relative risk of a rear-seat occupant being injured compared to that for a front-seat occupant now that front-seat occupants are generally restrained by seatbelts.

Table 13. Occupancy and seatbelt use: weighted data

	Restraint Use			
	Used	Not Used	Not Known	Total
Driver	975	68	353	1,396
Front Seat Passenger	401	43	210	654
Rear	0	752	0	752
Not Known	0	2	0	2
	1,376	865	563	2,804

Seatbelt Use

Seatbelt use was determined from an examination of the seatbelt, from consideration of the injuries sustained by the occupant, and from the occupant's contacts with the interior of the car. Police reporting or self-reporting of seatbelt use was not used as a basis for determining seatbelt use.

In approximately three-quarters (73 percent) of the cases, it was possible to ascertain, with confidence, whether a seatbelt had been worn by a front-seat occupant. In the remaining cases (27 percent), it was not possible to determine if the seatbelt had been worn. Many of these cases were low-speed accidents, and in these accidents the forces are such that the characteristic use marks seen on seatbelt webbing and hardware do not occur, and, additionally, occupant contacts with the interior of the car, if they do occur, do not leave any

evidence. Thus, in a proportion of the cases where seatbelt use was not known, the seatbelt would have been used although there was no evidence to indicate this.

The overall seatbelt use rate for front-seat occupants, excluding those cases where seatbelt use was not positively established, was 93 percent. If it is assumed that all those for whom seatbelt use was not established were not wearing their seatbelt, then the use rate falls to 67 percent; if it is then assumed that all those for whom seatbelt use was not established were wearing their seatbelt, the use rate becomes 95 percent. Thus, the accident data indicate that the seatbelt use rate for front-seat occupants involved in accidents was between 67 and 95 percent. Use rates for drivers were generally slightly higher than for front-seat passengers (Table 14).

Table 14. Seatbelt use rates: weighted data

	Excluding Not Knowns	Including Not Knowns	
		Min	Max
Driver	94%	70%	95%
Front Seat Passenger	90%	62%	93%
All Front Seat Occupants	93%	67%	95%
Rear	0%	0%	0%

Front-Seat Occupant Injury Severity

Although the data base consists of injury accidents, approximately 21 percent of the front-seat occupants were uninjured. This stems from the fact that there can be, and frequently are, injured and uninjured people in the same vehicle. Table 15 gives details of the police assessment of the severity of the injuries sustained by the occupants, while Table 16 gives details of the maximum AIS rating (MAIS) of the occupants. A three-point injury classification system is used by the police. A fatality is a person who dies within 30 days of the accident. A slightly injured person is a person with injuries of a minor nature, these injuries being roughly equivalent to AIS 1 injuries. In each table, restraint use is also considered.

A comparison of the MAIS distributions for restrained and unrestrained front-seat occupants indicates that in towaway accidents, unrestrained occupants are approximately 2.6 times more likely to receive MAIS 4 to 6 injuries, 1.1 times more likely to receive MAIS 2 to 3 injuries, and 1.4 times less likely to receive MAIS 1 injuries, and 1.3 times less likely to receive no injuries than restrained occupants (Table 16). While these figures suggest restrained occupants are less likely to sustain serious injury than unrestrained occupants, the small number of unrestrained occupants (29 in the unweighted data base) means that the relative risk of injury between restrained and unrestrained occupants cannot be calculated with any degree of accuracy.

Table 15. Overall injury severity of restrained and unrestrained front seat occupants according to police classification: weighted data

Police Classification of Injury Severity	Restrained N	Restrained %	Unrestrained N	Unrestrained %
No Injury	281	20%	35	32%
Slight	667	49%	37	34%
Serious	343	25%	18	16%
Fatal	82	6%	20	18%
	1,373	100%	110	100%

Table 16. Maximum AIS of restrained and unrestrained front seat occupants: weighted data

MAIS	Restrained N	Restrained %	Unrestrained N	Unrestrained %
0	270	20%	17	16%
1	552	42%	31	30%
2	321	24%	32	30%
3	76	6%	3	3%
4	22	2%	10	10%
5	45	3%	9	9%
6	33	3%	3	3%
	1,319		105	
N.K.	52		6	
	1,371		111	

Interestingly, there were differences in the police assessment of injury severity and the investigating teams' assessment of the severity of the injuries. A comparison of the number uninjured between the police classification (Table 15) and the MAIS classification (Table 16), based on an examination of medical records and occupant questionnaire returns, indicates that a proportion of those classified as having no injury by the police were in fact injured. Likewise, it was found that a proportion of those classed as having slight injuries by the police did not have an injury assessable under the AIS system.

Pattern of Injury to Restrained Occupants

Table 17 shows the distribution of the injury severity for each of the five body areas for restrained occupants. It can be seen that, overall, the chest and legs were the most frequently injured body areas: 47 percent of restrained occupants sustained a chest injury and 47 percent a leg injury. Head injuries were sustained by only 26 percent. If, however, only nonminor injuries are considered, the head was the body area most frequently injured, followed by the chest and then the abdomen. AIS 4 to 6 injuries were sustained in roughly equal proportions by the head, chest, and abdomen.

Table 17. Pattern of injury by injury severity for restrained occupants: weighted data

AIS	Head		Chest		Abdomen		Arms		Legs	
	N	%	N	%	N	%	N	%	N	%
0	1,013	74%	730	53%	974	71%	926	67%	732	53%
1	107	8%	419	30%	324	24%	370	27%	513	37%
2	184	13%	133	10%	7	-	65	5%	81	6%
3	18	1%	38	3%	16	1%	14	1%	50	4%

5	18	1%	22	2%	43	3%	0	-	0	-
6	28	2%	5	-	0	-	0	-	0	-

All Severities of Injury

For each injured occupant, the most severely injured body area has been identified. Where there were several body areas with injuries of the same severity, each region has been counted. Table 18 shows the rank order of involvement of different body areas by impact type counting all severities of injury sustained by those with any severity of injury. It can be seen from this table there are considerable differences in the relative importance of different body regions between different impact types. Leg injuries were the most frequently sustained injury by occupants in frontal impacts and by nonstruck side occupants in side impacts. Chest injuries were the most frequently sustained injury by struck side occupants in side impacts. Abdominal injuries were less frequent in frontal impacts than in other impact types.

Nonminor Injuries

Over half those injured sustained MAIS 1 injuries. It is perhaps more useful to consider nonminor injuries (AIS 2+) sustained by only those with nonminor injuries (MAIS 2+) (Table 16). When this is done, the head emerges as the body area most frequently injured for all impact types except struck side occupants where torso injuries were more frequent (Table 19). Serious abdominal injuries were relatively infrequent in frontal impacts but were frequent in side impacts.

Seatbelt Effectiveness in Fatal Accidents

The Data

Data from two sources have been used to examine the circumstances of accidents in which restrained front-seat occupants are fatally injured. The first data set consisted of 48 accidents investigated by the various teams currently conducting in-depth studies of crash injury(31); the second data set consisted of 49 accidents for which details were obtained from police reports. In the 97 accidents available for analysis, there were 109 fatally injured front-seat occupants seated in 100 cars: 74 of these fatally injured occupants were drivers and 35 were front-seat passengers.

While the data from the in-depth studies contained detailed information on the extent of the damage to the vehicle, the location of occupant contacts with the interior, and the causes of injury to the occupants, the data obtained from police records lacked this information. Consequently, no attempt has been made to classify the accidents by impact speed nor have the specific causes of injury been considered.

The Representativeness of the Data

The age distribution of the drivers was similar to that occurring nationally for all fatally injured drivers, the most frequent age group being the 20 to 29 year age group and the second most frequent, the 30 to 39 year age group. A comparison of the age distribution for fatally injured passengers was not undertaken due to the small numbers in the sample. The ratio of males to females in the sample was similar to that occurring nationally. In the sample, 81 percent of the fatally injured restrained drivers were males, whereas nationally, in 1983, 83 percent of all fatally injured drivers were male. For front-seat passengers, the corresponding figures were 49 percent for the sample and 50 percent nationally. Table 20 gives details of the age distribution of the fatally injured restrained drivers and front-seat passengers in the sample, together with the age distribution for all fatally injured drivers nationally.

The Collision Circumstances

The majority of the accidents in which restrained front-seat occupants were killed occurred on high-speed roads. Only 12 percent of those accidents for which the speed limit was known occurred on roads subject to a 30mph speed limit, whereas 73 percent occurred on roads subject to a speed limit greater than or equal to 60mph.

Approximately two-thirds of the vehicles were involved in accidents with other vehicles. Just over half the collisions with other vehicles were head-on collisions. Heavy Goods Vehicles (HGV's), or Public Service Vehicles

*Note: Irrespective of seatbelt status

(PSV's) were the other vehicle in just over a third of the cases where another vehicle was involved and in just under one-quarter of all the cases.

In three of the cases, the vehicle caught fire. However, in all these cases, the accidents were of such severity that the occupants would most probably have died from injuries sustained in the initial impact had there not been fire present.

The Vehicles

Table 22 gives details of the approximate ages of the involved vehicles. Age has been determined from the registration letter, which changes on August 1 each year. It will be noted there are no vehicles older than 5 years in the in-depth data. This is due to the fact that only vehicles less than 6 years old are examined in the current in-depth accident studies(31). The police data indicate that roughly half the restrained occupants killed are in vehicles more than 5 years old.

Gross intrusion was a characteristic of the accidents. Approximately three-quarters (74 percent) of the fatally injured restrained front-seat occupants were involved in accidents where there was gross intrusion, while a further 13 percent were involved in accidents where there was complete disintegration of the vehicle (Table 23). In the great majority (93 percent) of the cases where there was gross intrusion, the fatally injured restrained occupant was seated on that side of the car where the intrusion was greatest (Table 24).

	109	

The Occupants

Although there were 109 fatally injured restrained front-seat occupants in the 100 vehicles under consideration, these vehicles contained a total of 152 front-seat occupants. In addition to the 109 fatally injured restrained front-seat occupants, there was one fatally injured unrestrained front-seat passenger, 16 surviving injured restrained front-seat passengers, and 26 surviving restrained drivers. Table 25 gives details of status of the front-seat occupants by impact type. In approximately half the cases, the driver was the sole occupant, these accidents being predominantly distributed frontal or offside frontal impacts. In just over one-quarter of the cases, the vehicle was struck on the side and in the majority (74 percent) of these cases the fatally injured occupant was seated on the struck side.

The Injuries

Multiplicity of injury was a characteristic of restrained occupants fatally injured. The 99 fatally injured front-seat occupants for whom the number of fatal injuries could be established sustained a total of 182 fatal injuries, i.e., an average of 1.8 fatal injuries per fatality. Over half (60 percent) sustained more than one fatal injury (Table 26), while approximately one-fifth (21 percent) sustained more than two fatal injuries.

Just under half (46 percent) sustained maximal Injury Severity Scores (ISS = 75), most of these being associated with maximal AIS ratings (AIS = 6) (Table 27).

Discussion

In the preceding sections, some numerical aspects of seatbelt use, effectiveness, and the consequences of the seatbelt law on injury patterns have been considered. One advantage of detailed in-depth studies is that it allows the investigating team to make a thorough assessment of seatbelt performance on a case-by-case basis. It is difficult to quantify such experience because every collision is in some way unique. There are many ways of describing the impact conditions; crash severity and impact force direction being two of the relevant parameters. Other factors relate to vehicle design, which influences the kinematics of the occupants and their contacts. Finally there are parameters such as human tolerance, which influence the injuries sustained. However, the experience gained of seatbelt function in the real world of crashes examined by the various teams involved in in-depth crash injury studies(31) allows some comment to be made about the limits to seatbelt performance and about future developments that are likely to enhance the already good protection provided by seatbelts.

Intrusion

The most important limitation on the ability of the seatbelt to prevent death in a collision arises not from the functioning of the seatbelt itself, but from the destruction of the passenger compartment. This is particularly so in car/truck collisions, where there is geometrical and structural mismatch between the engaging vehicles(32). Approximately 25 percent of restrained occupant deaths in Britain now occur in car-to-HGV and car-to-PSV collisions. Single-vehicle, off-road crashes with hostile roadside furniture form another important part of this

Table 24. Seating position of fatally injured front seat occupant by location of intrusion for accidents in which there was gross intrusion

	Location of Intrusion					
	Frontal		Side		Other	
	Driver Side	F.S.P. Side	Driver Side	F.S.P. Side	Driver Side	F.S.P. Side
Driver	28	2	16	3	9	-
F.S.P.	1	9	-	7	-	6

Table 25. Front seat occupant injury severity by impact type

Status of Occupant		Frontal Impact			Side Impact		Other	Total
Driver	F.S.P.	All Front	Offside	Nearside	Right	Left		
Killed	None	13	12	3	8	5	7	48
Killed	Killed	4	2		1	1	2	10
Killed	Survived	4	3	2	5		2	16
Survived	Killed	8	3	3	1	6	5	26
		29	20	8	15	12	16	100

problem. In such crashes, the localised, unforgiving nature of structures such as trees, lamp posts, and sign supports produce levels of intrusion where seatbelt use becomes irrelevant to injury causation. While some reduction in occupant fatalities can probably be achieved by improvements in vehicle structural design, issues of compatability between vehicles of disparate mass, and policies on the design of roadside furniture, are of importance in reducing occupant fatalities.

Rear Loading

Serious injury to restrained front-seat occupants is more likely when the front-seat occupants are loaded from behind by unrestrained occupants or luggage. Great Britain, unlike many other motorised countries, has not yet required the mandatory fitting of rear seatbelts. In our in-depth studies, evidence of additional loading to the front seats by unrestrained rear-seat occupants is common when rear-seat occupants are present, and in severe frontal collisions this additional loading can cause injury to the restrained front-seat occupants. However, other objects besides rear-seat passengers load and injure correctly restrained front-seat occupants. This has been seen to occur in estate cars and hatchbacks where current designs of folding rear seats do not appear to be able to withstand the forces applied to them by luggage in accidents. Injury to restrained front-seat occupants as a result of rear loading by luggage has been seen in those exceptional accidents in which large, heavy objects have been carried in the luggage area. Thus, the design of rear seat backs with respect to load retention is of importance.

Rear Seatbelts

Currently, approximately 300 to 350 people are killed each year in Great Britain while rear-seat car occupants. Griffiths(4), from a study of fatally injured unrestrained car occupants, concluded that with 100 percent seatbelt use in the rear seats there would be a reduction of about 74 percent in the number of rear-seat occupants killed. This effectiveness rate is higher than for front-seat occupants as severe intrusion, which compromises an occupant's seating position, is relatively infrequent for rear-seat occupants. Thus, the mandatory fitting, and use, of rear seatbelts, assuming use rates similar to those for front-seat occupants, would result in a reduction of about 200 to 230 in the number of rear-seat occupants killed. Griffiths also reported that approximately 8 percent of fatally injured restrained front-seat occupants would not be killled if all rear-seat occupants were restrained. Since the introduction of mandatory seatbelt use, the number of front-seat car occupants killed has been about 1,800 per annum. Assuming that seatbelt use rates in the rear, with mandatory fitting and use, would be similar to those in the front, there would potentially be a reduction of approximately 100 to 120 in the number of restrained front-seat occupants killed if the fitting and use of rear seatbelts was made compulsory.

Overall, the mandatory fitting and use of rear seatbelts, assuming rear seatbelt use rates would be similar to those for front seatbelts, would potentially result in a further reduction of between 300 and 350 in the number of car occupants killed.

Occupant Kinematics and Contacts

During a frontal impact, a restrained occupant moves forward and is decelerated as a result of forces applied to the body by the seatbelt. As the seatbelt is loaded by the occupant, the belt stretches and contact with the interior can occur.

Injuries to the chest, from the forces applied to the chest by the seatbelt, have been seen. These injuries

Table 26. Number of fatal injuries sustained

Number of Injuries	Driver		F.S.P.		Total	
	N	%	N	%	N	%
1	27	39%	13	43%	40	40%
2	25	36%	13	43%	38	38%

N.K.	5		5		10	
	74		35		109	

Table 27. Injury severity score by posted speed limit

Speed Limit	Injury Severity Score					
	0-15	16-24	25-49	50-74	75	N.K.
30	-	-	6	1	3	1
40	-	-	8	1	8	1
50	-	-	-	-	2	-
60	1	3	14	7	17	7
70	-	1	4	5	10	-
N.K.	-	-	2	1	6	-
	1	4	34	15	46	9

normally only occurred in severe collisions, particularly if the restrained occupant was elderly or there was additional rear loading. The severity of these collisions was such that the occupant would most probably have been more severely injured if unrestrained.

A limit to the protection afforded by seatbelts comes from the restrained occupant running out of space and being injured as a result of contact with the interior of the passenger compartment. With current car designs, the interior geometry, crash pulse, and belt characteristics are such that a driver's face is likely to strike the steering wheel in that small proportion of frontal crash where the velocity change is greater than about 25mph. Such contacts do not normally result in fatal injuries, but they do generate significant soft tissue trauma, concussion, and occasionally facial bone fractures. Thus, consideration needs to be given to designing steering wheels for facial contact.

Knee contacts are also frequent for restrained occupants in severe frontal impacts, and thus the design of the knee contact zones is still of importance.

Seatbelt Design Features

A number of specific items of detailed design have emerged from these current studies and from previous in-depth studies carried out at Birmingham University. For example, the weakening of retraction springs has been seen to result in belt slack and consequent poor belt geometry; excessive slack and incorrect belt geometry have been noted when swinging arms, which have been used on two-door cars to improve rear-seat access by rotating the belt at the lower outboard mounting point, have failed to correctly align with the belt; poor belt geometry has also been noted for part of the car user population, particularly when the seat is at the extreme limit of its travel; damage to seatbelt webbing under crash conditions has been observed as a result of the belt catching on items such as seat back adjusters. All of these limitations to current seatbelt performance can be, and generally have been, improved by technical development.

Future Developments

In terms of improving seatbelt crash performance, the authors consider that the following will lead to a significant upgrading of the already good performance of current belt systems:

- Integration of the front-seat lower belt mounting points into the seat structure
- Matching the dynamic response of the seatbelt and the seat to the geometrical constraint of the compartment package for the actual population at risk, which may lead to knee contacts occurring by design as a means of controlling occupant kinematics for some segments of the population
- Preloading the belt system to remove slack and to couple the occupant dynamically to the crash characteristics of the front structure
- Changing steering wheel design to either diminish the frequency of driver face contacts or to make such contacts more benign through improvements in hub, spoke, and rim design or developing supplementary restraint systems such as the steering wheel airbag

In addition to the benefits that would come from the improvements in vehicle design outlined above, significant benefits would come from requiring that rear seatbelts be fitted in cars and by encouraging their use, possibly by legislation. In designing rear seatbelt installations, the characteristics of the population that use rear seatbelts need to be considered, a high proportion of rear-seat occupants being young children.

Conclusion

This paper has reported on some of the consequences of the mandatory seatbelt law in Britain. The main conclusions are—

1. The introduction of the mandatory seatbelt use law resulted in seatbelt use rates for front-seat occupants, rising from around 35 percent to around 95 percent.
2. There has been a reduction of approximately 25 percent in the number of car and light van front-seat occupants seriously injured or killed coincident with the introduction of the mandatory seatbelt use law.
3. The actual reduction in front-seat occupant fatalities is in line with the expected reduction.

4. While there have been increases in the number of pedestrians and pedal cyclists killed or injured as a result of being struck by a car or light van, the increases are not statistically significant.
5. The increase in the number of pedal cyclist casualties coincident with the introduction of the mandatory seatbelt use law is mainly due to an increase in accidents involving child cyclists on unclassified roads in residential areas and may reflect the increased use of BMX bicycles by children.
6. While the changes in the other classes of road casualties are statistically insignificant and are consistent with the random annual fluctuations and changes in traffic volumes and patterns, the reduction in front-seat car occupant deaths and serious injuries coincident with the seatbelt law is large, statistically significant, and not explainable in any other way than being related to the seatbelt law.
7. The data currently available do not support the hypothesis that risk compensation, well accepted for some developments in the field of active safety, applies to the mandatory use of seatbelts.
8. Accidents in which restrained occupants are killed are normally so severe there is gross intrusion into the passenger compartment with the result that the seatbelt has virtually no effect.

Acknowledgments

In a study such as this that relies on the cooperation of many different organisations and individuals, there are many people to acknowledge. The authors would like to express particular thanks to—

1. The Department of Transport, British Leyland, and Ford for providing financial support for the two University groups.
2. The Chief Constables and their officers in all the areas in which the investigation teams work for allowing access to accident data.
3. The consultants and other staff at the various hospitals in the study areas for their assistance in providing injury data.
4. The coroners in the study areas for their cooperation in providing copies of post-mortem reports.
5. The Department of Transport vehicle examiners in the West and East Midlands, Northern, and Western traffic areas for their assistance in collecting vehicle data.
6. The staff of the two Accident Research Units.

The opinions expressed in this paper are entirely those of the authors and are not necessarily the views of the sponsors.

Appendix 1

If

T = total deaths with zero belt use

D_B = number of deaths before the introduction of the law

D_A = number of deaths after the introduction of the law

U_B = seatbelt use rate before the introduction of the law

U_A = seatbelt use rate after the introduction of the law

e = seatbelt effectiveness rate

then

$$D_B = U_B.(1 - e).T + (1 - U_B).T$$
$$= (1 - U_B.e).T$$

and

$$D_A = U_A.(1 - e).T + (1 - U_A).T$$
$$= (1 - U_A.e).T$$

The expected reduction in fatalities R_F is thus:

$$R_F = (D_B - D_A)/D_B$$
$$= ((1 - U_B.e).T) - ((1 - U_A.e).T) / ((1 - U_B.e).T)$$
$$= ((U_A - U_B).e / (1 - U_B.e)$$

Collision Types and Characteristics of Bus Accidents—Their Consequences for the Bus Passengers and the Accident Opponent

K. Langwieder,
M. Danner, and
Th. Hummel
HUK-Verband, Automobile Engineering Department, German Association of Third Party, Accident, Motor Vehicle and Legal Protection Insurers

Abstract

The omnibus occupies an important position in the traffic scene in the Federal Republic of Germany; this paper furnishes statistical data on this fact. In the light of the national statistics, it is deduced that the risk of being killed or seriously injured as the occupant of a bus is low. This study covers 97 bus accidents with a collision in which occupants were injured; for the bus occupants, the risk of injury is given dependent on the accident opponent and kind of collision. For bus/car accidents, the risk to the car occupants, i.e., the passengers in the opposing vehicle, is also described. Moreover, this paper contains 142 accidents with injuries to the bus occupants without the bus being involved in a collision. These injuries resulted from the driving maneuvers of emergency braking, starting, and driving in a bend.

The majority of persons killed or seriously injured in this study met with their accident in long-distance coaches; rollover accidents are of particular significance. On the basis of this knowledge, measures are indicated that could achieve a further increase in the passive safety of buses.

As unfavorable road conditions played an essential part in the available accident material, an investigation was carried out to ascertain whether the accident would have been influenced by the use of an antilock brake system. These systems turned out to be of great advantage. About 4 percent of the bus accidents could certainly have been avoided, and probably even 15 percent.

The Bus Accident in the Federal Republic of Germany

The omnibus occupies an important place in the traffic scene in the Federal Republic of Germany. In 1983, 71,159 omnibuses were registered(1); thus, compared with 1970 (47,253 registered buses), the number has increased by more than 50 percent.

The safety of present-day bus transport is relatively high compared to other means of transport. On average, only 1.9 persons met with an accident per billion (10^9) passenger kilometers; the comparable figure with the car is 20 persons and with the motorcycle as high as 178(2) (Figure 1).

The high safety level of the bus, however, not only turns out to be relative, but the absolute accident figures also make this fact clear. In 1983, altogether 26 bus occupants (drivers and passengers) were killed, 523 seriously and 3,645 slightly injured(1) (Figure 2). For 1984, the figures were 34 killed, 563 seriously injured, and 3,638 slightly injured(3). Although the number of injured persons remains fairly constant each year, with such low accident figures one single serious bus accident can have considerable influence on the national accident statistics, as, for example, in 1966, when 68 bus occupants were killed or in 1980 when the comparable figure ws 43(1).

In view of the high mileage of buses and number of injured persons given above, the risk of being killed or seriously injured as a bus occupant is low, and today a very high level of safety has been achieved, but this study indicates even further possibilities for improvement.

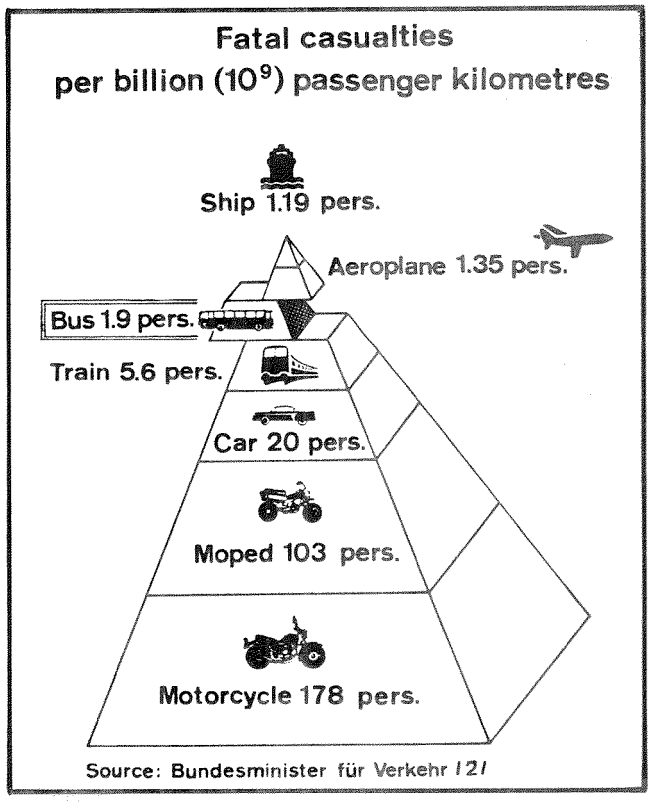

Figure 1. Relative risk to users of various means of transport

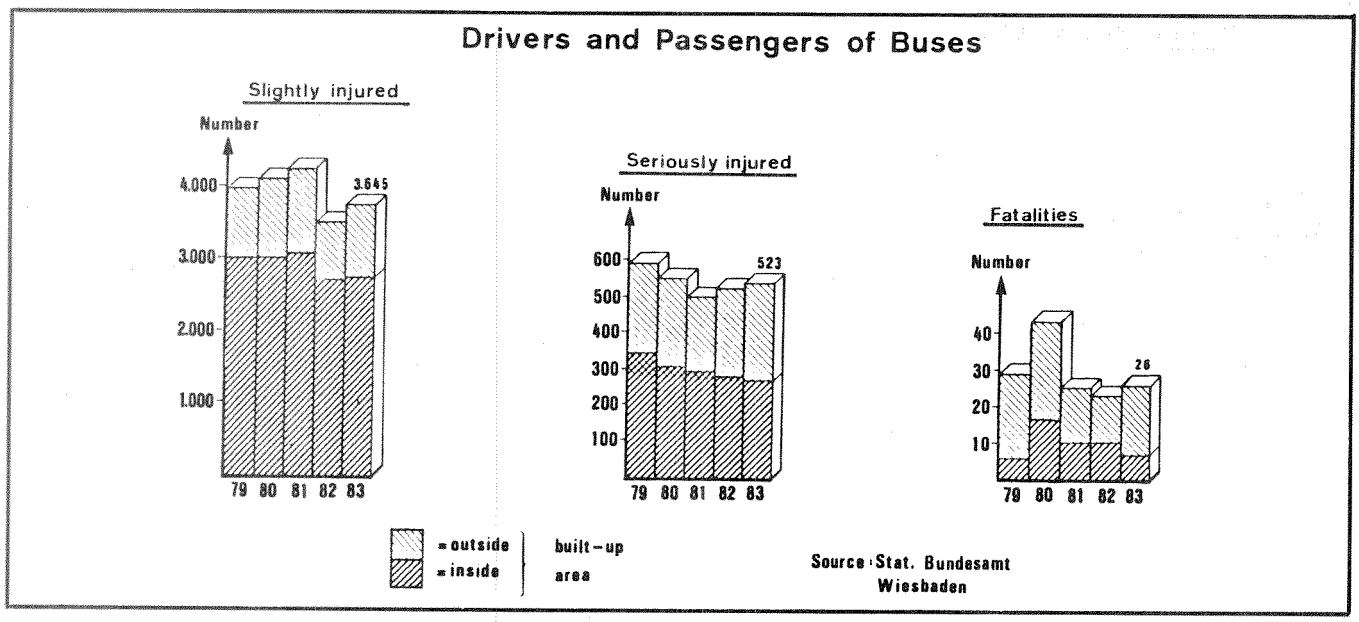

Figure 2. Bus occupant injured in accidents in the Federal Republic of Germany in 1979-83

Future considerations, however, will have to take into account traffic policies, economic aspects, and public acceptance to establish whether these measures—especially since extreme, isolated cases can never be avoided—can be justified with respect to cost/benefit rates and can be carried out uniformly on an international scale.

The Accident Studies of the German Motor Insurers

Since 1978, the accident research of the HUK-Verband has also included 239 bus accidents with injuries to persons. The selection of these accidents is based—with the exception of a few serious accidents—on the random principle. The bus accidents were recorded in the course of the continuous analysis of traffic accidents, which are made available by all the German motor insurers to the HUK-Verband for purposes of accident research. The condition for analyzing an accident is that at least one of the persons involved in the accident sustained injuries of AIS 1(4) or worse. The accidents were retrospectively evaluated by the HUK-Verband's own team of engineers in cooperation with doctors. The method of the HUK accident research is described in (5).

This study comprises only accidents of buses with a seating capacity of over 25; accidents with minibuses, bus collisions with two-wheeled vehicles or pedestrians, and accidents that occurred when bus occupants were boarding or alighting are not included.

The 239 bus accidents covered by this study are broken down into—

- 97 accidents with a collision
- 142 accidents without a collision

Altogether 100 buses were involved in the 97 accidents with a collision. The 142 accidents without a collision are accidents resulting from driving maneuvers, meaning emergency braking, starting, or driving in a bend.

Accident Characteristics With and Without a Collision

Bus Accidents Without a Collision

For the sake of completeness, bus accidents without a collision are mentioned here, as they also constitute a problem of bus safety, especially on a scheduled bus service. In these accidents, a dominant role (both with regard to frequency and to injury severity of the occupants) is played by emergency braking causing injuries, e.g., to standing passengers (Figure 3).

If all degrees of injury severity are included, in accidents without a collision head injuries dominate with 27.3 percent, followed by injuries to the chest with 19.2

Driving manoeuvre	Accidents caused by driving manoeuvres	Number of injured persons			
		MAIS*1	MAIS 2	MAIS 3	MAIS n.a.
Braking	120	47	5	5	93
Starting	13	7	-	3	3
Bend	9	4	1	-	4
Total	142	58	6	8	100

*MAIS = Maximum AIS /4/
n.a. = not ascertained

Figure 3. Frequency and severity of injuries in accidents without a collision caused by driving maneuvers by scheduled buses

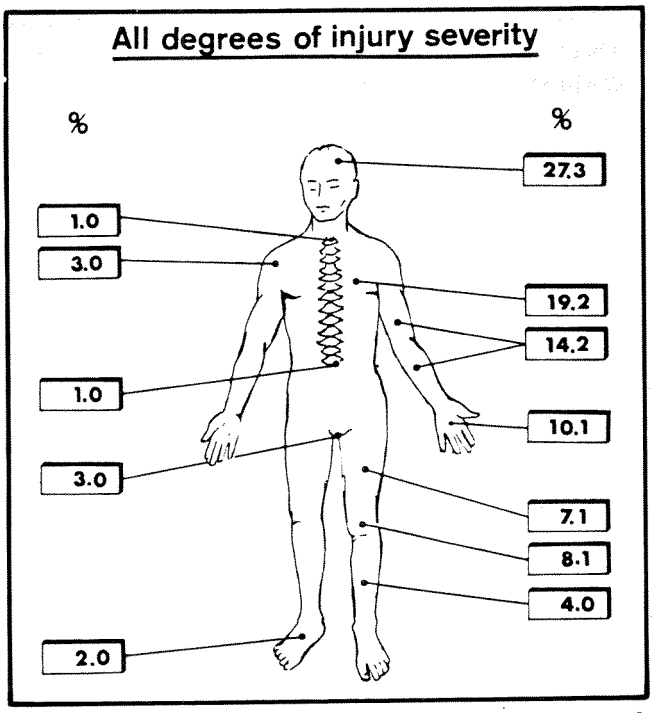

Figure 4. Frequency of injuries to the different parts of the body in accidents caused by driving maneuvers

percent and to the arm with 14.2 percent (Figure 4). Serious injuries (MAIS = 3) were observed in a total of only eight persons in 142 accidents, one case involving a serious head injury; injuries of MAIS 4 to 6 were not recorded in the 142 accidents without a collision.

In braking accidents, head injuries occurred with the greatest frequency. In accidents resulting from starting or driving in a bend, injuries to the chest were the most frequent. Most of these were chest bruises, although the available accident material does contain cases of multiple rib fractures. In general, only slight to moderate injuries result from driving maneuvers. When the occupants are standing in the regular scheduled bus, however, the long falling distances when the bus brakes may also cause serious injuries, such as fractured skulls, complicated

Bus Accidents With a Collision

Injury Risk Dependent on Operational Function of the Bus

Figure 5 shows the distribution of the bus accidents with a collision for the operational functions broken down according to scheduled bus, school bus, and long-distance coach.

fractures of the femur, or multiple rib fractures. Frequently, the occupants of the bus are old people who find it more difficult to hold tight or to support themselves than younger ones and who are exposed to a considerably higher injury risk simply by reason of their lower physical resistance.

Fifty percent of the buses concerned were involved in an accident on a scheduled service, about 35 percent on long-distance service, and about 15 percent on school bus service. To what extent this distribution agrees with the actual circumstances in the overall accident scene and national accident statistics cannot at present be ascertained for lack of comparative data. Figure 6 gives the number of accident victims according to the injury severity and the total number of bus occupants involved, again for the three operational functions of scheduled bus, school bus, and long-distance coach, in relationship to the four accident groups—bus/car, bus/truck, bus/bus, and single-bus accidents.

On a scheduled bus service, about one-third of the total of 1,990 bus occupants involved were recorded; of these 651 occupants involved in bus accidents on a scheduled service, no person was found to be killed, and the number of seriously and slightly injured persons is relatively low.

For long-distance coaches, the injury risk is, however, considerably higher: 38 of all 40 fatally injured persons were in long-distance coaches; the other two occupants were killed in school buses. This means the risk of being injured is altogether higher in school buses and coaches

Figure 6. Bus occupants involved and injured in the four accident groups depending on operational function

than in buses on a regular service. This statement, however, must take into account that much greater distances are covered by long-distance coaches and that long-distance coaches travel at higher speeds, and this generally results in a higher injury risk as well.

Apart from the higher risk of injury in long-distance travel, Figure 6 also shows another very important finding, namely that in the case of single-bus accidents there is indeed a higher risk of serious/fatal injuries compared with the general bus risk. This point is dealt with later.

Risk of Injury Dependent on Accident Opponent and the Kind of Collision

The effects of bus accidents, unrelated to the accident opponent or the kind of accident, are given in Figure 7. All data here refer to the maximum injury severity of the bus occupants in each case.

The central result in Figure 7 is that out of the altogether 40 persons killed in the accident material under consideration, as many as 34—that is, 85 percent—were killed in single-bus accidents—to be more precise, in single-bus accidents with rollover. In the other accident groups (bus/car, bus/truck, and bus/bus), not one single rollover occurred, not even as a secondary event after the collision with the accident opponent.

The high risk of injury in rollover accidents is further confirmed by the equally high number of seriously injured bus occupants: 114 out of a total of 208 persons who were seriously injured sustained their injuries in rollover accidents.

Insofar as one would like to increase bus safety even further, one has to start with accidents with a rollover, which in the available accident material accounted for 85 percent of the killed and more than 50 percent of the seriously injured bus occupants, although these rollover accidents amount to only 7 percent in the total material.

Very serious accidents also result from bus/truck and from the rare bus/bus collisions. In the 40 bus/truck collisions recorded, 5 persons were killed and 66 seriously injured.

In the case of a bus/truck collision, only those bus occupants whe are seated in the direct intrusion area are normally affected by the risk of serious or fatal injuries. In contrast to this, in rollover accidents there is risk of very serious injuries in every case for a relatively large number of occupants by impacting the interior side or roof or by being ejected out of the bus.

Figure 7 also shows that the risk of injury for the bus occupants in bus/car collisions is relatively low, and this corroborates the findings of the HUK study presented in 1981(6), in which this was also stated. Nor in the case of the 43 bus/car accidents now available was any person killed in the bus. Even in serious bus/car collisions, the strain on the bus occupants is not so great that substantial risks of injury exist.

The risk for the car occupants is, however, serious. Although the shape of a bus resulting from the lattice-work girder structure is less dangerous than that of a truck, the bus front is so rigid that if the car is totally deformed, the bus front is relatively only slightly damaged (Figure 8). In the accident in Figure 8, the car driver was killed, but the 36 bus occupants were only slightly injured

Figure 7. Number of bus accidents and of the bus occupants injured in them dependent on the accident opponent and the kind of accident

Figure 8. Bus/car frontal collision in which the car driver was killed and several bus occupants slightly injured

or not at all. There would therefore still seem to be room for improvement with regard to partner protection in the case of the omnibus.

In contrast to truck/car collisions, in bus/car collisions it is frequently possible to observe, however, that after the collision the car skids away from the bus, which reduces the strain on the car occupants. But the high-speed change remaining is clearly reflected in the risk of injury to the car occupants (Figure 9). In 43 bus/car accidents, 22 car occupants were fatally injured, 29 persons sustained serious injuries, and 21 slight injuries. In several of these cases, however, safety belts, if they had been used, would have resulted in decreasing the injuries to the car occupants.

The distribution of the collision types for bus/truck and bus/car accidents is shown in Figure 10. In the left-hand half of the bus diagram, the areas of impact in bus/car accidents are given, and in the right-hand half those in bus/truck accidents; the overall percentages refer in each case to the total front, rear, or side areas of the bus. Here no distinction has been made between left/right, partial offset, etc.

If all cases including every category of injury are counted, three collision types dominate: front/front (bus/truck 30.2 percent, bus/car 55.8 percent), front/side (bus/truck 16.3 percent, bus/car 18.6 percent), and side/front (bus/truck 11.6 percent, bus/car 20.9 percent), the first-mentioned impact area referring to the bus in all cases. Another noticeable feature is the relatively high number of rear-end collisions of trucks onto buses, which represent 20.9 percent of the bus/truck collisions.

As previously presented in Figures 6, 7, and 9, no bus occupant was killed in bus/car accidents in the available material. The total of four seriously injured bus occupants in bus/car collisions sustained their injuries in front/front collisions as a consequence of the deceleration resulting from the collision and not from intrusion, and the slight injuries, too, occurred mainly in frontal collisions (Figure 8).

In bus/truck accidents, over 50 percent of all seriously or slightly injured bus occupants sustained their injuries as a result of a bus being involved in a frontal collision in which the front of the bus ran into the front, side, or rear of a truck (Figure 11). The primary cause of injury here is the rapid deceleration in the longitudinal direction of the bus, which throws the occupants forward, and not the intruding bus structure.

The bus occupants who were killed were almost exclusively in the indirect intrusion area of the truck (Figure 12). The local structure loads are then so high that it seems difficult to provide any effective protection against intrusion. In contrast to this, in frontal collisions the bus occupants are usually not affected directly by the intruding bus structure and are thus injured less severely.

	Injured bus occupants Drivers and passengers			Injured car occupants Drivers and passengers

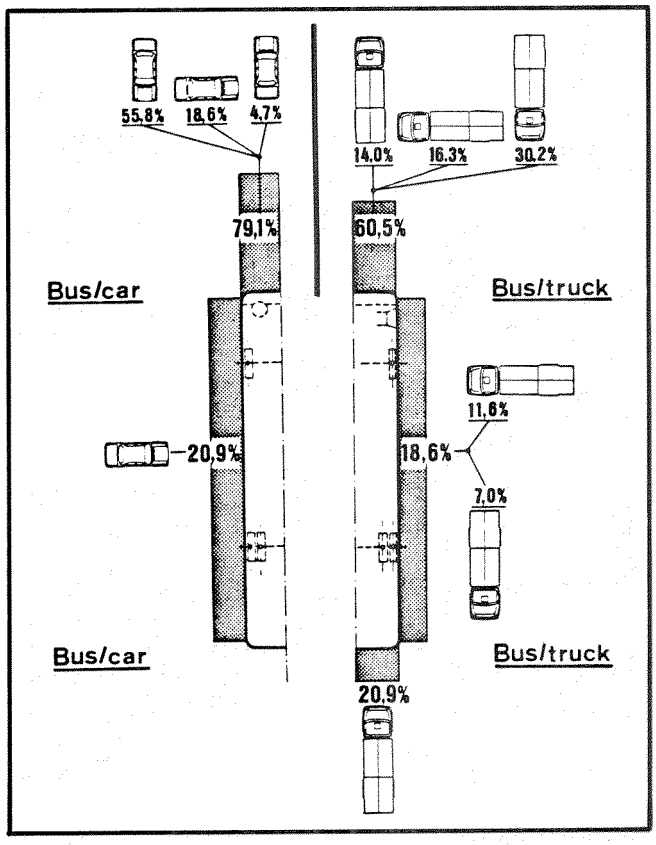

Figure 10. Distribution of the impact areas in bus/car and bus/truck collisions

Risk of Injury in Rollover Accidents

The extremely high risk of injury in bus accidents with a rollover has already been mentioned several times. In Figure 13, the consequences of the accident for the bus occupants are presented for all 7 rollover accidents based on the 97 bus accidents with a collision.

The following points of emphasis emerge:

- In 5 out of 7 rollover accidents, at least 1 bus occupant was fatally injured.
- The proportion of fatalities in rollover accidents related to the total number of bus occupants affected is above average.
- The risk of injury rises considerably in a rollover of half a turn or more.

- A large proportion of the fatally injured occupants were ejected out of the bus.
- The occupants who were ejected were also crushed to death by the bus in most cases.
- Even when they remained in the bus, there was an increased risk of serious/fatal injuries, as the interior was in most cases considerably restricted by the roof being crushed down sideward and by the bended roof posts (Figure 14).
- The chance of being involved in a rollover accident without being injured is relatively low.

Figure 11. Typical damage to a bus in a serious collision of a bus running into the rear of a truck, resulting in seriously and slightly injured bus occupants

In rollover accidents with fatalities, two injury mechanisms in particular can be ascertained:

- The occupant is ejected and crushed to death by the bus.
- The occupant remains in the bus and is hurled against the roof, while at the same time the interior is usually additionally restricted by the intrusion of the roof.

To further reduce the risk of injury in rollover accidents, the occupants in the bus would have to be prevented from being ejected or thrown around in the bus interior, but, in addition, it would have to be insured that the available interior space remains largely intact.

The Avoidability of Bus Accidents

Apart from increasing passive safety to avoid the results of accidents, avoiding the accident altogether is, of course, a better possibility of protecting the occupants of a vehicle. The analysis of bus accidents showed that one of the essential factors is the state of the road; critical road conditions, such as wet or icy surfaces, play a major role in bus accidents. The frequency distribution of the various road conditions presented in Figure 15 results from the available bus accident material (only collision cases and single-bus accidents). The road condition "dry" was registered in only 51.6 percent of all cases (by way of comparison, in car accidents with injury to persons(5) the condition "dry road" occurred in 60.9 percent of all cases). This means that unfavorable road conditions (damp, wet, snow, ice) play an important part in bus accidents. More than one-third of all accidents took place on a wet/damp road, and about one in seven on snow or ice. In the single-bus accidents, the road condition "ice" was recorded in even 4 out of 11 cases.

With regard to the avoidability of an accident, the available accident material was examined to see whether the accident would have been influenced by using an antilock brake system (in the material recorded, no bus was equipped with such a system).

The possible useful effects of the antilock brake system were divided into four categories, namely:

- None, for example when the brakes were not applied at all.
- Possible, but slight, for example when the intensity of the accident could have been decreased by reducing the braking distance, although the accident would have occurred all the same.
- Probable, if the accident could have been avoided as a consequence of external conditions, although this would have required a quick and appropriate reaction on the part of the driver.

Figure 13. Number of injured and uninjured bus occupants in the seven rollover accidents in the relevant HUK accident material

- Certain, if the emergency braking with an antilock brake system alone could have avoided the accident.

Figure 16 shows that in about 40 percent of the cases, an antilock brake device would have had an—at least slight—advantage, while it is certain that 4 percent and probable that even 15 percent of the accidents could have been avoided. Especially in the case of bus/truck and single-bus accidents, which represent a high risk for the bus occupants, there would have been an above-average advantage.

HUK-Verband, the association of all German motor insurers, has recommended, in view of the advantages to be expected from automatic antilock brake devices, that vehicles fitted with such a device should be given a 10 percent reduction in the fully comprehensive insurance. This recommendation was taken up by the insurance companies in 1984. The insurers thus want to take into account the lower accident risk of vehicles equipped with this system. But this reduction in the insurance premium is also meant to be an incentive to acquire vehicles thus equipped and so to make a contribution to increasing traffic safety.

Conclusions for Possible Safety Measures

In relation to the whole traffic scene, the risk of being injured as the occupant of an omnibus is very slight. In view of the total number of bus occupants involved in accidents in road traffic, it is not appropriate to demand additional cost-intensive safety measures. But the inquiries of this study have shown, nevertheless, there are risks for bus occupants that could be further reduced with the help of technical measures.

These measures would have to be concentrated mainly on long-distance coaches, as it is here that far more serious and fatal injuries occur compared with scheduled services; moreover, safety measures are also possible in the case of this operational function, since constantly changing bus occupants and standing passengers are not to be expected, as on scheduled services.

The injuries that occur in accidents without a collision, especially on scheduled services, could be further reduced by appropriate seat construction and making interior components less dangerous.

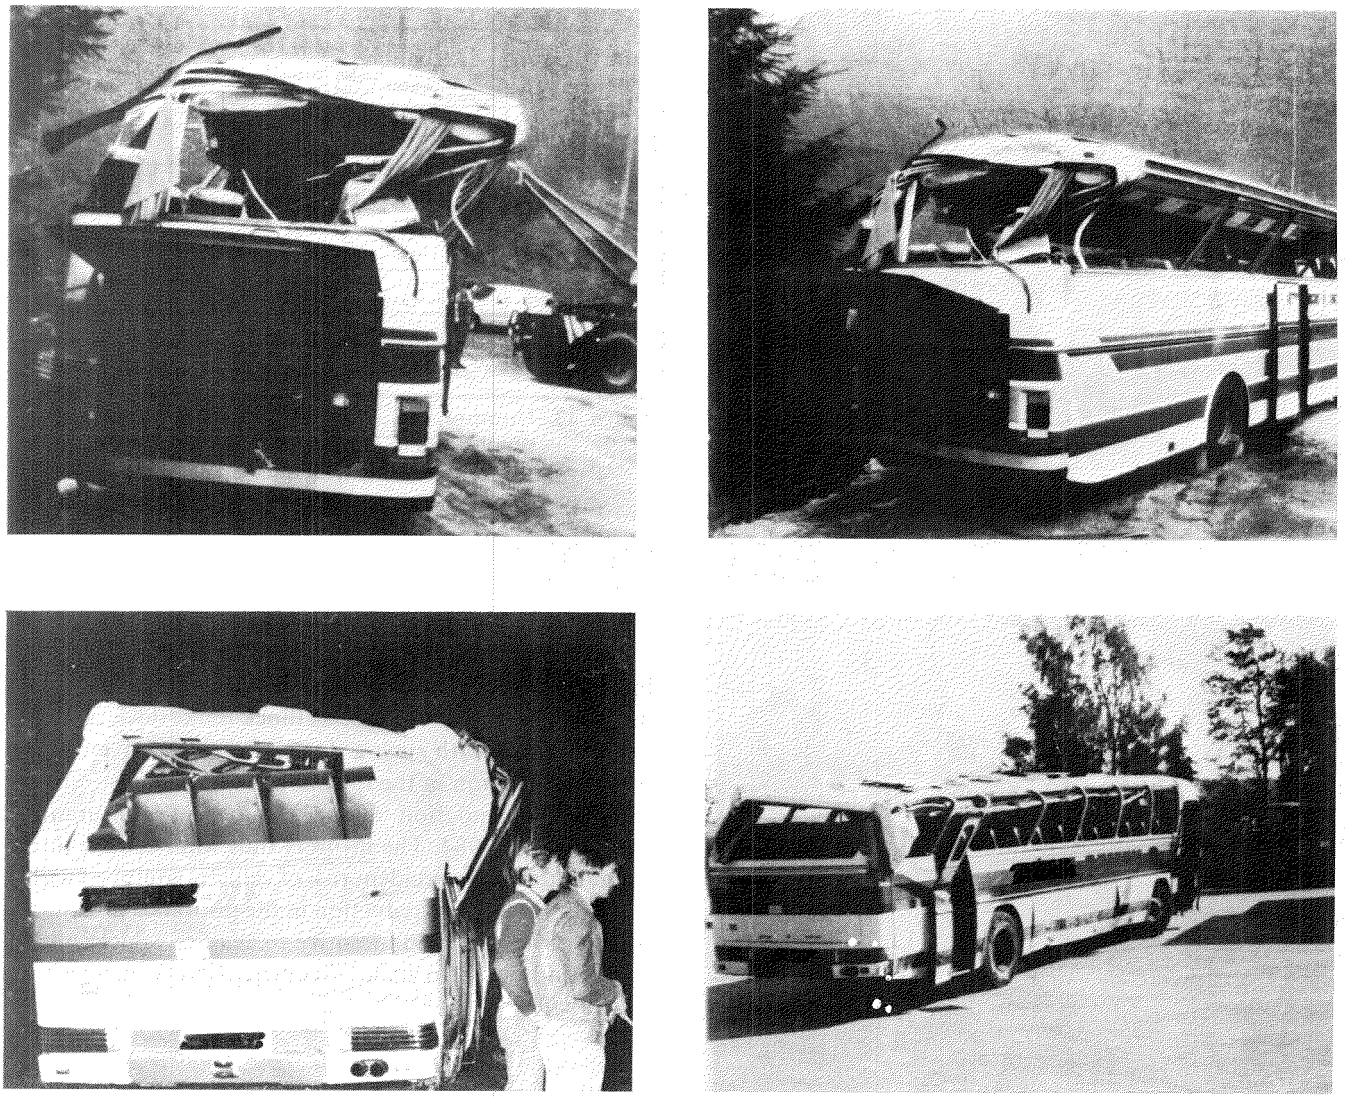

Figure 14. Typical damage to a bus caused by rollover accidents—roof bent sidewards, restricting the passenger space

Single-bus accidents with rollover have turned out particularly dangerous: 85 percent of all persons killed and 50 percent of those severely injured were found in a proportion of this kind of accident of only 7 percent. The serious/fatal injuries are caused, on the one hand, by the intrusion of the roof and, on the other hand, by ejection of the occupants. The intrusion in the roof area often arises by the roof being bent sideways when the bus rolls over, and this greatly restricts the passenger space (Figure 14).

If the aim is, therefore, to increase the safety of buses even further, the measures must be concentrated mainly on reducing the risk of injury in rollover accidents. In this case, the following two measures should be aimed at in conjunction with each other:

- A roof construction to prevent the roof bending away sideward and being deformed from above
- Safety belts on all seats of the coach, including driver's seat, as this seems to be the only possibility of avoiding the passengers being thrown around in the bus or being ejected out of the bus

Although the use of lapbelts would result in the occupants being restrained in their seats, an optimum protection would be provided here, too—as in the car—by the use of 3-point belts, which is technically feasible but, on account of the additional costs, appears to be only partially possible. The question has to be asked as to how far expenses are justified in view of the cost/benefit rate and with respect to acceptance by the bus occupants.

Serious injuries are frequently sustained by bus occupants as well when the bus is involved in a frontal collision and they are thrown forward and injure themselves on the seat backs in front of them, for example. By

constructing the seat backs so they absorb the fall of the occupants, a reduction in injury risk could be achieved, but here, too, better protection of the occupants from injuries could be expected from the use of 3-point safety belts.

Summary

In the area of omnibus safety, there are few data and studies that enable a detailed statement on the actual risk to bus occupants. The aim of this study is to identify focal points in the accident scene and possible technical countermeasures derived from them. The following emerged from our studies:

- The omnibus is the safest of all mean of road transport in the Federal Republic of Germany, and each year few bus occupants are injured in view of the large number of people conveyed by them.
- When discussing national statistics and bus accidents with injuries to persons, a careful distinction has to be made between accidents with and without a collision and the type of bus.
- Accidents without a collision caused by driving maneuvers occur chiefly in scheduled bus services; emergency braking plays an important part, head injuries being found most frequently. The injuries resulting from driving maneuvers are unfavorably influenced by the long distances standing passengers fall or by the seats being inadequately designed.
- In accidents with a collision, there are still substantial safety reserves for further bus development, above all in the area of active safety, although this also applies to passive safety to a limited extent.
- About 50 percent of the bus accidents in which occupants are injured occur when the road conditions are unfavorable.
- Considerable advantages are to be expected from the use of antilock brake devices in buses. About 40 percent of the collisions with injured passengers would be positively influenced by such a device. Most certainly 4 percent and probably as many as 15 percent of the accidents could be avoided.
- Although rollover accidents amount to only 7 percent of the bus accidents with a collision, they account for 85 percent of the persons killed and more than 50 percent of all seriously injured occupants. Most of the buses involved in this type of accident were long-distance coaches.
- A large proportion of the killed occupants were ejected out of the bus. If the risk of injury in rollover accidents is to be reduced below its present level, the occupant must be restrained in his seat by protective measures, such as a safety belt; in addition, it must be insured that the passenger space remains largely intact.
- The use of 3-point belts—in conjunction with an appropriate roof construction—would provide bus occupants with optimum protection, but this measure has to be discussed from the viewpoints of cost/benefits and acceptance.
- It has been observed that in rollovers with roof impact the interior is greatly restricted by the roof being bent away sideways; what is decisive is the diagonal loading of the roof posts, not the strictly vertical impact on the roof.
- In the case of technical innovations and their effect on bus safety, the fact that the life of buses is relatively long must, however, be considered, so it will take some time before technical improvements will begin to take effect on buses generally.

This study indicates possible ways of further improving the safety of omnibuses, but the economic costs and especially the need to coordinate safety standards on an international level will also have to be considered.

Acknowledgments

The authors are indebted to all the member insurance companies of the HUK-Verband, in particular, for

making their claims records readily available for this study, and to Messrs. Finkbeiner, Heider, and Zistler, members of the HUK staff who carried out accident analysis and evaluation work. The authors also owe a debt of gratitude to the various police departments whose active support made it possible to supplement the picture material already available.

Fatality Rates in Toyota Cressidas With Automatic Belts

Carl E. Nash and
Barry Eisemann
National Center for Statistics and Analysis,
National Highway Traffic Safety Administration

Abstract

Automatic belts in Toyota Cressidas have increased belt usage by front-seat occupants of these cars to more than 95 percent. This paper compares the fatal accident experience of these cars with that of the fairly similar Datsun (Nissan) 810/Maxima automobiles (which are equipped with manual belts used by about 20 percent of their occupants). It shows the result of the increased belt usage is a decrease in fatalities among Toyota front-seat occupants. In fatal accidents where no front-seat occupants of the Toyotas or Datsuns are killed, the Toyotas have a higher involvement rate than the Datsuns. Also, on average, the fatally injured front-seat occupants of the Toyotas are 7 years older than those in the Datsuns.

Background

The concept of an automatic safety belt has been around since the late 1960's. A paper presented at the First International Technical Conference on Experimental Safety Vehicles in Paris on January 27, 1970, by Mr. R.D. Lister of the United Kingdom discussed the development of a 3-point passive belt whose upper and lower outboard anchors attached to the rear of the door of an automobile and whose inboard anchor was attached to a reel located between the seats. An alternative design put the reel at the lower door anchor. Dynamic tests of this system at the Transportation Road Research Laboratory showed it to be ".. comparable with that of the conventional belt ..."(1)

In 1973, Volkswagen showed a prototype passive belt system in a Beetle. For each front-seat occupant, the VW system had only a shoulder belt attached between the top rear of the door and a reel between the seats. For lower body restraint, VW provided an energy-absorbing knee bolster at the lower edge of the instrument panel.

This system was commercialized in 1975 on the Volkswagen Rabbit and was offered on this vehicle in the United States throughout its production run. The Volkswagen design has an emergency release buckle located at the door frame, and an ignition interlock to prevent starting the vehicle if the belt is detached. However, the ignition interlock can be disabled by disconnecting a wire under the seat, or the belt can be detached after starting the vehicle without affecting its operation.

Belt usage in the Rabbits with automatic belts has been observed to be 76.6 percent in NHTSA's most recent 19-city survey(2). By comparison, belt use was observed to be 28.4 percent for manual-belt Rabbits in the same survey. The overall fatality rate, per registered vehicle year, in the Rabbits with automatic belts was 18.2 per 100,000 vehicle-years compared with 22.6 for manual-belt models(3). The automatic-belt cars had a fatality rate 19 percent lower than in Rabbits with conventional lap/shoulder belts.

Toyota Automatic Belts

All 1981 and later Toyota Cressidas have automatic belts. Toyota uses a track over the front door frame, a motor, and a plastic strip to move the upper end of the shoulder belt forward, out of the way, when the front door is opened and in place when the door is closed. Cressidas have knee bolsters for lower body restraint and manual lapbelts. Thus, when the belts are in place, they are similar in configuration to the VW belts except for the added manual lapbelts.

Since the Toyota automatic belts are not detachable, we expect (and observe) higher use rates with them than with VW automatic belts. Furthermore, because they automatically move well forward of the seat for entry, they are very convenient. Finally, since all Cressidas have four doors, the mounting point of the upper end of the belt is sufficiently forward that it does not put much pressure on the shoulder of an average person (although it may cut across the neck of a person of shorter stature).

The purpose of this paper is to assess the front-seat fatality rates in automatic-belt-equipped 1981-1984 Toyota Cressidas. In earlier work, NHTSA compared fatalities in the automatic-belt Cressidas with fatalities in pre-1981 Cressidas that had manual belts. The automatic-belt cars were found to have a 21 percent lower fatality rate than the manual-belt cars(4).

For the present work, we used the Datsun (Nissan) 810/Maximas, which are similar cars with manual belts, as the control fleet for comparison. Except for differences in the restraint systems, Cressidas and 810/Maximas are similar in size, weight, pricing and market class, body styles (4-door sedan and 4-door station wagon only), seating configuration (two individual front seats), drive train (front mounted, in-line 6-cylinder engine driving the rear wheels), and performance. We have no direct information on the demographics of the people who drive either model.

Analysis

Belt usage in Toyota Cressidas, as measured in the 19-city survey, was 97.5 percent, up from 95 percent a year earlier. This was measured in 1984, a period when no State had a mandatory use law, and when overall belt use in the survey was 14.4 percent(5). The comparable belt usage in Datsuns was 20 percent.

We used car-years of operation as a measure of exposure. U.S. calendar year sales figures from *Automotive News*(6) are shown in Table 1. We assumed they approximate new car registrations for the same model year. Further, we assumed the cars of a given model year began to go into service on October 1 of the previous year and continued to do so at a constant rate for 1 year until all new cars of that year were sold and registered. While this is an oversimplification, using the same basis for both Cressidas and 810/Maximas should minimize any error. We also assumed the driving patterns for the two cars are similar, although we have no direct information on this. The total number of car-years of operation is 322,000 for the Toyota Cressidas and 491,000 for the Datsun 810/Maximas.

Accident data for this paper are from the Fatal Accident Reporting System files for calendar years 1981 through 1984(7). Front-seat occupant fatalities are shown in Table 2. The rate of fatalities per registered vehicle-year is found by taking the ratio of front-seat occupant fatalities to the number of car-years of operation. The results of this analysis are shown in Table 3.

To test whether these two vehicle populations are otherwise alike in their fatal accident experience, we compared fatal accidents in which no front-seat occupants of these models were killed. Table 4 shows the result.

There were 41 such accidents for the Cressidas and 34 for the 810/Maximas during accident years 1981 through 1984 when 810/Maxima exposure was 50 percent greater than that of the Cressidas. Thus, the Cressidas were involved at a much higher rate than the 810/Maximas in fatal accidents in which someone other than a front-seat occupant was killed.

To see if there were other differences between the two car models, we looked at the age and sex of people killed in them. The occupants of the Toyotas were, on average, 7 years older than the occupants of the Datsuns. But the difference was most pronounced for those involved in multivehicle accidents where the average age of fatally injured Toyota front-seat occupants was 12 years older than the average age of similar Datsun occupants. Figure 1 shows the spread of ages of front-seat occupants of the vehicles.

The age spread of those killed mirrored the age spread of drivers of vehicles involved in all fatal accidents. For the Cressidas, the average age of drivers was 44, while the average age of drivers of the 810/Maximas was 39. There was little difference in the ages of male and female drivers or in the ages of drivers killed versus those who survived.

Since it is well known that older people are more susceptible to accident injuries, the reduction in front-seat occupant fatalities in the Cressidas is more striking. However, since we do not have information on the demographics and driving patterns of either vehicle, we cannot draw more qualitative conclusions from these data. We found no particular differences in the ratio of male to female fatalities in the two car models.

Ejections occurred mostly in single-vehicle accidents in both models. In the Datsun 810/Maximas, 15 of the fatally injured front-seat occupants were ejected while four of the Toyota Cressida front-seat fatalities were ejected. Most, although not all, ejections occurred when the vehicle rolled over in the accident. We do not know whether the ejected Toyota occupants were restrained by the lap and shoulder belts.

Table 1. Sales of Toyota Cressida and Datsun 810/Maxima models

	Model Year			
Make and Model	1981	1982	1983	1984
Toyota Cressida	29,583	37,448	39,755	34,456
Datsun 810/Maxima	35,853	54,187	76,209	68,209

Table 3. Fatality rates for Cressida and 810/Maxima front seat occupants

Model	Single-Vehicle	Multi-Vehicle	Overall
Toyota Cressida	3.7	5.3	9.0
Datsun Maxima/810	4.9	7.5	12.4

(Rates are per 100,000 vehicle-years of operation)

Table 4. Fatal accidents in which all front seat occupants of Cressidas and 810/Maximas survived

Model		Accidents with Fatalities in: Rear Seat	Pedestrian	Other Vehicle	Total
Toyota	Number	6	16	19	41
Cressida	Rate	1.9	5.0	5.9	12.7
Datsun	Number	1	16	17	34
810/Maxima	Rate	0.2	3.3	3.5	6.9

(Rates are accidents per 100,000 car-years of operation of the Cressidas or 810/Maximas)

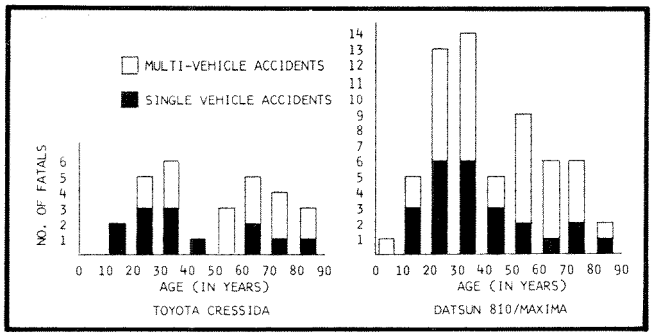

Figure 1. Numbers of front-seat occupants of Cressidas and 810/Maximas, by age groups, killed in accidents

Conclusion

We find the low fatality rates for front-seat occupants of the Toyota Cressidas with automatic belts to be generally consistent with the observed high belt use rate in them and the effectiveness estimated for automatic belt systems.

In short, the research demonstrated that belt use in the absence of belt use laws was significantly higher in the automatic-belt-equipped Cressidas than in the manual-belt-equipped Maximas. Consistent with the higher belt use, fatalities were significantly reduced.

Trends and Forecasts of the Japanese Traffic Accident Situation

Keiko Takegawa
Traffic Safety Policy Office, Director-General's Secretariat, Management and Coordination Agency

Abstract

The number of people killed in road traffic accidents in Japan had increased from year to year until 1970 and the number of deaths and injuries recorded in the same year were 16,800 and 980,000, respectively, or a total of nearly 1 million casualties, resulting in the introduction of the phrase "traffic war." Under these circumstances, insuring traffic safety became a top priority social issue, and, as part of a national attempt to cope with this problem, the Fundamental Law Related to Traffic Safety Measures was enacted in 1970. Based on this law, the national and regional governments pursued comprehensive and powerful traffic safety policies and measures in various areas, including the improvement and provision of traffic safety facilities. As a result, the number of deaths and injuries from traffic accidents in 1979 was reduced to approximately 8,500 and 600,000, respectively, the former representing a decrease by nearly half that recorded in 1970.

Since 1980, however, the trend has reversed, and the number of deaths has followed an upward path; the death toll has exceeded 9,000 for 3 consecutive years from 1982 through 1984. A prediction study conducted by the Traffic Safety Policy Office of the Management and Coordination Agency in 1984 estimates the number of deaths will continue to rise and will reach approximately 10,600 in 1990. To suppress this increase in the number of deaths, legislation that reinforces the compulsory use of helmets for moped drivers and seatbelts is planned for enactment in the near future.

Trends in the Traffic Accident Situation in Japan From 1960 to 1984

As shown on Figure 1, the number of deaths from traffic accidents in Japan continued to increase until 1970, and the annual death toll recorded in the same year reached 16,765. This figure of 16,765 is from police

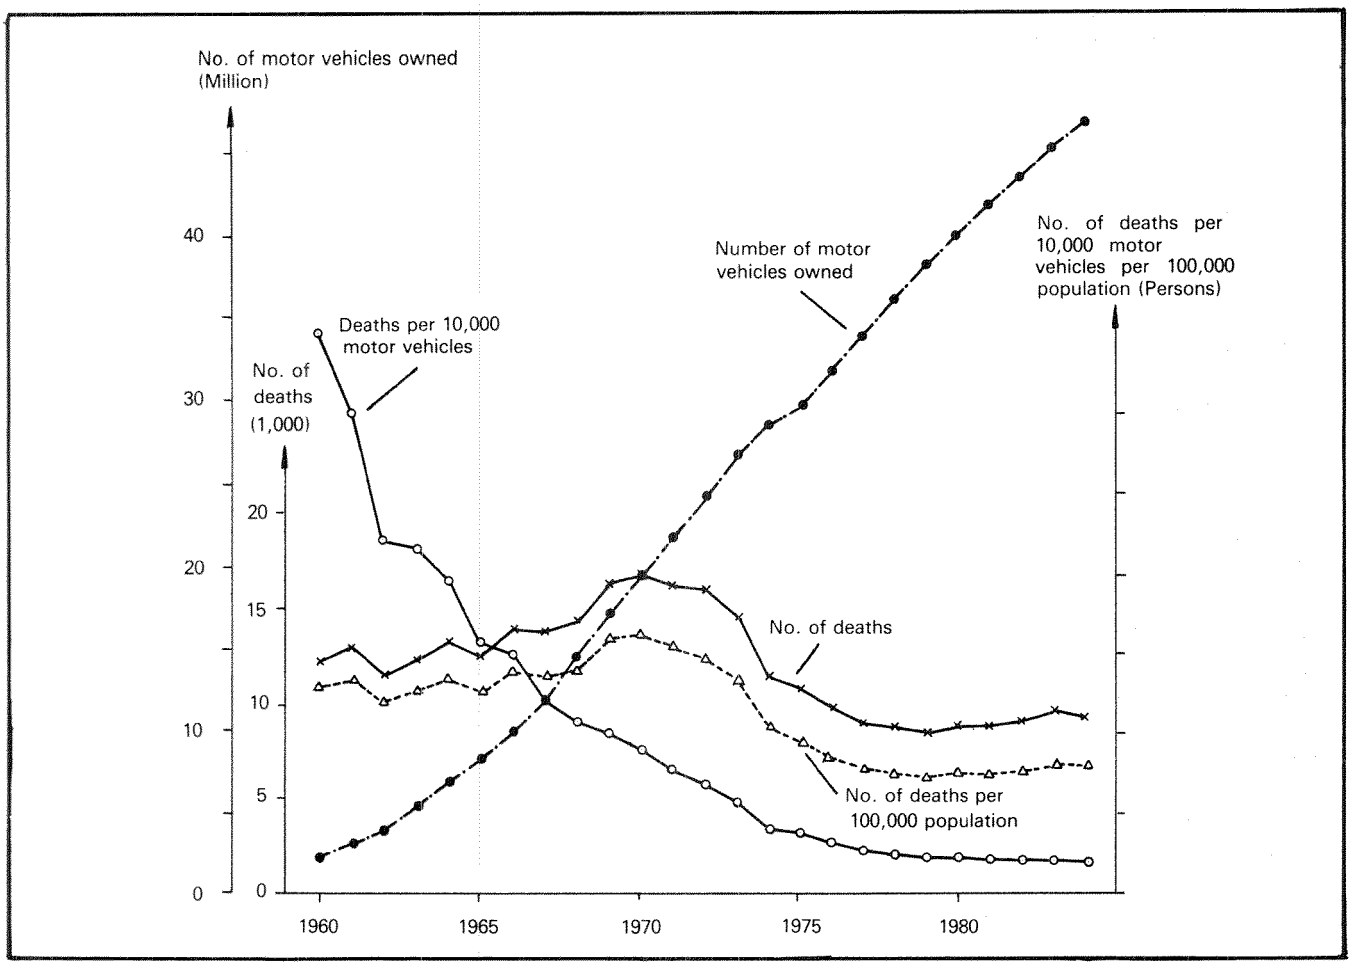

Figure 1. Traffic accident situation in Japan

statistics, for which prompt compilation is required, and refers to persons who die within 24 hours after the accident. The Ministry of Health and Welfare produces different statistics based on the number of all those who die as a direct result of the accident. According to these data, the death toll in 1970 was 21,101. In addition, the number of persons injured in the same year was 981,000, thus approximately 1 million people falling victim to traffic accidents in that year. It was during this time the phrase "traffic war" came to be widely used, and certainly the phrase was appropriate to describe a tragic situation producing an annual casualty toll of 1 million.

Under these circumstances, insuring traffic safety became a top priority social issue, and, as part of a national attempt to cope with this problem, the Fundamental Law Related to Traffic Safety Measures was enacted in 1970. Based on this law, the national and regional governments pursued comprehensive and powerful traffic safety policies and measures in various areas, including the improvement and provision of traffic safety facilities. As a result, the number of deaths from traffic accidents was reduced to 8,466 in 1979, or approximately half the number recorded in 1970. The number of injuries also decreased to 596,000.

However, the trend has reversed since 1980 and the death toll, which had continued to decrease for 10 years, began to show an upward curve. In particular, the death toll exceeded 9,000 for 3 consecutive years from 1982 through 1984, and the situation has been causing much concern. A slight decrease in the number of deaths has been recorded in 1984, but this may be attributed to the reduction in the amount of traffic due to heavy snow between January and March. Consequently, one should not hold an optimistic view that the trend in the death toll figure is headed downward. What has caused the trend of the number of deaths from traffic accidents to change from a downward to an upward curve?

Taking another look at Figure 1, one can see that though the number of those killed in traffic accidents has begun to increase since 1980, the number of deaths per 10,000 motor vehicles (excluding motorcycles) is stable. In Table 1, the figures corresponding to Japan not in parentheses have been taken from National Police Agency statistics; those in parentheses, from statistics by the Ministry of Health and Welfare. The figures corresponding to France and Italy represent deaths within 6 and 7 days, respectively, after the accident; the figures corresponding to the other countries refer to deaths within

Table 1. International comparison of traffic accident situations (1983)

Country	No. of deaths	Deaths per 100,000 population	Deaths per 10,000 motor vehicles
F.R.G.	11,732	19.1	4.2
France	11,946	21.9	5.0
Italy	7,685	13.5	3.6
Netherlands	1,756	12.2	3.4
U.K.	5,445	9.8	3.1
U.S.A.	44,600	19.0	2.7
Japan	9,520	8.0	2.1
	(12,919)	(10.8)	(3.0)

30 days after the accident. The table shows that Japan's traffic safety level ranks quite high in terms of both deaths per 10,000 motor vehicles and deaths per 100,000 population. Moreover, it can be seen from Figure 1 it would be quite difficult to substantially reduce the number of deaths per 10,000 vehicles from the current level. Meanwhile, the number of motor vehicles owned is expected to continue to climb. Will Japan have to experience another "traffic war"? A close look at the Japanese traffic situation follows.

Why Did the Number of Deaths From Traffic Accidents Begin To Follow an Upward Path Since 1980?

Figure 2 shows the trends in the number of deaths from traffic accidents by type of road user. It can be seen that though the total number of deaths has been on the increase since 1980, the tendency does not necessarily apply to all road user types. The frequency of deaths in pedestrian and bicyclist accidents has continued to follow a downward curve even after 1980. Figure 3 shows the total length of pedestrian/bicycle paths is presently five times that in 1970. The number of traffic signals has also increased by nearly six times. The decline in the number of pedestrian and bicyclist deaths can be attributed to such improvements in the provision of traffic safety facilities, promotion of traffic safety education for young children, etc.

As seen on Figure 1, the number of motor vehicles owned is now 2.4 times that in 1970 and is expected to continue to rise for some time. Meanwhile, as shown on Table 2, the number of motor vehicle occupant deaths per 10,000 motor vehicles had been decreasing since the 2.88 persons recorded in 1970 and has stabilized since 1979 at around 0.77 persons. Unless the number of motor vehicle occupant deaths per 10,000 vehicles is reduced, the death toll will continue to grow correspondingly with the number of motor vehicles owned.

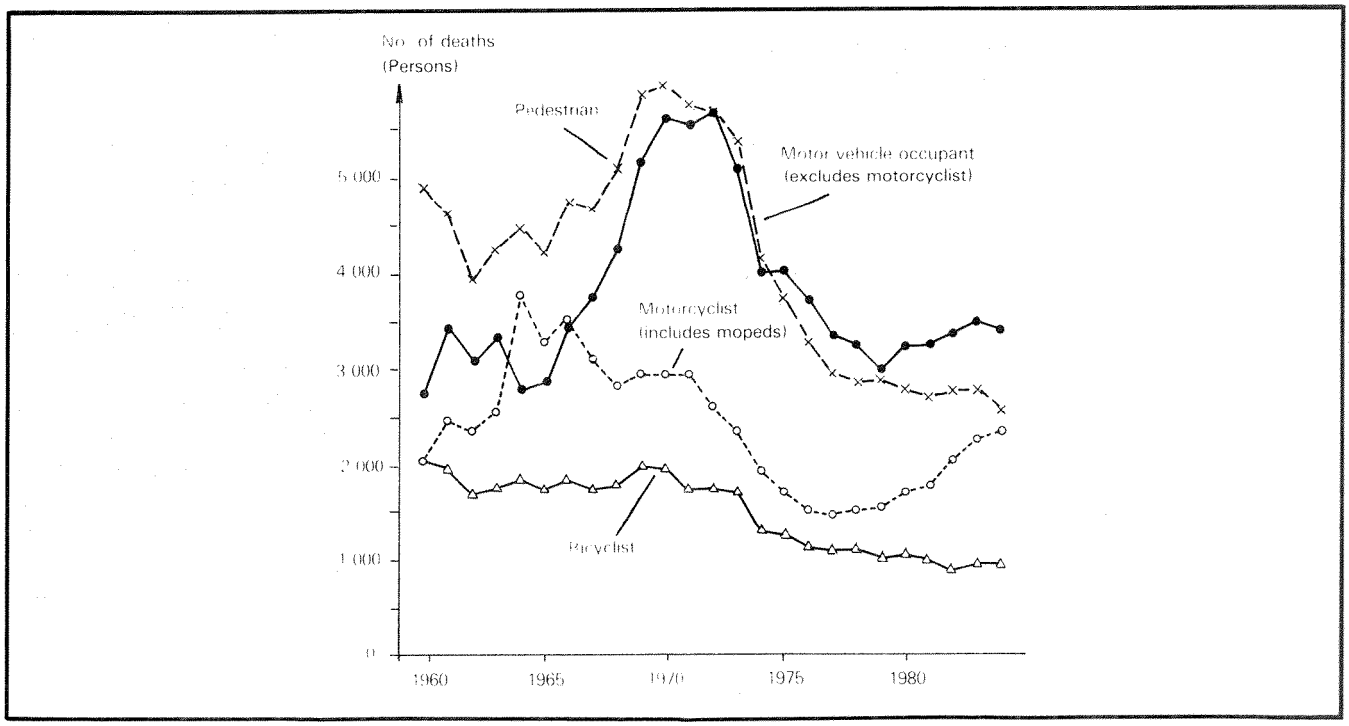

Figure 2. Trends in the number of deaths by type of road user

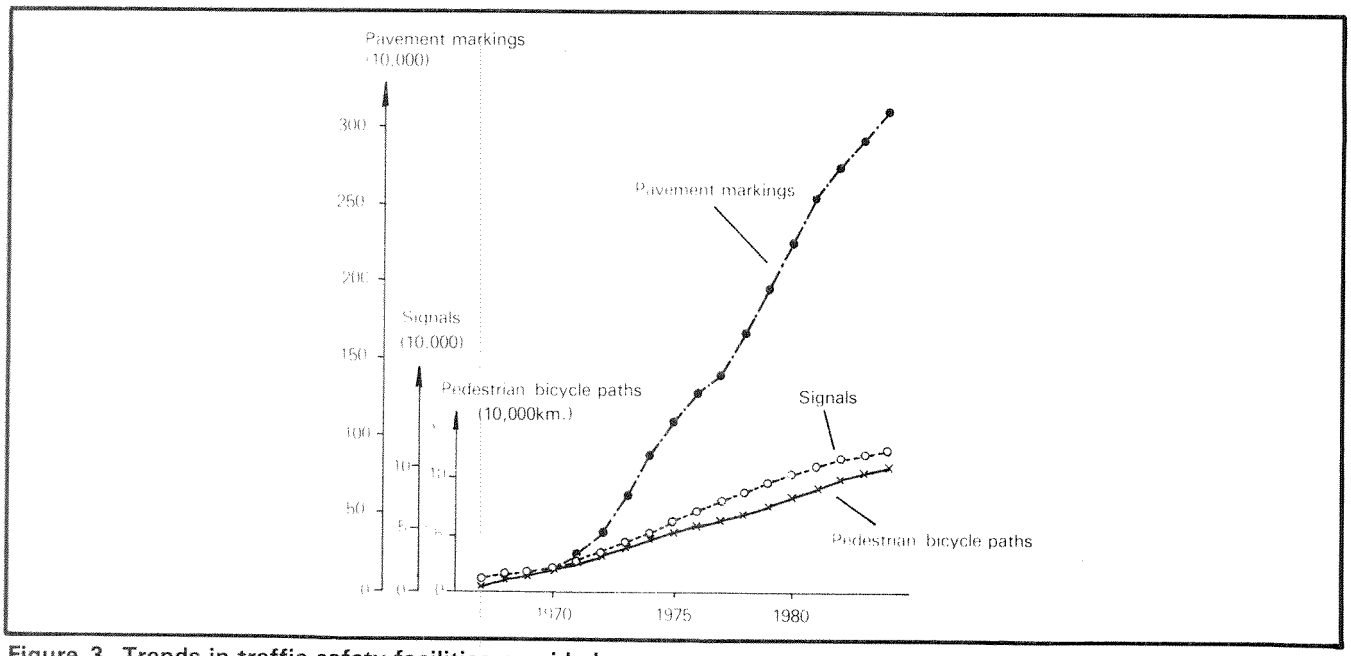

Figure 3. Trends in traffic safety facilities provided

The problem accumulating gravity in Japan in recent years is the growth in the number of motorcyclist (including moped) deaths. The trend of the number of those killed while riding motorcycles had already changed from a downward to an upward curve in 1978, and the death toll of 2,322 recorded in 1984 is 1.6 times the figure recorded in 1977, namely 1,467. Why has there been such an increase?

On Figure 4, one can see the number of motorcycles owned differs substantially among the four categories of motorcycles classified by engine capacity. It is further observed in Table 3 the number of those killed while riding the cycle per 10,000 cycles also varies considerably by cycle category. In the moped category of 50cc or less, the number of deaths per 10,000 cycles is low but the number of cycles owned is showing rapid growth; the number of cycles owned is decreasing but the number of deaths per 10,000 vehicles is low in the 2nd class moped of 51 to 125cc; the number of cycles owned in the light motorcycle category of 126 to 250cc is still relatively low but increasing in recent years and the number of deaths per 10,000 cycles is growing; in the motorcycle category of 251cc or more, the number of cycles owned is still low but climbing in recent years and the number of deaths per 10,000 cycles is dramatically high. These tendencies are reflected in the number of motorcyclist deaths shown on Figure 4. As in the case of motor vehicles, there is concern that the number of motorcyclist deaths will increase if nothing is done. Moreover, in addition to the rapid increase in the frequency of deaths, there are other factors that cause the motorcycle accidents to be viewed as a serious problem. The problem is further analyzed in the following section.

What Can Be Learned From the Number of Deaths in Various Road User Situations by Age Group?

Figure 5 represents the number of deaths in various road user situations by age group. With respect to motorcycles, distinction has been made between the motorcycles, whose engine capacity is more than 50cc, and the mopeds, which have a capacity of 50cc or less. It is observed that an overwhelming number of those killed while riding motorcycles are boys of upper secondary school age between 16 and 19. The same sex and age group also make up a large portion of those killed in moped accidents, but one sees a relatively large number of elderly as well as women are also killed in moped accidents. Hence it is the high number of deaths in youths, with long futures ahead, that adds to the gravity of the motorcycle accident problem. Concerned about this situation, a considerable number of Japanese upper secondary schools have implemented traffic safety campaigns, "Three-No-Movements," calling for the pro-

Table 2. Number of motor vehicle occupant deaths per 10,000 motor vehicles

1970	1971	1972	1973	1974	1975	1976	1977	1978	1979	1980	1981	1982	1983	1984
2.88	2.55	2.33	1.88	1.40	1.34	1.16	0.99	0.89	0.78	0.80	0.77	0.76	0.77	0.72

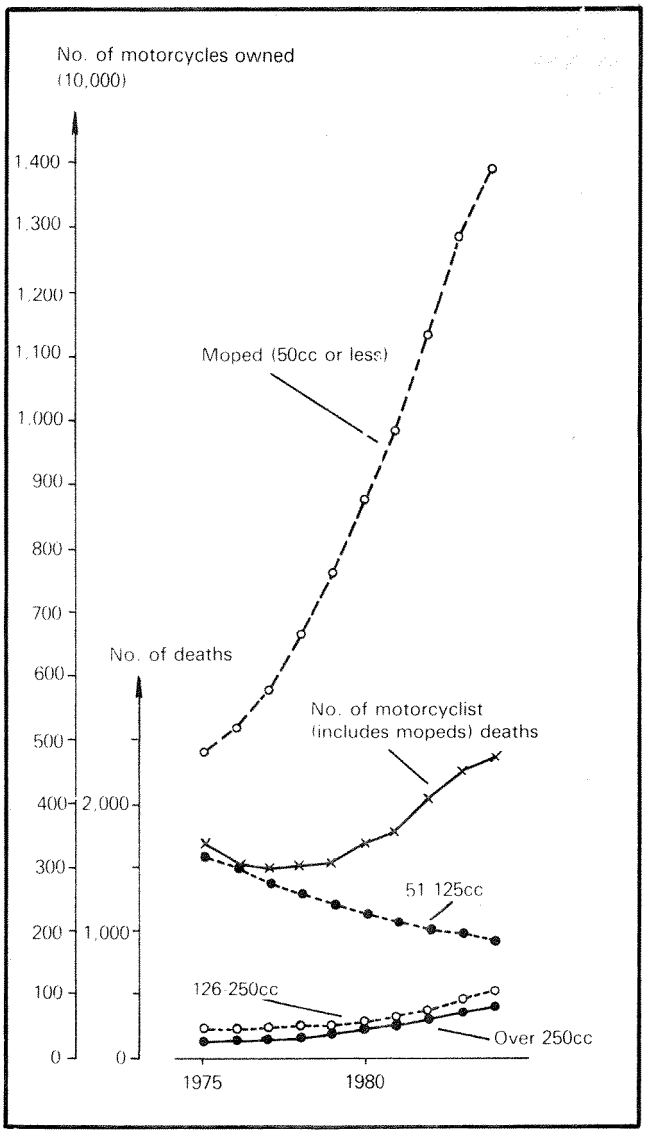

Figure 4. Number of motorcyclist deaths and number of motorcycles owned by cycle category

hibition of motorcycle purchase, motorcycle riding, and motorcycle license acquisition by their students.

The frequency of deaths in youths applies to motor vehicle accidents as well. In Japan, the legal age for riding motorcycles is 16 and that for driving motor vehicles is 18. Consequently, the peak in the death toll shifts between the two vehicle categories. In both cases, safety measures directed toward the young and beginner drivers are in urgent need.

With respect to bicyclists and pedestrians, the target populations are the children and the elderly. With the aged population, the problem seems to be not only the decline in their physical fitness but difficulty in adapting to the large amount of motor vehicle traffic, due to the relative delay of motorization in Japan. Thus, traffic safety education for senior citizens is more important today than ever before. With regard to children, the number of those killed in traffic accidents has steadily declined as a result of active efforts in traffic safety education through kindergartens and children's traffic safety clubs for preschool children between 0 and 6 and through elementary schools for children between 7 and 14. Nevertheless, the death toll is still high, and drivers are reminded through various traffic safety slogans to be particularly careful with children and elderly pedestrians.

Forecasting Traffic Accident Trends up to 1990

The Traffic Safety Policy Office of the Management and Coordination Agency has been issuing every 5 years since 1970 forecasts of traffic accident trends for the following 5 years. Accordingly, a forecast for the 5 years ending 1990 was undertaken in 1984 using the procedure described below. The procedure is also diagrammed in Figure 6.

First of all, in predicting the number of accidents, accidents were classified into five categories by the weaker party, namely, pedestrian accidents (all accidents involving pedestrians), bicycle accidents (all accidents involving bicycles but excluding pedestrian accidents), moped accidents (all accidents involving mopeds but excluding the preceding two), motorcycle (excluding mopeds) accidents (all accidents involving motorcycles but excluding the preceding three), and motor vehicle accidents (all accidents excluding the preceding four).

A multiple regression model that best describes the trends in the number of accidents in each prefecture by each accident category was produced, and the predicted numbers were substituted for the variables into the model to obtain the predicted number of accidents in each prefecture by accident category. The sum of the predicted figures for the 47 prefectures resulted in the national total of predicted number of accidents by accident category.

Table 3. Number of motorcyclist deaths per 10,000 cycles by cycle category

	1975	1976	1977	1978	1979	1980	1981	1982	1983	1984
Moped 50cc or less	1.51	1.38	1.30	1.14	1.03	0.97	0.87	0.82	0.79	0.76
51-125cc	1.34	1.14	1.13	1.04	1.01	0.98	0.83	0.94	1.03	1.06
126-250cc	1.73	1.55	1.55	1.24	1.61	1.85	2.31	3.38	3.96	3.64
Over 250cc	17.56	13.93	10.96	12.67	11.15	11.61	10.94	10.74	9.77	8.96

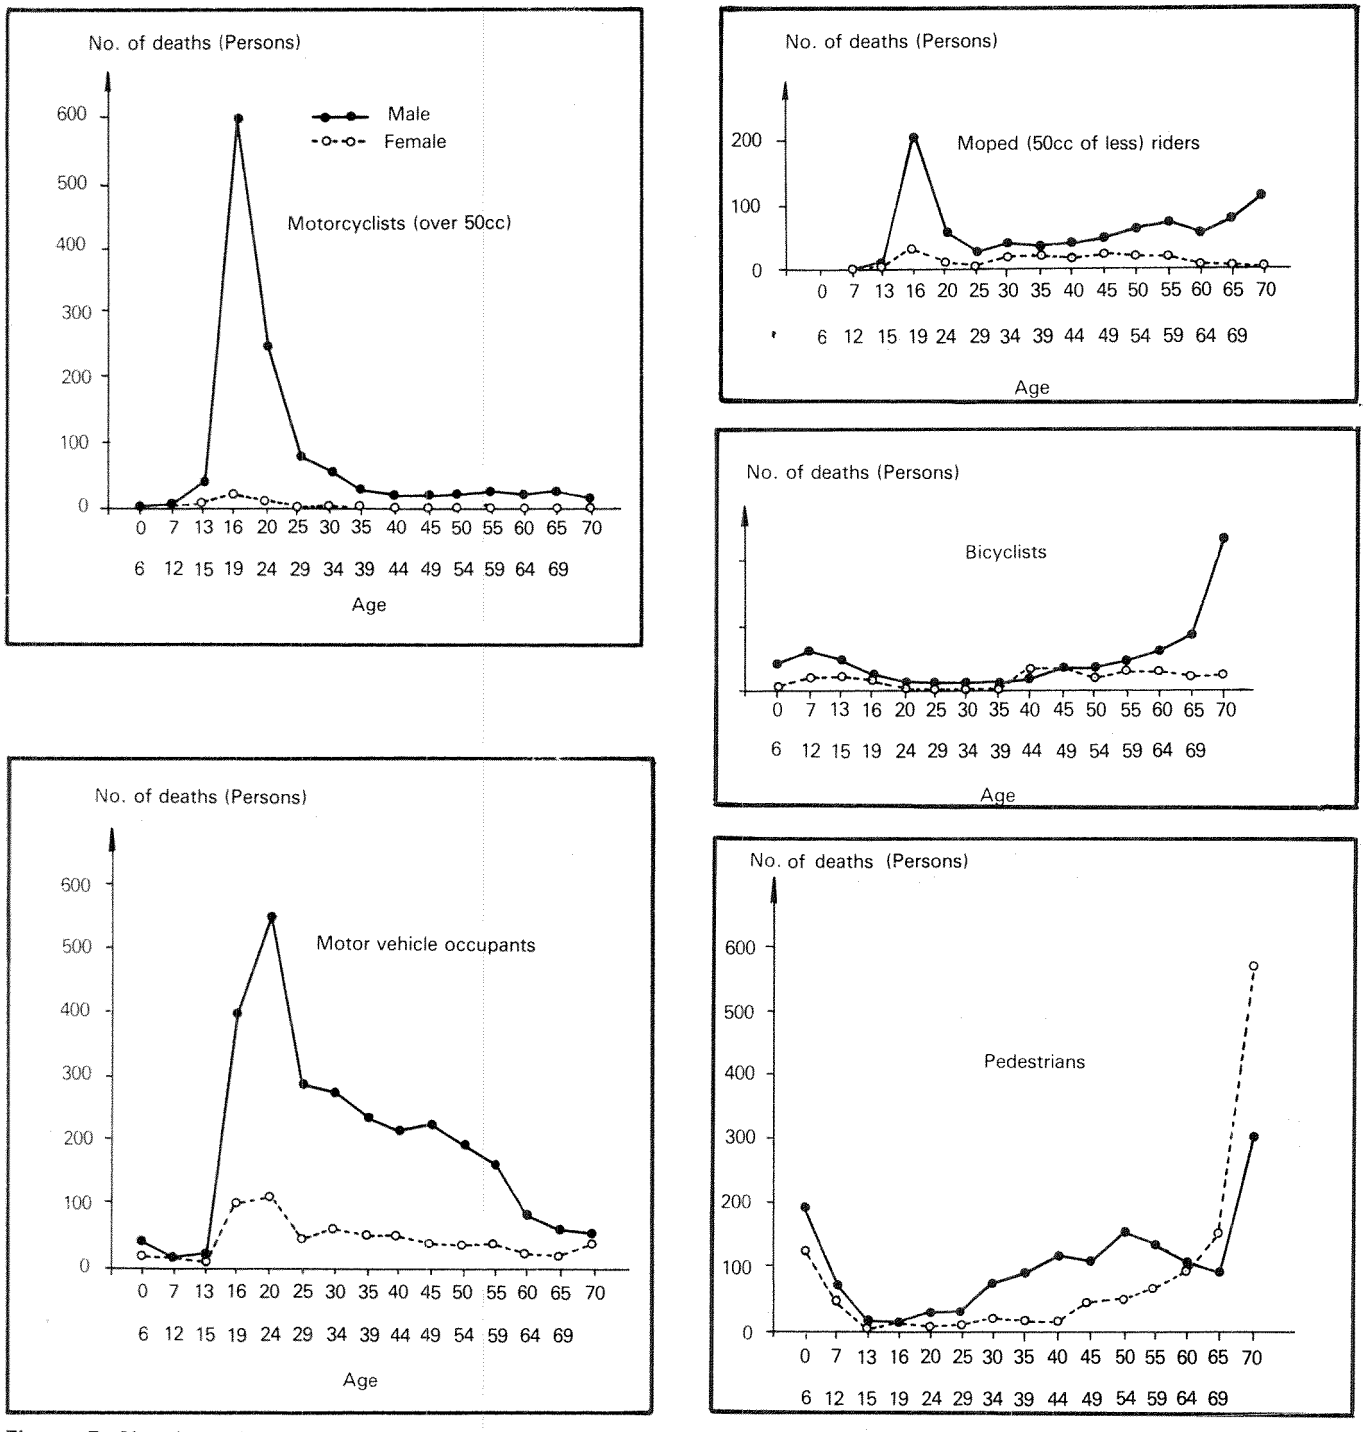

Figure 5. Number of deaths in various road user situations by age group (1983)

The forecast of the national death toll was calculated by first predicting the death rate by accident category (pedestrian death/pedestrian accident, etc.) in the same manner as that used for calculating the accident frequency above; then this death rate by accident category was weighted by the accident category structure ratio in each prefecture to produce the death rate in each prefecture. These prefectural death rates were then multiplied by the number of accidents in each prefecture to result in the prefectural death totals. The sum of these prefectural totals is the national death toll.

The national total of the predicted number of deaths by type of road user was obtained by multiplying the national total of the predicted number of accidents by accident category with the predicted death rate by accident category. In so doing, the predicted national death toll obtained above was established as the control total.

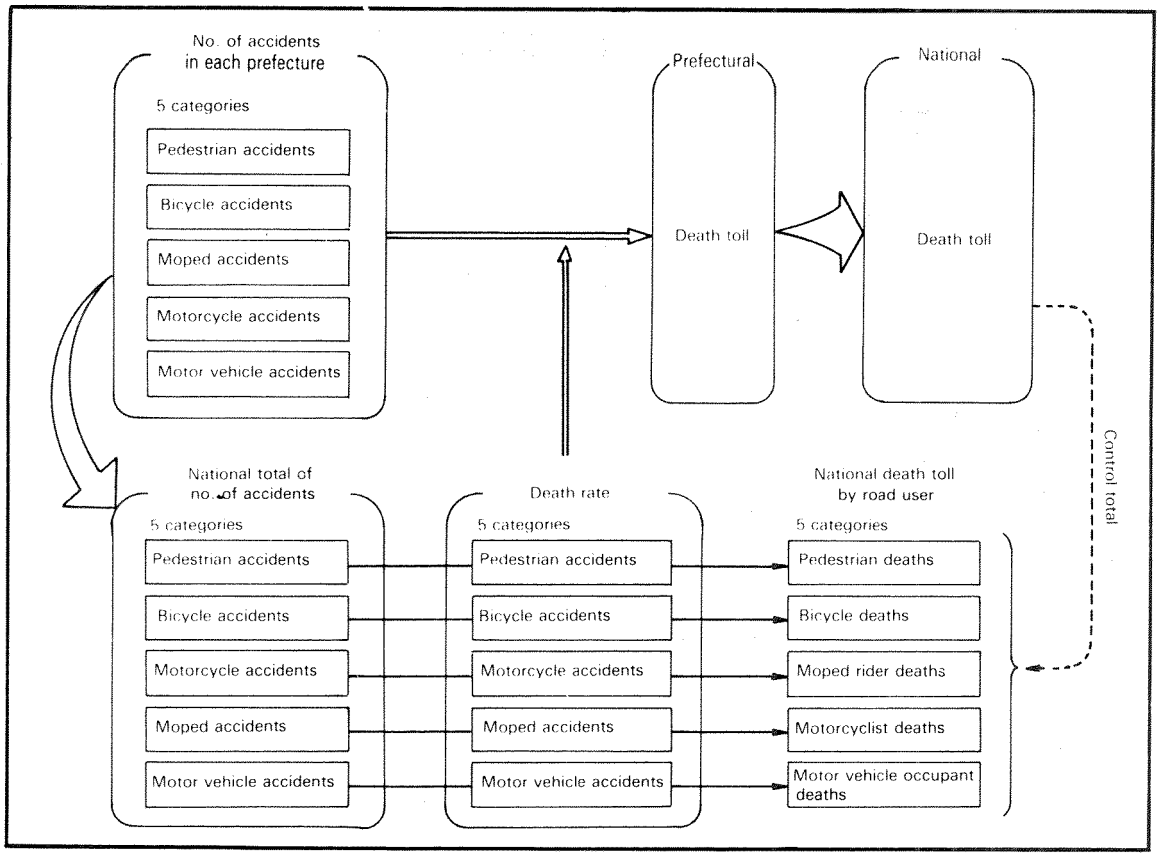

Figure 6. Traffic accident forecasting procedure

The result has been graphed in Figure 7. It estimates the total number of deaths at 10,600 in 1990. Taking a look at the figures by type of road user, one sees that the number of pedestrian or bicyclist deaths will be reduced to 2,600 and 700, respectively. On the other hand, however, the number of those killed while riding motor vehicles, motorcycles, and mopeds will each climb to 4,400, 1,500, and 1,400.

To cope with this anticipated increase, a legislation to reinforce the compulsory use of seatbelts for motor vehicles and helmets for mopeds will be enacted in the near future. The compulsory wearing of seatbelts and helmets is required in the existing law. However, the scope of application under the existing law is narrow, and no punitive measures accompany its violation. Consequently, the new law is designed to assign one penalty point upon its violation.

The Traffic Safety Policy Office of the Management and Coordination Agency has also conducted a prediction study of the effect of seatbelt and helmet-wearing. The study estimates that a seatbelt use rate of 90 percent will reduce the number of deaths by approximately 2,000, and a helmet wearing rate of 100 percent by moped riders will decrease the death toll by about 350, thus holding the total number of those killed at approximately 8,200 in 1990.

Furthermore, mopeds, as a rule, will be required to make right turns on roads with three lanes or more on one side by going through two traffic signals, just as bicycles and pedestrians, under this new legislation.

In addition, Tokyo has experimentally introduced double-stage right-turn signals (completely separate signal indications for vehicles proceeding straight and those making right turns), double stop lines at intersections (a separate stop line for motorcycles located ahead of the stop line for other vehicles, which is expected to reduce the number of accidents in which motor vehicles turning left entangle motorcycles, and collisions between motor vehicles making right turns and motorcycles proceeding straight), and installation of exclusive lanes for motorcycles as safety measures for motorcycles.

Future of the Motorized Society

Figure 8 shows that though the growth rate has recently declined a little, the number of passenger vehicles is still climbing at a rapid pace. The number of trucks in recent years shows a tendency of leveling off or a slight decrease. The number of light motor vehicles has started to rise rapidly since 5 years ago.

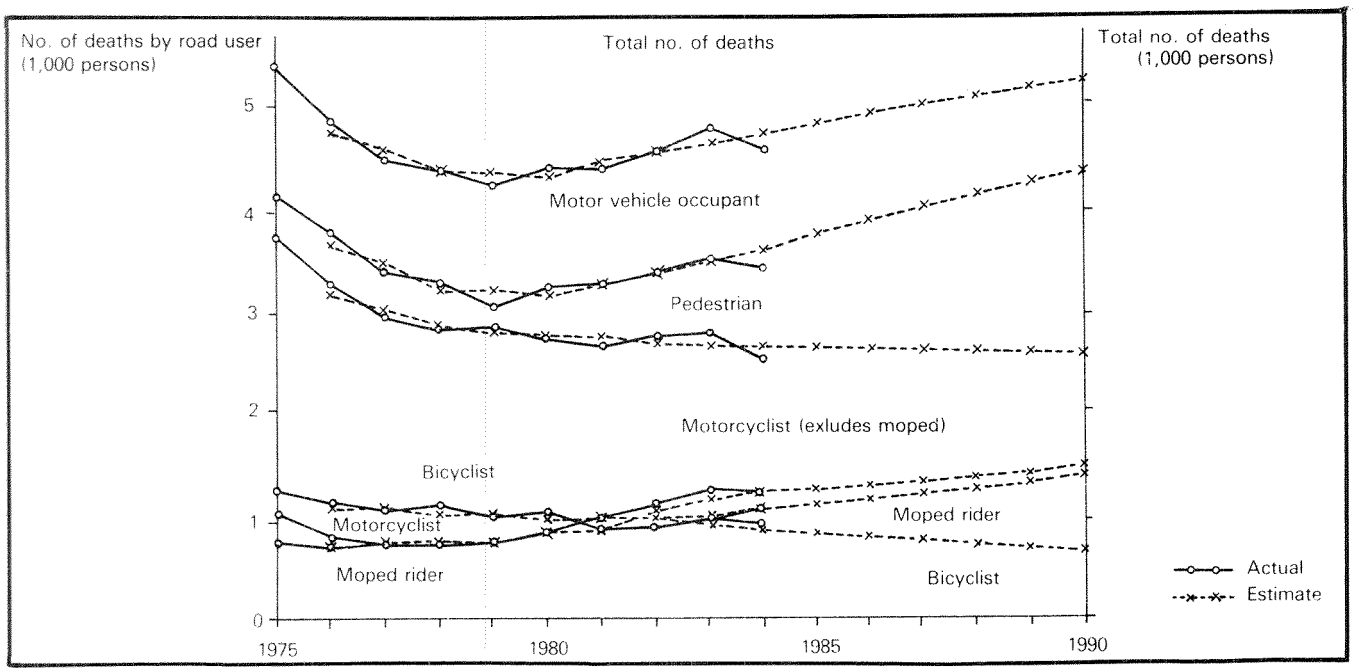

Figure 7. Forecast of traffic accident deaths up to 1990

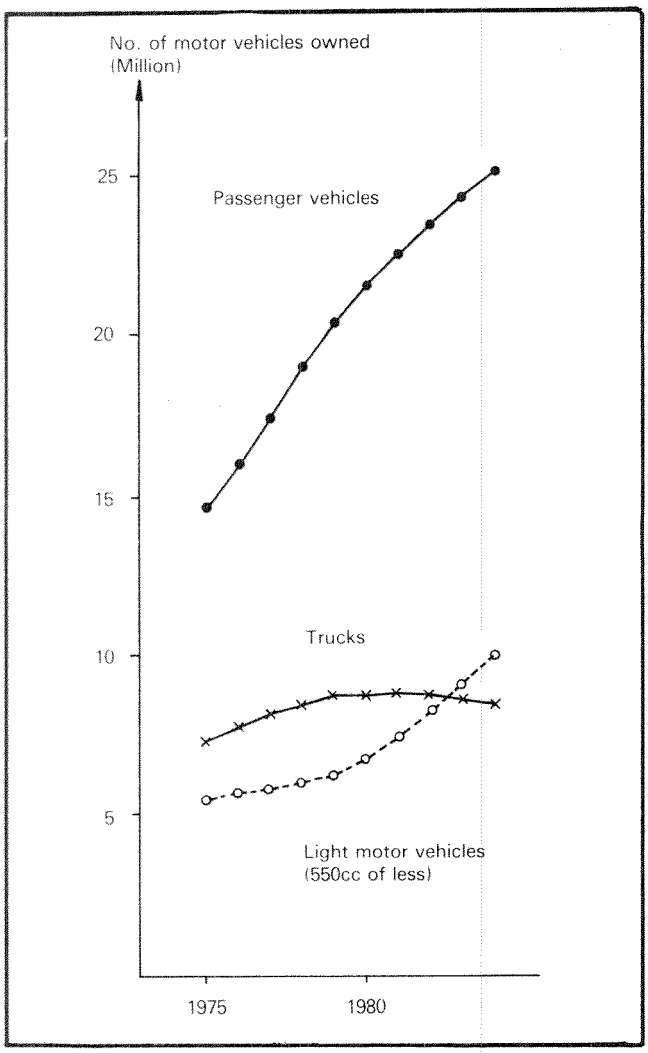

Figure 8. Trends in the number of motor vehicles owned

Motorization began relatively late in Japan, and, therefore, the number of driver license holders in the elderly age group is relatively low, as shown in Figure 9. However, the number of aged with a driver's license is expected to rise sharply in the future. Similarly, the number of women possessing driver's licenses had been relatively low hitherto but has been growing rapidly and is expected to continue to grow in the future.

In the past, it was mainly the young male population that shaped the motorized society. However, this society is expected to change into a diversified society participated in by a variety of population in terms of age group and sex. Accordingly, the types of vehicles in demand will also diversify.

With the coming of such a motorized society showing growth both in terms of size and diversification, it is absolutely necessary to reduce the number of those killed per 10,000 motor vehicles, which seems to have stabilized. This may not be easy, as seen above; however, unless this is accomplished, it is inevitable the number of those killed in traffic accidents will continue to rise correspondingly with the increase in the number of motor vehicles owned. In this context, it might be said that traffic safety measures must now make a new turn to meet this challenge. The reinforcement of compulsory use of helmets for moped riders and seatbelts for automobile occupants is one of such efforts. It is important that each motor vehicle is safe for its occupant and, of course, for the pedestrians and bicyclists. Furthermore, it is essential that parties concerned develop constructive ideas in the areas of traffic regulations, road structure, traffic safety education, etc., to pursue comprehensive traffic safety policies and measures.

The Safety Performance of Production Vehicles in Side Impacts

Hampton C. Gabler III
Transportation Systems Center, Research and Special Programs Administration, U.S. Department of Transportation

James R. Hackney
National Highway Traffic Safety Administration, U.S. Department of Transportation

Abstract

The National Highway Traffic Safety Administration (NHTSA) has tested 12 current production cars in a series of controlled side impacts. As measured by the impact responses of NHTSA side impact dummies, the cars were found to vary dramatically in their capability to provide occupant protection. For the median-aged side-struck occupant, the potential for serious thoracic injury was found to range from a low of 9 percent for the 4-door AMC Concord to a high of 97 percent for the 2-door Nissan Sentra.

This paper investigates these differences in safety performance and reports those vehicle design parameters that are key to thoracic side impact protection. From the available data, the study concludes that the design parameter most crucial to occupant protection in side impacts is the Door Effective Padding THickness (DEPTH).

Problem Statement

NHTSA has undertaken a research project to characterize the safety performance of the vehicle fleet in side impacts and evaluate the feasibility of improving occupant protection in side impacts. The results of the NHTSA Thoracic Side Impact Protection Program are presented by Hackney(1). In that study, 10 current production passenger cars were tested in side impacts and found to vary dramatically in their capability to provide occupant protection.

The objective of this paper is to investigate these differences in safety performance and suggest design parameters that are key to thoracic side impact protection.

Background

This section presents an overview of those findings of the NHTSA Thoracic Side Impact Protection Program (TSIP) that bear on the safety performance of current production vehicles. Two additional tests not presented in (1), a Dodge 400 and a third Chevrolet Citation, are included in the discussion below.

Vehicle Crash Test Description

The accident configuration for the TSIP crash test series was designed to be representative of the side impact environment. The National Crash Severity Study (NCSS) accident files revealed that the most prevalent side impact angle was 90°. The NCSS files further showed the threshold for serious injuries occurs at a striking/struck vehicle velocity ratio of 30/15mph.

Based on the statistics presented above, the accident configuration chosen for actual crash testing was a 90° impact at a striking/struck vehicle velocity of 30/15mph. The striking vehicles in all cases were 3,000 lb movable deformable barriers with frontal force-crush characteristics near the upper bound of production vehicles. To represent the fleet, 12 production cars, listed in Table 1, were chosen for testing as a struck vehicle.

Table 1. Twelve production vehicles

1981	Chevrolet Citation	4 door	*
1982	Chevrolet Citation	2 door	
1981	Plymouth Horizon	4 door	
1981	Dodge Omni	2 door	
1981	Ford Granada	2 door	
1981	Ford Granada	4 door	
1980	AMC Concord	4 door	
1982	Nissan Sentra	2 door	
1981	Volkswagen Rabbit	2 door	
1982	Honda Civic	4 door	
1982	Dodge 400	2 door	

*Two tests were conducted on this model

All impacts were delivered to the occupant compartment on the driver's side of the struck vehicle approximately 37in forward of the centerline of the front and rear wheels as shown in Figure 1.

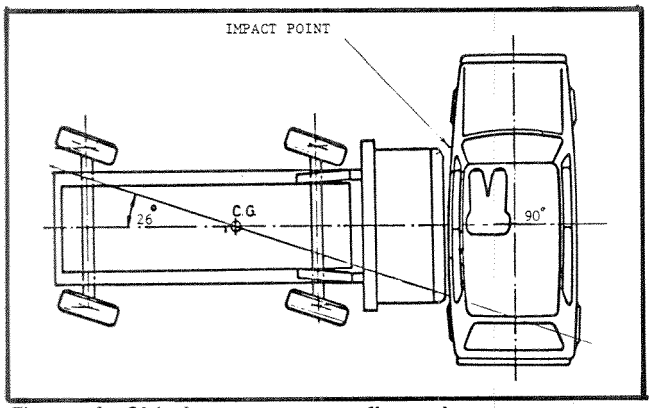

Figure 1. Side impact test configuration

Occupant Instrumentation

To measure the dynamic response of occupants, each crash test used two NHTSA Side Impact Dummies (SID). One SID was positioned in the driver's seat, and the second SID was positioned in the rear seat behind the driver. The dynamic impact lateral response of each SID was recorded by the following accelerometers:

- Lower left rib (primary)
- Lower left rib (redundant)
- Upper left rib (primary)
- Upper left rib (redundant)
- Lower spine (primary)
- Lower spine (redundant)
- Pelvis
- Head

In the results that follow, the primary and redundant channels for the rib and spine were averaged prior to use.

Occupant Responses

The peak occupant responses and the thoracic probability of injury are tabulated in Table 2 for each crash test. The peak rib and spine accelerations were used to predict the probability of thoracic injury for 23- and 41-year-old occupants. The 23-year-old occupant corresponds to the median age for side-struck occupants. The 41-year-old occupant corresponds to the median-aged side-struck occupant incurring thoracic injuries of AIS >= 3. Both ages are based on NCSS data.

By using the Thoracic Trauma Index developed by Eppinger(2), the SID responses can be related to the probability of thoracic injury. The Thoracic Trauma Index (TTI) is defined as follows for a 50-percentile human:

$$TTI = 1.4*Age + 0.5*(ribg + t12g)$$

where

Age= age of the occupant

ribg= max (lurg, llrg)

lurg= left upper rib peak acceleration

llrg = left lower rib peak acceleration

t12g= lower spine peak acceleration

For our study, the SID peak rib acceleration was first adjusted as shown below(1,2) to approximate the response that would be seen by a human:

ribg = SID ribg for SID ribg <= 60

ribg = (SID ribg)*0.5 + 30 for SID ribg > 60

The TTI was used to predict the probability of injury at the Abbreviated Injury Scale (AIS) levels of 3, 4, and 5. The relationship between the TTI and the probability of injury is shown in Figure 2.

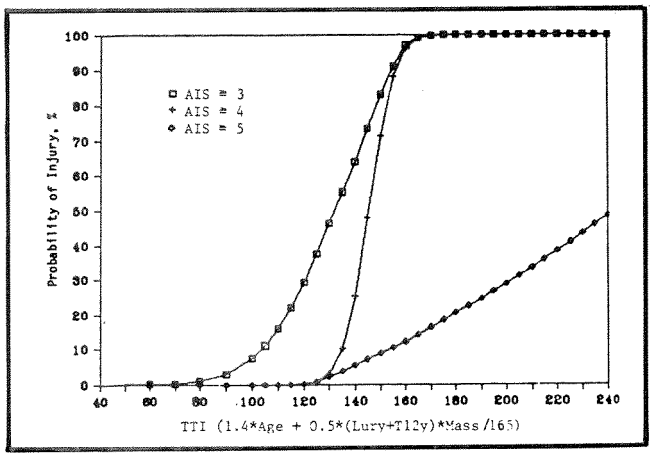

Figure 2. Thoracic trauma index

The probability of injury for each of the crash tests is given in Table 2 and ranked in Figures 3 and 4. The probability of injury varies widely among the tested struck vehicles. Injuries of AIS >= 3 for a 23-year-old driver vary from a low of 9 percent for the 4-door AMC Concord to a high of 97 percent for the 2-door Nissan Sentra. Injuries of AIS >= 4 fs4 for a 41-year-old driver vary from a low of 1 percent for the Concord to a high of 100 percent for the Sentra. These findings indicate that current production passenger vehicles vary substantially in their capability to provide occupant protection.

Other Aspects of Vehicle Safety Performance

In addition to the thoracic safety performance evaluation of the production vehicles, other safety-related performance aspects were noted during the crash test series. In two of the cars, the Honda Civic and the Plymouth Horizon, the right front passenger door opened during the crash event and allowed ejection of the driver from the vehicle. In the Plymouth Horizon test, the driver actually came to rest on the surface of the test track. In the Honda Civic test, the driver was not fully ejected.

In the test of the 4-door Ford Granada, the driver side B-pillar buckled significantly during the crash event. Post-test inspection showed that the spot welds at the base of the B-pillar had failed during the impact. This quality control problem with poor welds has been a common problem seen in other experimental side impact tests.

Occupant Responses vs. Vehicle Characteristics: Theory and Methodology

The objective of this paper is to determine what parameters of the struck vehicle design are most influential in affecting the occupant impact responses. The investigation will be limited to the responses of the driver.

In general, the occupant response to impact is a function of several parameters:

$$Rv = F(A, Di, Dv)$$

$$Ro = G(Rv, Dc)$$

where

Rv = response of the struck vehicle
Ro = response of the struck occupant
A = accident configuration
Di = structural design of the impactor
Dv = structural design of the struck vehicle
Dc = design of the struck vehicle occupant compartment

The response of the struck vehicle is a function of the accident configuration, the design of the impactor, and the design of the struck vehicle. The vehicle design includes both the energy-absorbing capability and the geometry of the structure. The accident configuration description includes the impact velocity, the impact angle, and the impact point. The response of the struck vehicle is described in terms of its acceleration profile upon impact and the intrusion of the door into the occupant compartment.

The response of the struck occupant is a function of the vehicle impact response and the design of the occupant compartment. In the case of side impact, the occupant compartment design includes both the energy-absorbing characteristics of the door and the initial occupant-to-door clearances.

In our study, the designs of the impactor and the accident configuration were held constant for each of the crash tests. With these constraints, the computation of the occupant responses becomes a simplified function of the energy-absorbing capability of the vehicle and the design of the occupant compartment. Symbolically, the relationship becomes:

$$Ro = G^*(Dv, Dc)$$

where G* represents a reduced form of the function G described above.

In this paper, we will mathematically search for the relationship between occupant impact responses and vehicle design parameters. First, we will characterize the design and response of each vehicle as a set of discrete parameters. Second, we will use a stepwise regression technique to determine occupant response as a function of the vehicle response. Finally, we will examine the results of the regression analysis to identify those design parameters most critical to occupant protection in side impact.

Vehicle Characteristics

For this study, the characteristics of the vehicle design and the occupant compartment design were divided into three categories:

- Vehicle geometry and mass
- Vehicle structural response
- Door structural response

Vehicle Geometry and Mass

For our investigation, the geometry and mass of each vehicle were described with the following 10 parameters:

- Number of doors
- Vehicle weight
- Wheel base
- Vehicle length
- Vehicle width
- Vehicle center of gravity
- Arm to door initial clearance
- H-point to door initial clearance
- Axle height
- H-point height

These parameters are tabulated in Table 3 for each vehicle—with the exception of the axle and H-point height. The axle height and the H-point height are tabulated in Table 4.

*Static crush averaged over interval from 30" to 42" from impact target point

Struck Vehicle Impact Response

The struck vehicle impact response was described with the following three parameters:

- Lateral Delta-V
- Static Crush (axle height)
- Static Crush (H-point height)

These parameters are tabulated in Table 4 for each vehicle.

Delta-V, the change in struck car velocity, was computed from an accelerometer mounted on the front door sill on the undeformed side of the car. Static crush, tabulated at axle height and H-point height, is an average of post-test measurements taken over a range from 30in to 42in rearward of the targeted impact point. This area, on the side of the car, encompasses the location of the driver.

Door Impact Response

The door impact response was described with the following six parameters:

- Door-to-pelvis contact velocity
- Door-to-lower rib contact velocity
- Door-to-upper rib contact velocity
- Door effective padding thickness at the pelvis
- Door effective padding thickness at the lower rib
- Door effective padding thickness at the upper rib

The door structural parameters are tabulated in Table 5 for each vehicle. Door effective padding thickness measurements are unavailable for the Volkswagen Rabbit as all impactor accelerometer channels were lost during that crash test.

Door Kinematics Model

The calculation of door contact velocity and effective padding thickness uses a variation of the method proposed by Strother and Morgan(3). In their idealized representation, the side impact is modeled as a one-dimensional system that can be readily analyzed from the velocity time traces of the system components.

The velocity time history of the impactor center of gravity, the door, and the occupant is shown in Figure 5. Door contact time, t3, is defined as the time at which the occupant velocity first becomes greater than zero. From the time of door contact, the contact velocity can be determined from the door velocity history. The relative displacement between the vehicle and the occupant can be determined by computing the area between the appropriate two velocity traces over the time interval of interest.

In this paper, we define a new parameter—the door effective padding thickness or DEPTH. DEPTH is defined as the relative displacement between the door and occupant from the time of contact, t3, until the time of separation, t4. From the crash observer's perspective, DEPTH is the amount the occupant crushes the door.

DEPTH is the maximum deflection measured between the occupant accelerometer and the door accelerometer. Depending on the location of occupant instrumentation, this will include a portion of the dummy compression as well as the crush of the door. As measured by the rib accelerometers, DEPTH includes compression of the dummy skin between the ribs and door surface. The effect of skin compression is considered negligible. Likewise, compression of the dummy at the pelvis contact point is considered insignificant as the pelvis is rigid.

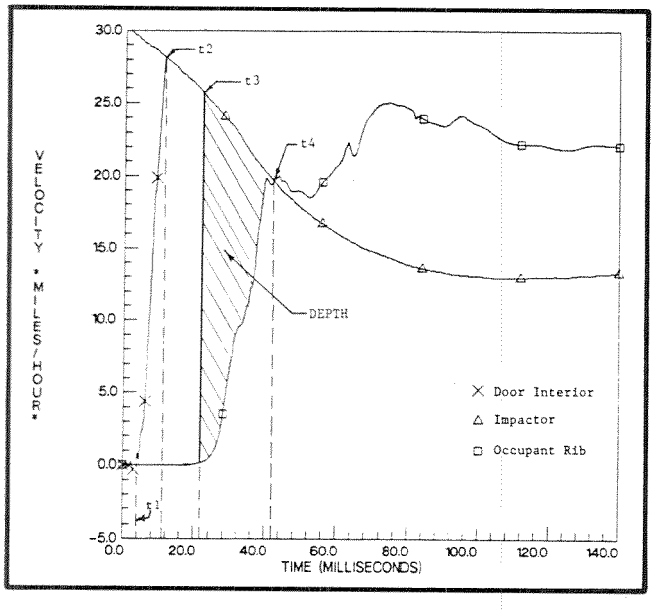

Figure 5. Door-occupant kinematics

Door Kinematics Model: An Example

Following is an example of a side impact event, as seen by the door kinematics model. This hypothetical scenario will demonstrate the physical nature of the DEPTH quantity and clarify the framework we have used to categorize our side impact tests. For our example, we will use one of the rib accelerometers to represent the occupant. However, the scenario applies equally to the pelvis. The door reference point, which we discuss below, physically refers to a hypothetical location within the door interior and not to either the door exterior or interior skin.

The side impact event can be separated into two sequences of events. The first is the deformation of the door interior as a result of the collision with the impactor. The second is the deformation of the door interior as a result of occupant impact. The deformation of the door exterior begins immediately upon impactor contact with the door exterior at t = 0. Although the door sheet metal begins to buckle immediately, the door reference point does not begin to accelerate until time t = t1 (typically about 3 to 4ms after impact). The door reference point ramps up quickly in velocity until such time, t = t2, as the door velocity and the impactor velocity are equal. Between time t = 0 and t = t2, the door exterior and impactor are crushing under the forces of impact. Using our model, we assume the deformation of the door exterior ends at t = t2.

At some time later, the occupant-to-door impact, the so-called second collision, begins. Initially, the door reference point and the occupant's rib are separated by the door-to-occupant clearance as well as the undeformed thickness of the door. Upon impactor contact with the car, the occupant begins to slide laterally across the seat toward the inside surface of the door. At time t3, the occupant collides with the door inside surface. By his own inertia, the occupant proceeds to intrude into the door—crushing the door interior structure and compressing the occupant's thorax in the process. Occupant intrusion into the door continues until t = t4 when the impact energy of the occupant is expended, and the occupant velocity equals the door velocity. The maximum intrusion of the occupant, reached at t = t4, is defined as DEPTH.

Analysis Using the Door Kinematics Model

In our crash tests, the inner panel of the driver's door was instrumented with 3 to 4 accelerometers. Because of the severity of the impact to the door, few of the door accelerometers survived the crash test or provided meaningful data throughout the entire event. Within 20ms of initial impact, the majority of the door accelerometers had either been physically damaged or had rotated in such a manner that their sensitive axis was no longer aligned with the direction of impact.

Examination of the door acceleration channels prior to accelerometer damage, however, does provide one important clue to the door behavior. In all cases, the velocity of the door inner panel ramps up quickly and appears to reach the impactor velocity very early in the event, i.e., t2 = 8-13ms. Beyond t = t2, the door acceleration measurements are of questionable validity. From t = t2 until the impactor and struck vehicle separate, the door (as opposed to the door inner panel) is assumed to move together at the same velocity. This assumption implies that all exterior vehicle crush and impactor crush have occurred by the time of occupant contact. It should be emphasized that while these assumptions are well suited to our study, i.e., for 30/15mph 90° side impacts, their applicability to other studies is not guaranteed—especially when extrapolated to alternate accident configurations.

For our study, the door contact was defined to have taken place once the occupant velocity exceeded a threshold velocity of 0.2mph. The time of door-to-occupant contact was computed for each of the cars and found to vary from 17 to 27ms for both the upper and lower rib, and from 12.5 to 20ms for the pelvis. For our study, the door is assumed to reach the impactor velocity prior to contacting the occupant, i.e., $t2 < t3$. Door contact velocity is then equal to the impactor velocity at the time of contact. The time of door/occupant contact, t3, and the time of door/occupant separation, t4, are tabulated in Table 6 for the 12 tested vehicles.

Door contact velocity was found to vary only slightly from car to car. Door contact velocity at the left upper rib varied from 25.2 to 27.1mph. Door contact velocity at the left lower rib varied from 25.2 to 26.8. Door contact velocity at the pelvis varied from 27.1 to 28.3.

DEPTH, at the pelvis and ribs accelerometers, was determined by computing the relative displacement between the door and occupant from the time of contact, t3, until the time of separation, t4. Once again, for $t > t3$, the door velocity is assumed to equal the impactor velocity.

Occupant Responses vs. Vehicle Characteristics: Regression Analysis

Comparison of the vehicle characteristics versus measured occupant responses suggests that lower peak occupant accelerations are observed in vehicles with a greater DEPTH. To statistically determine the relationship between the vehicle design and occupant injury, the vehicle structural characteristics and occupant responses were paired and examined through stepwise regression. The computed linear fits are shown below and presented in Figures 6a, 7a, 8a, 9a, and 10a.

PELG	=	318.3 + -18.1*Dpel + -5.6*Dlur	R**2 = .876

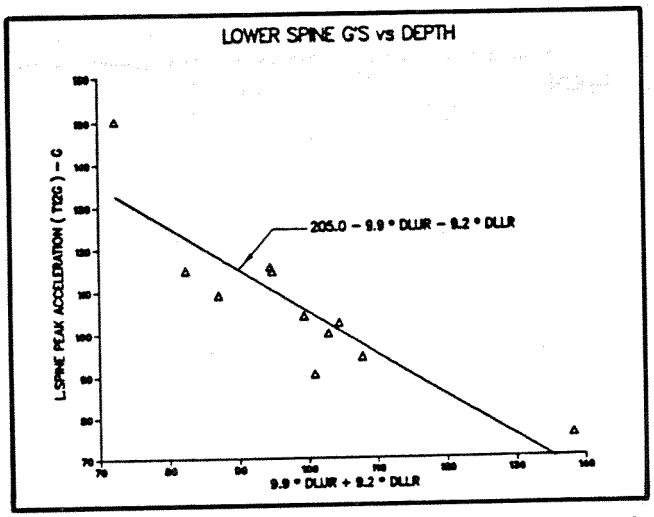

Figure 8A. Lower spine peak acceleration versus DEPTH at the upper rib and lower rib contact points (R^2 = .783)

After substituting the average DEPTH for the DEPTH at the individual body regions, the stepwise regression was completed a second time. The computed linear fits are shown below and presented in Figures 6b, 7b, 8b, 9b, and 10b.

The Importance of DEPTH

These mathematical fits indicate that sufficient DEPTH is crucial to providing the occupant with impact protection. Those vehicles with only a limited DEPTH, e.g., the Nissan Sentra, force the dummy to rapidly accelerate to the velocity of the intruding structure—resulting in high occupant responses. Those vehicles with a more generous DEPTH, e.g., the Honda Civic and AMC Concord, permit the occupant to ramp up to peak velocity more gently.

PELG	=	308.3 + -23.8*Davg	R**2 = .817

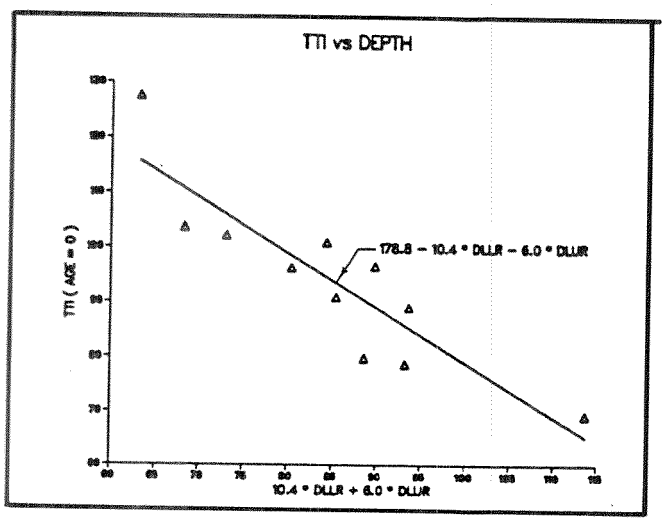

Figure 10A. TTI versus DEPTH at the lower rib and upper rib contact points (R^2 = .794)

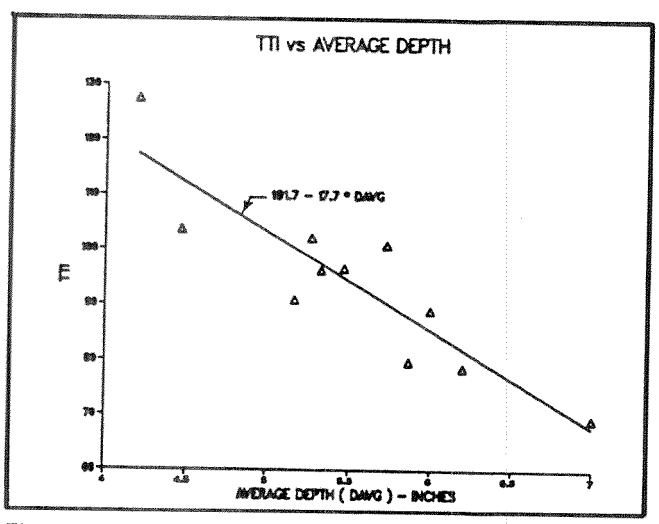

Figure 10B. TTI versus average DEPTH (R^2 = .796)

This finding is reinforced by an earlier study(1) that found that added door padding in production cars dramatically reduced the probability of injury in side impacts. In that study, several stock Volkswagen Rabbits were retrofitted with 3in of interior door padding and subjected to both high- and low-speed side impacts at both 90° and 60° impact angles. The supplemental padding was found to reduce thoracic injury by as much as 65 percent in high severity accidents(4).

From an impact energy perspective, peak occupant forces (and hence peak accelerations) would be expected to be proportional to the energy absorption in the door structure. This energy absorption is related directly to the stiffness (force-deflection properties) of the interior door structure and the interior door padding thickness. The fact that dummy peak g's and TTI are strongly correlated with the available DEPTH indicates that the force-deflection characteristics of the 12 doors are similar over the range of deflections observed in the tests.

This conclusion is reinforced by a study conducted by Willke and Monk(5), which measured the interior door stiffness of seven different vehicles. In this study, the door was crushed and backed by the same honeycomb impactor employed in our test series. The stiffness was reconstructed from the acceleration time history of a rigid thorax propelled into the crushed door assembly. Figure 11 shows the results of the experiment. With few exceptions, the force-deflection characteristics for the test group were quite similar over the range of crush. For comparison, Figure 11 also shows the stiffness of the honeycomb backing by itself.

Although this analysis appears to show that a certain minimum DEPTH is essential, this finding does not preclude the possibility that other vehicle design parameters may improve side impact protection. The manufacturer may choose vehicle designs that alter other

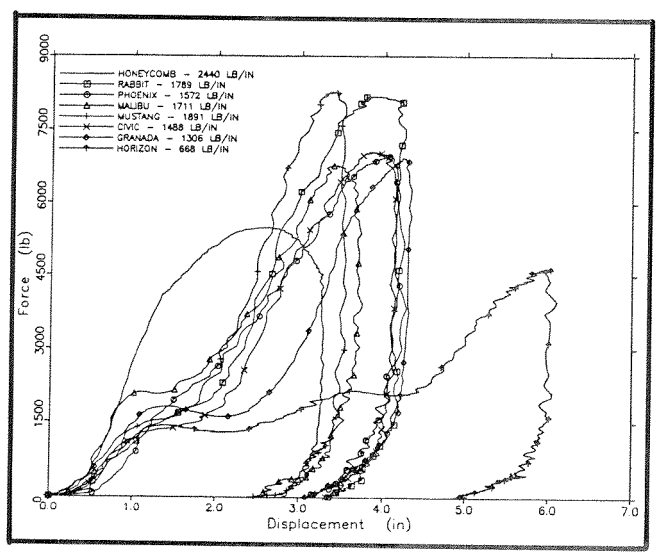

Figure 11. Interior door stiffness

factors that affect occupant protection. Two parameters that are potential candidates (and were reasonably constant in this study) are the occupant-to-door contact velocity and the inner door force-deflection characteristics. A significant reduction in the contact velocity and/or optimal force-deflection characteristics could be expected to improve side impact crashworthiness.

DEPTH vs. Vehicle Design Parameters

In the previous section, the peak occupant g's and TTI were shown to be strongly correlated with the DEPTH. The vehicle design parameters that influence the DEPTH remain to be determined. The candidate parameters include the total thickness of the door, the door attachments to the surrounding structures, the strength of these surrounding structures, the location and size of internal door hardware (window and window-operating mechanisms), and the location and size of the door beam.

The total thickness of the door, at the occupant contact locations, gives the maximum available DEPTH (unless outward bending of the door occurs during occupant impact). For crash events in which the door is not impacted, this total thickness, minus the space occupied by the internal door hardware and door beam, should be directly correlated to thoracic side protection.

The stiffness of the external sheet metal is insignificant. If exterior door stiffness were solely dependent on the external sheet metal, an almost total loss of DEPTH would be expected for even low-speed impacts into the occupant compartment. Therefore, it is very important that the side structural design provide load paths that maintain as much effective padding thickness as possible. This may be accomplished by efficient use of the door beam and the surrounding structures. The door beam should be located as close to the external sheet metal as possible and must carry some of the impact forces to the surrounding structures.

In our test, significant loading of the A- and B-pillars occurs. Similarly, the accident data show in most side impact events that the surrounding structure (A-pillar, B-pillar, sill, and roof header) is frequently impacted. To protect the side-struck occupants, the surrounding structures must provide adequate forces to maintain reasonable occupant compartment integrity and load paths for the forces that are transmitted from the door.

Some of the production vehicles in our tests, particularly the Honda and Concord, appear to perform this function very well. The designs for the modified vehicles in (1) included additional methods of load transmission between the door, sill, and A- and B-pillars. These simple changes also seemed to function very well.

In the ideal situation, the door would perform exclusively as an energy dissipation element: 100 percent of the door thickness would be maintained during impact, and the door would have optimum padding characteristics. Present vehicle designs do not have this luxury. The door must provide the required mechanical functions of housing the window, the window-operating mechanisms, and the door-opening mechanisms. Careful safety design considerations are required to minimize the loss of occupant protection due to these mechanical requirements. The hardware for these requirements should restrict the possible DEPTH as little as possible. Any hard points should be located away from the potential occupant contact zones.

Much of the design information discussed above has not been completely assembled and analyzed for the tested vehicles. Therefore, no definite conclusions can be drawn as to the scope of existing design parameters that provide better safety performance. However, data from this test series have been studied that may reflect the significance of the exterior door stiffness and the strength of the surrounding structure. These data include the static crush at the axle height and the number of doors on the subject vehicles.

The computed linear fit between the average DEPTH and these two parameters is shown below and presented in Figure 12.

Davg 7.2 + -0.242*AxleCrsh + 0.392*Ndoor
R**2 = .886

where

Davg	=	average DEPTH = Dpel + Dllr + Dlur)/3
AxleCrsh	=	static crush at the axle height
Ndoor	=	number of doors
R	=	statistical goodness of fit measure

The static crush at the axle height may be considered as directly proportional to the exterior door stiffness. The number of doors may have a direct relationship to the strength of the surrounding structure as well as exterior door stiffness.

Although this paper computes a single value of DEPTH for each vehicle, DEPTH may be dependent on the

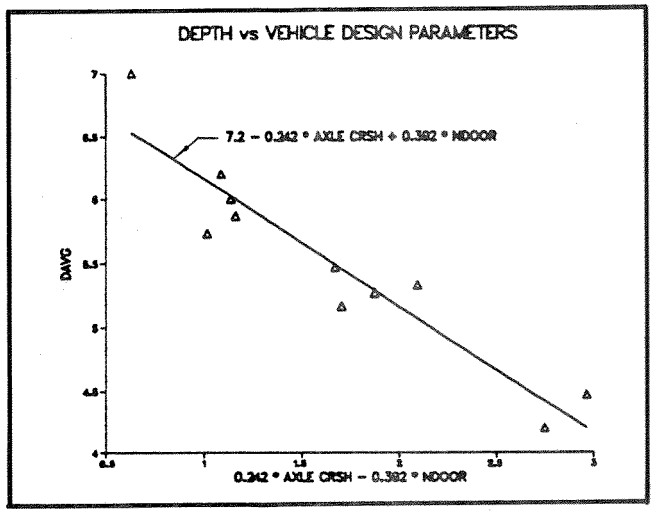

Figure 12. Average DEPTH versus vehicle design parameters (R_2 = .886)

location of occupant contact along the inner door width. It should be emphasized that the values of DEPTH presented here were computed for the contact regions experienced by a 50th percentile occupant. Different size occupants and/or different seating positions will result in correspondingly different contact points. It is important that the maximum possible DEPTH be maintained throughout the potential area of occupant impacts (the contact zone).

Implications of DEPTH on Component Testing Approaches

The use of component tests or full systems tests continues to be a subject of considerable interest and debate(6). The component test with its somewhat simpler, less expensive procedures and feasibility of application early in the vehicle design stage is very appealing. The full systems test with its closer relationship to the real accident event provides an easier transition to benefit calculations.

The findings presented in this paper have an important bearing on the design of a component test procedure. The regression analysis shows a strong correlation between—

- Occupant responses and DEPTH
- DEPTH and exterior door static crush (precrush)

The challenge of a component test is to design an experiment that avoids the expense of a full systems test but faithfully replicates the impact conditions seen by the struck driver. The two elements from the above analysis most relevant as input to a component test design are the contact velocity of the thorax to the interior door surface and the precrush of the exterior door.

From the presented data, the contact velocity is seen to be relatively constant for the tested production vehicles. Door-to-thorax contact velocity for the 30/15mph 90° impact condition is 26.1 +/- 1.0mph. This implies the impact velocity of a component test device should approximate this 26mph velocity to replicate a near real-world event. However, if a manufacturer chooses to make changes to the side structure of his vehicle that influence this velocity, the component test will not recognize these changes.

The second element, the precrush of the door, is the amount the door exterior must be crushed prior to a component test to repeat the conditions of a full systems test. The static crush of the exterior door as defined here is the permanent deformation of the door exterior measured at the end of the crash test. Recalling our door kinematics model, permanent deformation of the door is completed prior to occupant contact with the door. For our test configuration, the permanent deformation of the door and the required precrush are equivalent. For side impacts to the occupant compartment, a method for determining the correct door precrush for the component test approach will have to be developed if correlation to real-world events is to be obtained.

Based on the results presented above, we conclude the fidelity of door component test is greatly influenced by the fidelity of the door precrush and proper choice of the contact velocity. Until adequate methods are developed for determining these two elements, the economic justification for door component tests as an alternative to a full systems tests appears tenuous at best.

Future Studies

Several activities are planned by NHTSA to further evaluate the safety performance parameters of production vehicles in side impacts and to investigate potential improvements to side impact test procedures and side impact protection. These activities include—

1. Continued full systems testing of production vehicles. Additional production vehicles, including vans and light trucks, will be selected and tested in the 30/15mph, 90° condition. Resulting data will be used to supplement the above studies and more fully evaluate the importance of DEPTH across the complete vehicle fleet.
   Since the original group was tested, NHTSA has modified the SID dummy to improve the durability of the dummy leg. NHTSA has also finalized the side impact test procedure with significant refinements to the seating procedure for the SID. Based on two recent tests (May 1985), preliminary results suggest that, rather than mixing the pre- and postmodification SID tests, the two groups should be analyzed independently.
2. Collection of the vehicle parameters that are assumed to influence the DEPTH. Data collection efforts on the original 12 vehicles and all vehicles selected for testing will include these parameters as outlined earlier. These efforts will require some vehicle tear down and subsystem testing.
3. Component testing concurrently with the full systems tests of the selected vehicles. Component tests based on the forthcoming MVMA test procedure and utilizing the MVMA-designed thoracic test device will be conducted on all the selected vehicles. The results of these tests along with the results of ongoing MVMA tests will be used to assist in the evaluation of the relative elements between real-world side impact events and component test results.

Conclusion

This paper has examined the results of 12 side impact tests using current production cars with the objective of

determining the effect of vehicle design on the response of side-struck occupants. Our conclusions are—

- Current production cars vary widely in their capability to provide occupant protection in a side impact. For a 23-year-old driver, the probability of a thorax injury of AIS >= 3 was measured to range from a low of 9 percent for the AMC Concord to a high of 97 percent for the Nissan Sentra.
- For the vehicles tested, the door effective padding thickness (DEPTH) was found to be the single design parameter most crucial to occupant protection in side impacts.
- Four-door cars, in general, provide greater DEPTH than two-door cars.
- DEPTH is largely determined by the static crush of the vehicle at the door exterior—the more fully crushed the door, the lower the available DEPTH.
- The fidelity of door component tests is greatly influenced by the fidelity of the door precrush. Because accurate determination of the door precrush requires a full systems test, additional research is required to evaluate the feasibility of door component tests as a viable alternative to full car crash tests.

Our conclusion is that the wide variation in occupant side impact protection can be directly attributed to differences in the struck vehicle design. When the door and side structure provide adequate impact energy absorption, thoracic injuries are reduced. Furthermore, crashworthy doors and side structures do not appear to require exotic design modifications. The feasibility of enhanced side impact protection has been demonstrated by several of the current production cars tested in this study.

Acknowledgment

The authors wish to express a special word of thanks to Joseph Kanianthra for his expert and timely assistance in preparing much of the data in this paper for graphic presentation.

Abstract

The level at which forces are transmitted from the striking vehicle in side impacts may influence the response of the struck car in several different ways. A better contact between the front bumper of the striking and the sill area of the struck car has been considered to be desirable in this respect.

In side impacts, the most frequent direction of the impact is from 3 and 9 o'clock, while the direction of the forces is usually from 2 and 10 o'clock due to the velocity of the struck car. A European car and the EEVC moving deformable barrier have, therefore, been used in a crabbed mode to study the problem of load transfer at different levels above the ground. Volvo and Saab cars were used as targets in 55km/h side impact with an APROD-81 side impact dummy placed on the struck side in the front seat. The results indicate that a difference in the level at which the loads were applied could influence the deformations, the kinematics of the struck cars, and the loading of the occupant.

Studies of the mechanisms of injury to pedestrians hit by cars have indicated that a reduction of the severity of the injuries to the lower extremity could probably be achieved by lowering the point of first impact. This would not necessarily influence the overall kinematics of the body in a negative way. An attempt has been made to assess the influence on different injury-related parameters by lowering the level of first contact and increasing the compliance of the car front structures. As tools for this study, a physical and a mathematical model of the pedestrian with particular emphasis on the lower extremity have been used. The results indicate a lowering of the level of load transfer would have more influence on some injury-related parameters and changing the compliance of these structures more influence on others.

The results of this combined project support the theory that a lower level aboveground of the leading force transmitting structures of the car front would be beneficial in both types of accident.

Introduction

Traffic safety research in Sweden is being discussed continuously and coordinated by representatives from the Swedish Road Safety Office (TSV), the Chalmers University of Technology (CTH), the Swedish Road and Traffic Research Institute (VTI), the Saab Car Division, and the Volvo Car Corporation.

The question of optimal bumper height related to side and pedestrian impact consequences has been debated; especially a risk of conserving the existing requirements governing bumper heights seemed to be impending.

This work, initiated by these discussions, has been a joint project between TSV, CTH, VTI, the Saab Car Division, and the Volvo Car Corporation.

In developing and testing the crashworthiness of passenger cars, the frontal fixed barrier testing at 30 and 35mph has been stressed for many years. Only recently have the side impact properties been discussed more. Together with the frontal impact protection, the bumper design and height have been regulated through low-speed impact performance requirements.

Often there is a conflict between the requirement for frontal protection and possible aggressiveness of the car front in impacts with the side of other cars and with pedestrians. Therefore, there is a need to optimize the car front both for frontal and for side and pedestrian impacts. The bumper height is an important part in this.

The objective of this investigation was to show that legal requirements leading to certain bumper heights may have to be reconsidered in view of their effect in side and pedestrian impacts.

The investigation had four phases. A literature study was made (see appendix), and the bumper level was measured for present cars under varying conditions. Side impact tests were made with a mobile deformable EEVC barrier in a crabbed mode at varying heights against Saab and Volvo cars. Finally, a new pedestrian dummy leg was impacted with a car front structure at varying heights, and several leg parameters were measured.

Traffic Environment and Bumper Heights for Stationary and Braking Vehicles

It is often said that guardrails are built to be compatible with the bumpers of passenger cars. As part of this project, an investigation was made of the traffic environment in Sweden and to some extent in the United States.

It became evident that guardrails in Sweden are positioned at the hub level of truck wheels. No evidence was found that lowering the bumper would be unpractical with the exception of loading ramps for cars on trucks and railroad cars. In the United States, the guardrails on the highways have been engineered to specific standards. The lowest horizontal rail is positioned level with car bumpers. However, due to movements in the ground, this level can vary ±75mm. A new type of guardrail is being installed in some States where the lowest nominal height is 250mm. New Jersey concrete barriers have been designed with the existing bumper heights in mind, and a lowered bumper may create forces that tend to lift up the front of the car and cause it to turn over. A number of people are being killed in the United States where guardrails have been involved. It is essential to investigate carefully any negative effect of a lowered bumper. This brief look into the U.S. traffic environment has not revealed any major problems for lowering bumper heights.

Ramp standards are considered to have very little influence on bumper heights as the bumper seldom is the lowest point of the car. Many modern cars have front air dams (spoilers) positioned considerably lower than the bumper, showing the potential to lower the bumper. The U.S. requirements in P581(1) set the impactor height at 406 to 508mm. The ECE R42(2) limits it to one value, 445mm. On a selection of current passenger car models, bumper (centerline) heights were within a range from 430 to 500mm. These values could, of course, be lower in real traffic conditions with loaded vehicles and possible dive motion due to braking. The height reductions due to brake diving were measured and found to be from 70 to 100mm.

In many accidents, the impacting car had started to brake before impact. According to a French investigation(3), this was the case in 54 percent of the investigated pedestrian impacts. It takes, however, a considerable time and distance for the full vehicle dive action. As shown in Figure 1, the dive motion has a frequency of approximately 1Hz, which means that the maximum amplitude is reached 0.25s after initiation. With time for the driver to react and apply the brakes, the vehicle will travel about 8m before the dive is completed at an initial speed of 57km/h. It seems probable, therefore, that a full dive is not reached in most cases.

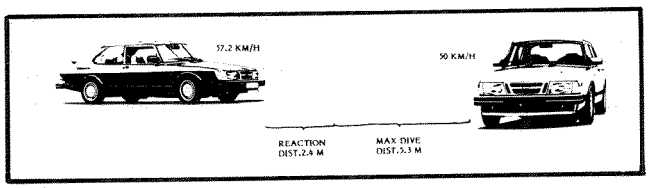

Figure 1. Front end dive (pitch) at braking with frequency of approximately 1Hz (maximum dive after 0.25s)

Side Impact Evaluation

Test Methods

A total of 10 dynamic tests were made according to the following description.

EEVC MDB

The Mobile Deformable Barrier (MDB) as specified by EEVC(4) was used in eight tests. Polyurethane foam blocks delivered by Fritzmeier GmbH (version II) were used as front elements (Figure 2).

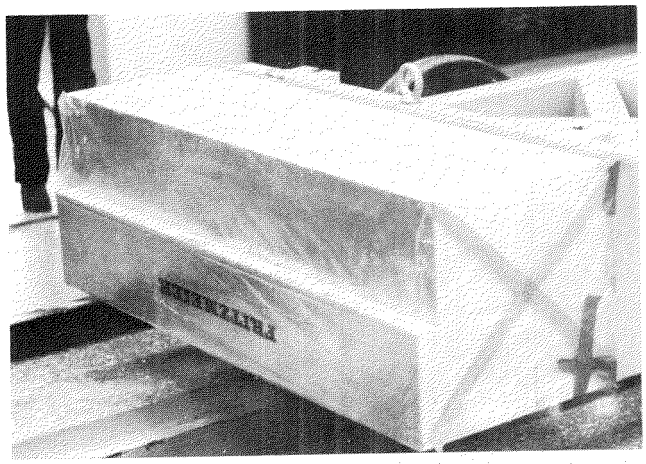

Figure 2. Front block of the MDB

Bullet Cars

In two tests, Peugeot 305 (1979) cars were used as striking vehicles (bullets). The reason for using this car was that its front construction was considered typical for the European car population. In all other tests, the EEVC MDB was used.

Crabbed Configuration

Although not specified by the EEVC, it was regarded as interesting(5) to find out how the EEVC MDB would perform in a crabbed configuration (Figure 3). The angle was 27° and the impact speed was 55km/h (34mph), resulting in a perpendicular speed of 48km/h (30mph) and a longitudinal speed of 24km/h (15mph). The Peugeot cars were also modified to this 27° crabbed configuration (Figure 4).

Ground Clearance

The MDB was made with an adjustable front plate, and the ground clearance was varied at the following

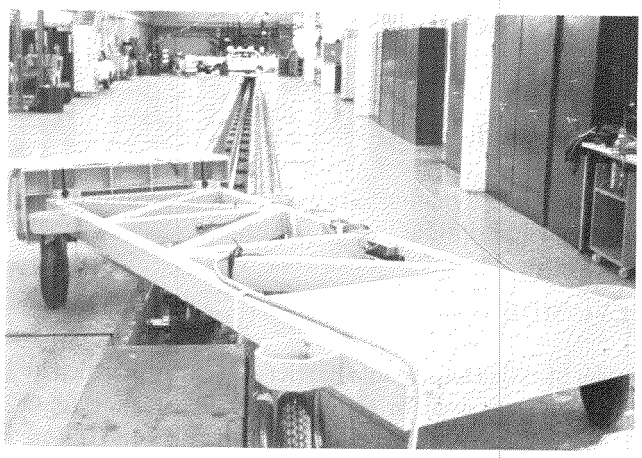

Figure 3. Crabbed EEVC MDB

Figure 4. Peugeot prepared for crabbed configuration

levels: 200, 250, 300, and 350mm. The Peugeot cars were used at their nominal ground clearance, which is hard to specify since there is no good definition of this value on the front of a real car. In one of the tests with the Peugeot cars, the impacted (target) car was lifted 100mm at its suspensions to simulate the effect of a lower ground clearance of the bullet car (Figure 5).

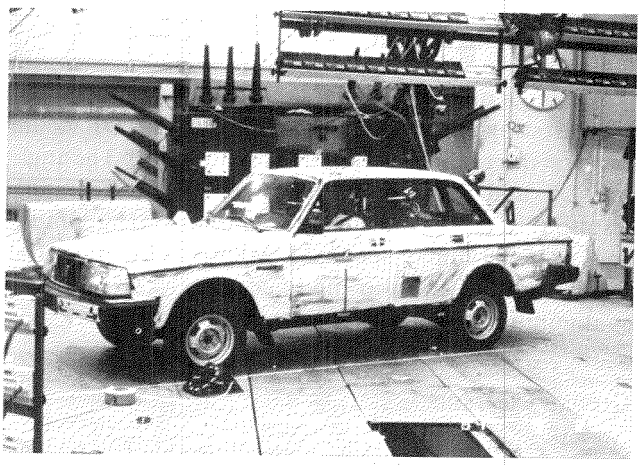

Figure 5. Elevated target car

Target Cars

Medium-size Volvo and Saab cars were used as targets. The impact point was such that the left corner of the bullet vehicle hit the target vehicle at a point 940mm (37in) in front of the centerline of the wheelbase. All impacts were made on the driver's side (Figure 6).

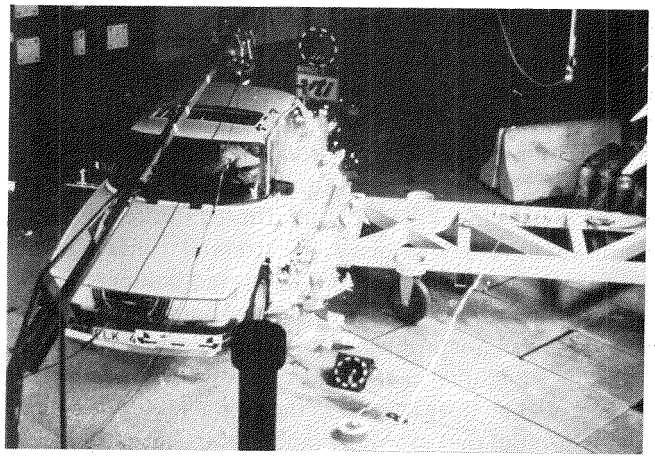

Figure 6. Impact configuration

Dummy

An APROD-81 dummy(6) was used in the driver's seat in all tests. The dummy was instrumented with 3-axial accelerometers in the head, chest, and pelvis. Lateral chest deflection was also measured at two levels (Figure 7).

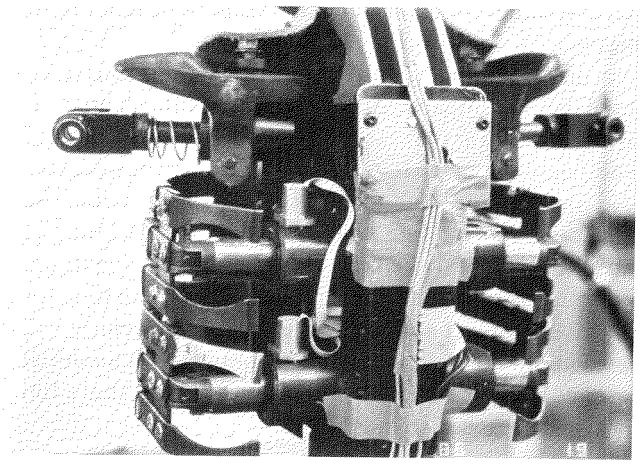

Figure 7. APROD-81 chest mounted on Part 572 dummy

Instrumentation

Apart from the dummy measurements mentioned above, the accelerations of the bullet vehicle and the target vehicle were recorded. The dynamics of the inside and outside door panels just behind the driver's seat were measured by steel rods installed transversely in the compartment. All measurements were made according to

ISO 6487(7)(Figure 8). Photographic coverage consisted of four high-speed 16mm cameras (Figure 9). To measure the permanent deformations of the impacted cars, a special measuring device was built (Figure 21).

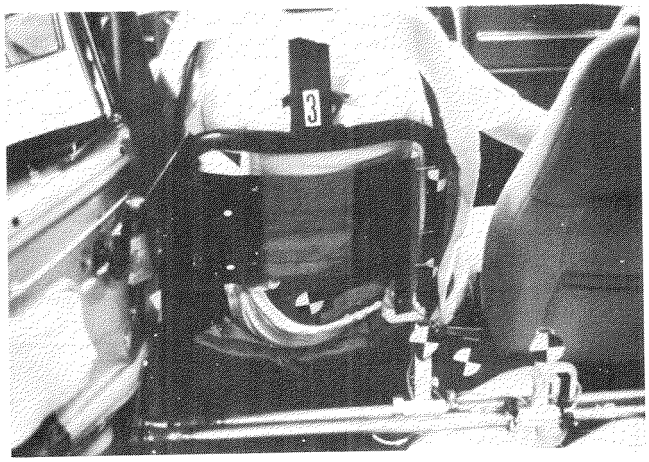

Figure 8. Inside view of target car (measuring rods for acceleration of outside and inside door panels visible at bottom of picture)

Figure 9. Target car in position for impact

Side Impact Test Results

The impact speed of the bullet vehicles was in the range of 55.0 to 56.1km/h. In the following diagrams, the peak values of some significant parameters are plotted against the ground clearance of the bullet vehicles. Several other parameters have been studied, but they have not given any additional information and are therefore not reported. Head accelerations, for instance, were of such a low magnitude, due to no head impact, that the HIC values were below 100. In the case of the MDB, the ground clearance is the nominal clearance to which the barrier front was installed. Because of the difficulty in determining the exact ground clearance for the Peugeots, when used as a bullet vehicle, the values for these tests are plotted at a ground clearance called normal and at a 100mm lower level.

The following symbols are used in Figures 10 to 12:

In the left part of the figures, △ and □ indicate values for the target cars, respectively, when impacted by the EEVC MDB.

In the right part of the figures, O indicates values for the target car when impacted by the Peugeot.

The chest measurements in Figures 10 to 13 indicate the loads on the chest decrease when the ground clearance is lowered.

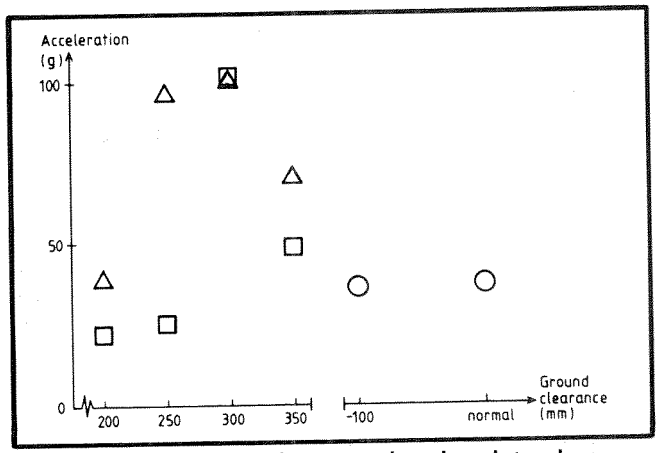

Figure 10. Maximum chest acceleration, lateral

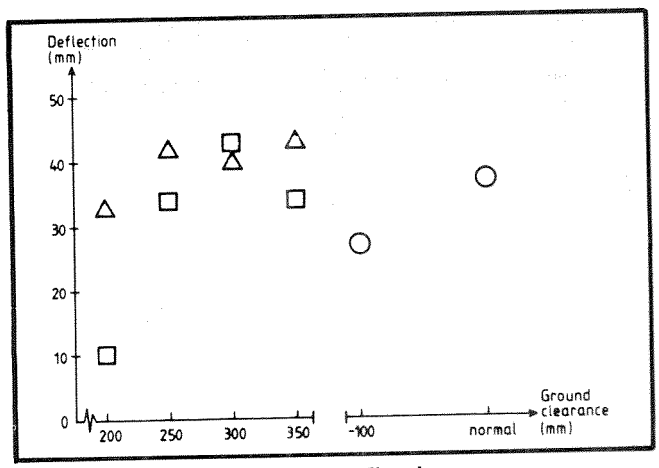

Figure 11. Maximum chest deflection, upper

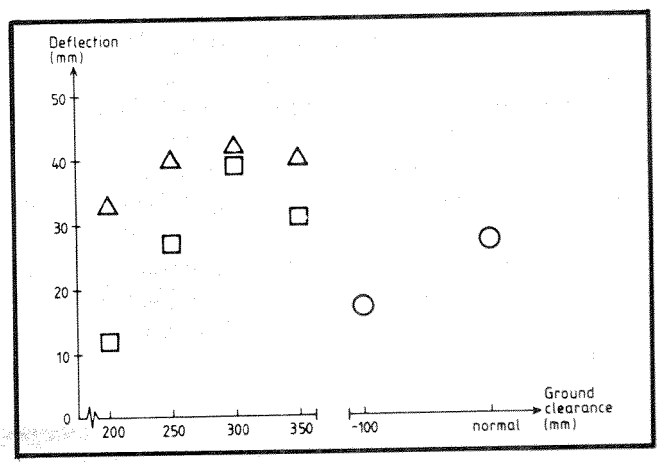

Figure 12. Maximum chest deflection, lower

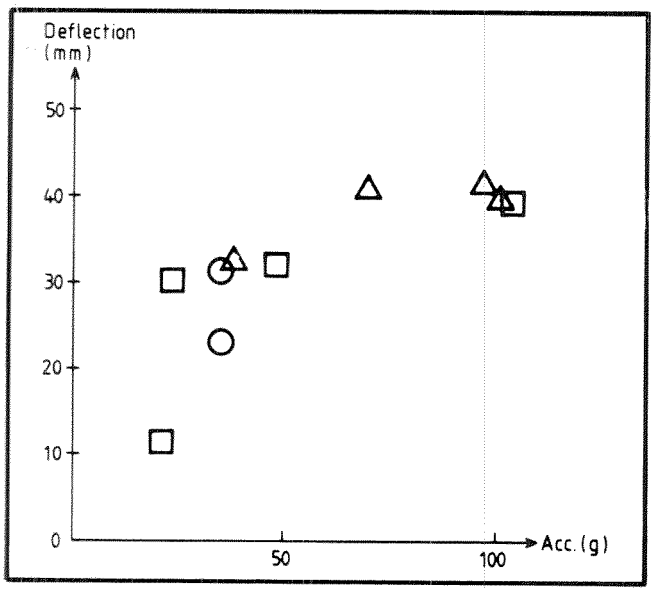

Figure 13. Relation between maximum chest acceleration lateral and maximum chest deflection (mean of upper and lower deflection values)

The maximum acceleration recorded in the pelvis of the dummy shows the same tendency as in the chest, i.e., a lower bumper level will result in lower accelerations in the pelvis (Figure 14).

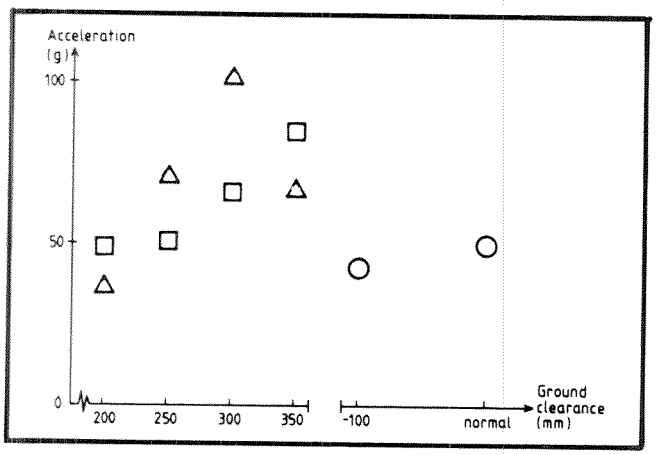

Figure 14. Maximum pelvis acceleration, lateral

The maximum velocity integrated from the acceleration measurements in the dummy is shown in Figures 15 and 16. The pelvis velocity is higher than the chest velocity, and the relationship between the ground clearance and these variables is more pronounced for the chest.

The permanent deformations of the side of the impacted vehicles were surveyed by a deformation measuring device (Figure 21). Deformations at the B-pillar at different levels are presented in Figures 17 to 20. The tendency of these deformations in relation to the ground clearance is as expected, and the magnitude of the deformation is approximately the same regardless of the type of bullet vehicle.

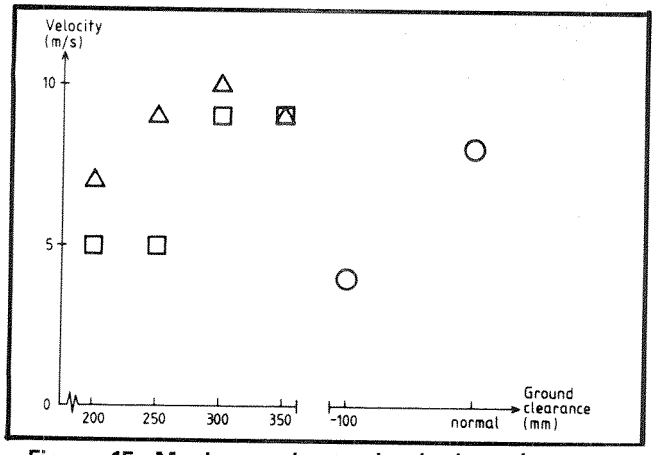

Figure 15. Maximum chest velocty, lateral

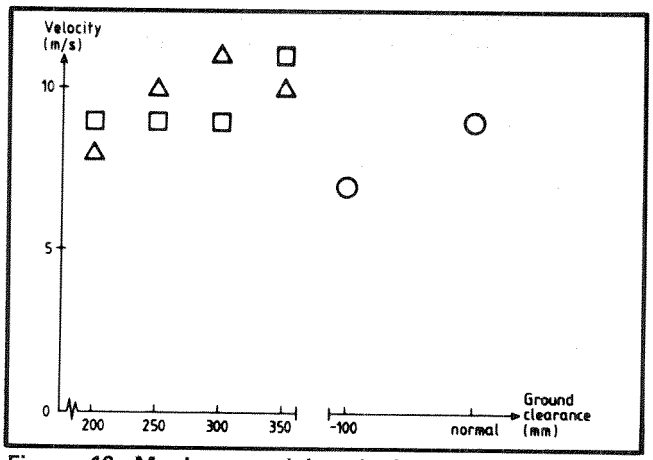

Figure 16. Maximum pelvis velocity, lateral

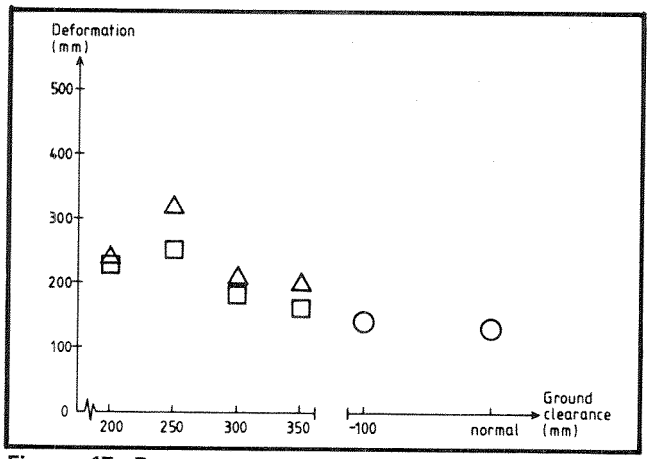

Figure 17. Permanent vehicle deformation at the B-pillar 300mm above ground level

In these figures, there is also a tendency that the deflection has a peak at the 250mm ground clearance level. This may be due to the fact that the EEVC front elements are not of a homogenous construction. There are calibration holes in the blocks, and in some circumstances these holes may coincide with strong parts of the target vehicle. This microscale phenomenon is not revealed in the macroscale verification tests in the specifications where the whole segment is evaluated. Further research about this problem is recommended.

Pedestrian Impact Evaluation

Mechanical Model

The dummy leg used in this project is a simplified version of the leg in a rotationally symmetrical adult pedestrian dummy developed to measure the aggressiveness of the car front in a collision(8).

The main purpose of this work was to measure the forces and torques in the lower extremities, especially at knee level in impacts at different bumper heights.

The dummy leg consists of two steel tubes simulating the long bones of the human upper and lower legs and a steel bar simulating the knee. To enable comparisons of results from previous experiments with cadaver legs, parameters such as mass, length, center of gravity, and moments of inertia were chosen in accordance with the real conditions in these experiments (Figure 22). The forces in the vicinity of the knee were measured with strain gauges mounted on steel tubes simulating the upper and lower legs. The bending moment, the shear force and, if necessary, the tensile force, and the torque about the longitudinal axis can be calculated from these data. The steel bar simulating the knee was designed to withstand the same lateral bending moment as a human knee. The bending strength of the knee in a lateral collision was calculated using strength data for the medial collateral ligaments, the cruciate ligaments, and the geometry of the knee(9,10).

The fact that the dummy was simplified to include only three elements is not believed to seriously affect the forces around the knee during the first part of the events(11).

Test Setup

The concentrated mass of the body was connected to the dummy leg by a universal joint. The dummy was

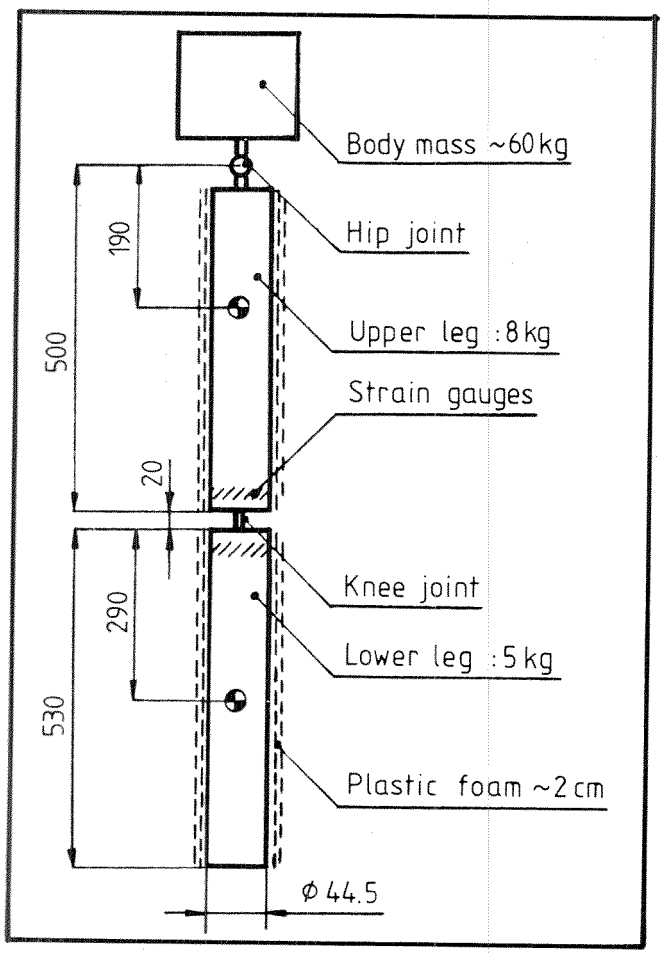

Figure 22. Mechanical model of rotationally symmetrical pedestrian leg dummy

balanced on a platform in an upright position by means of wires until a few milliseconds before collision. The impact height was varied by lowering or raising the platform supporting the dummy leg. The data from the strain gauges were registered according to SAE 32116, and the collisions were filmed with a 16mm high-speed camera at 500fps.

Two test series were made with the same dummy leg. During the first series of tests, only two types of bumpers were used:

- Rigid nondeformable steel bumper, 30mm high
- The same bumper with 150mm plastic foam

The tests were performed at a constant velocity of 26km/h at four different impact heights:

- Very close to the knee (h = 0.45m above the ground)
- Between the knee and the center of gravity of the lower leg (h = 0.28m)
- Near the center of gravity of the lower leg (h = 0.25m)
- Below the center of gravity of the lower leg (h = 0.18)

In the second series of tests, a complete car front from the National Highway Traffic Administration (NHTSA) of the U.S. Department of Transportation was used as shown in Figure 23. The point of impact was chosen very close to the knee (h = 0.45m). The velocity was varied from 30km/h down to 10km/h.

Mathematical Model

The MADYMO Crash Victim Simulation Programs were validated using the laboratory impact tests made on the rotationally symmetric dummy leg. The problem was to simulate a dummy leg with a knee joint consisting of a steel bar by means of a mathematical model intended primarily for ball-and-socket joints. The standard model in MADYMO describing the resistance in a joint against the relative movement of the two connected elements consists of a nonlinear spring, a viscous damper, and a dry friction component connected in parallel with each other. With this construction, it is not possible to simulate the elastic part of an elastic-plastic material having hysteresis in the unloading phase (Figure 24).

Such a simulation requires a series connection between a dry friction and a nonlinear spring or a differential description of the material. However, if the elastic region (Figure 24) is small compared with the total region used in the simulation, it may be sufficient to use the dry friction component of the total moment. In the simulations presented, the knee joint has been described using only the dry friction component of the resistive moment in the steel bar. The value of the dry friction component has been estimated both from material data for standard steel 2172 and empirically from test data from a statistic bending test. The characteristics of the soft parts of the leg, like the force-penetration function, were also determined by means of static tests. This should be kept in mind while comparing the results of the simulations with the results of the dynamic tests.

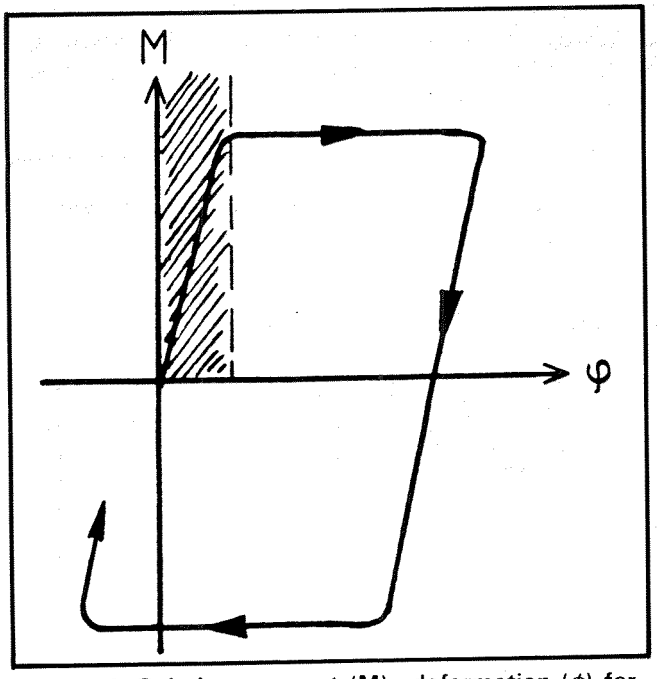

Figure 24. Relation moment (M)—deformation (ϕ) for an elastic-plastic material with hysteresis

Pedestrian Impact Test Results

Forty tests were made with the mechanical model in two series.

Figures 25 to 27 show the bumper force (at the point of impact), the shear force, and the bending moment about the knee for various impact heights in the first series of tests.

The bending moment about the knee in both series is expressed as a percentage of the maximum bending moment a living human knee can withstand without

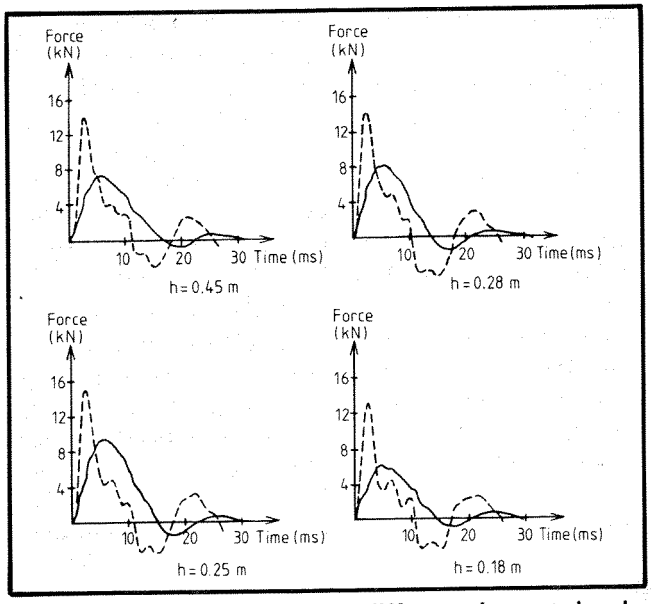

Figure 25. Bumper force for different impact levels (solid line—soft bumper; dashed line—rigid bumper)

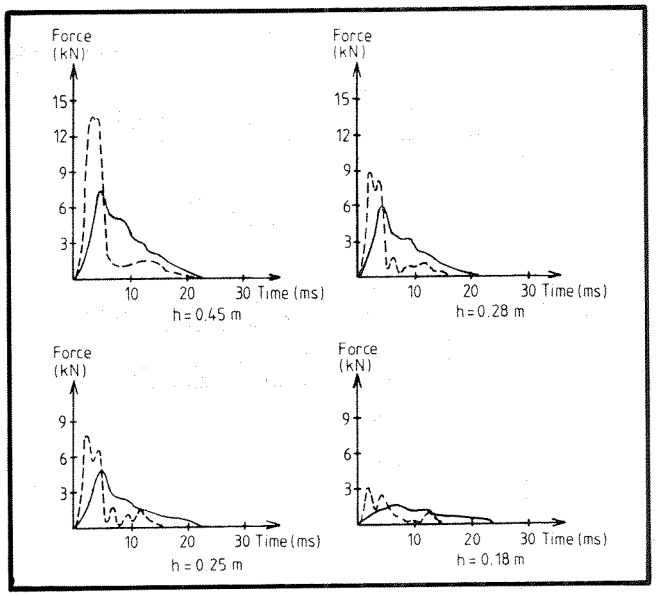

Figure 26. Shear force about the knee for different impact levels (solid line—soft bumper; dashed line—rigid bumper)

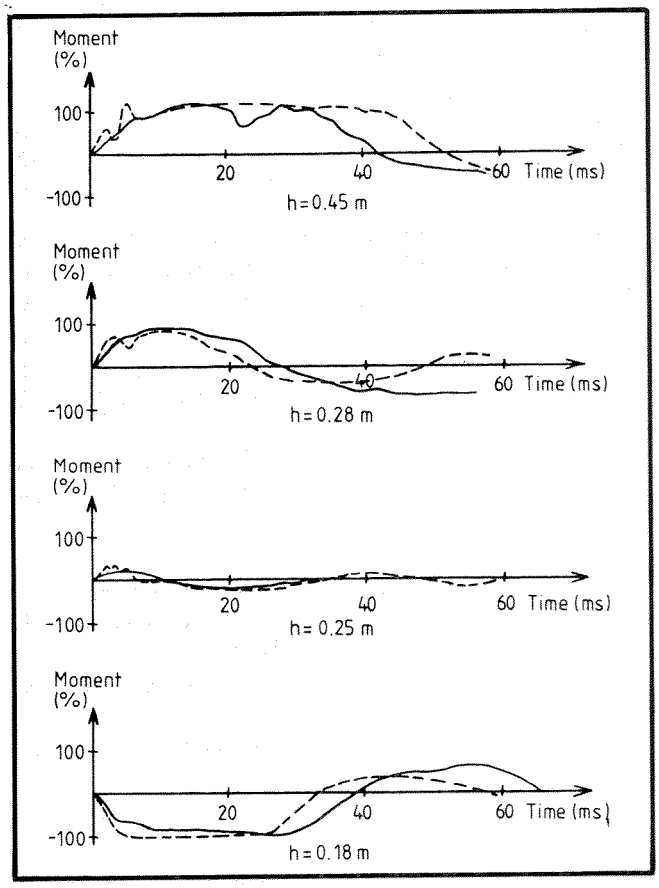

Figure 27. Bending moment about the knee for different impact levels (solid line—soft bumper; dashed line—rigid bumper)

being injured. Bending moments exceeding 100 percent can tear the ligaments and/or result in fractures, e.g., the tibial condyle.

Figure 28 shows the bending moment about the knee as a function of the impact velocity in the second series of tests.

The peak bumper force varied between 13.5 and 15.0kN for the rigid bumper and between 6.0 and 9.5kN for the soft bumper (Figure 25). The force pulses were somewhat more extended in time for the soft bumper. The time histories of the shear forces about the knee (Figure 26) were similar to those of the bumper forces. The peak values were 50 percent lower for the soft bumper. The bending moments (Figure 27) were 100 percent when the bumper levels were 0.45m and 0.18m above the ground. The bending moment is low (30 to 40 percent) only at impacts near the center of gravity of the lower leg.

The inertia of the lower leg and foot are probably the most important injury-causing factors when the impact point is high (h = 0.45m). The injury-producing effect of the inertia is seen even at low velocity (10km/h) (Figure 28).

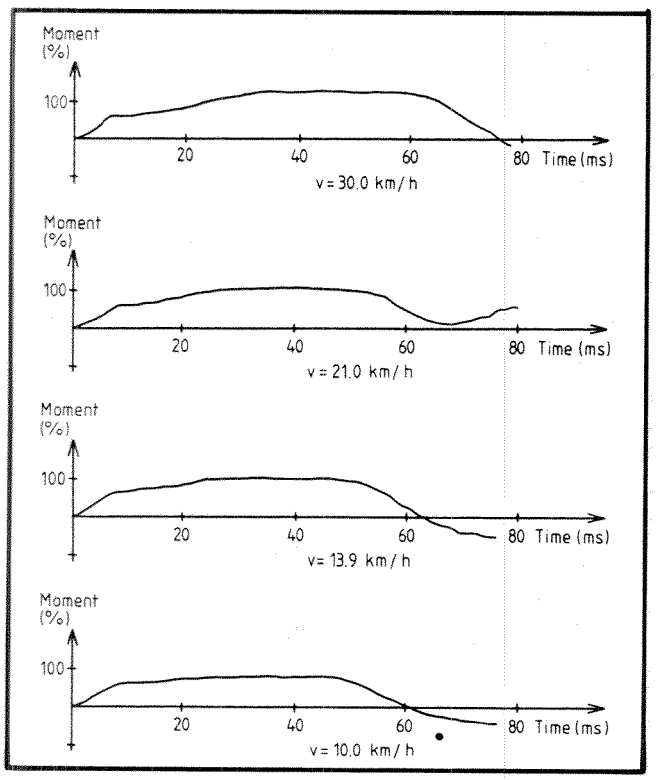

Figure 28. Bending moment about the knee for different velocity (h = 0.45m)

Figures 29 to 31 show the results of the mathematical simulations and the evaluation with the mechanical model. Despite the misleading graphics, the struck object does not represent the general shape of a complete dummy but only the simulated mass concentrated in a sphere, the upper, and lower leg. The concentrated mass of the body is connected to the leg by a ball joint. The foot and the ankle are integrated in the lower leg. There is no frictional force between the leg and the ground. The impactor represents a hard bumper without a car front, and the bumper is rigid. All three simulations (Figures 29 to 31) are made with a constant velocity of 26km/h. The impact heights were h = 0.45m (Figure 29), h = 0.25m (Figure 30), and h = 0.18m (Figure 31).

As expected, the best correlation between the experimental results and the mathematical simulations is obtained for the case where the deformation in the knee joint (steel bar) is plastic during the major part of the event, i.e., the case where h = 0.45m (Figure 29). In both of the other cases (Figures 30 and 31), the deformation is either elastic or in the vicinity of the elastic limit, thus

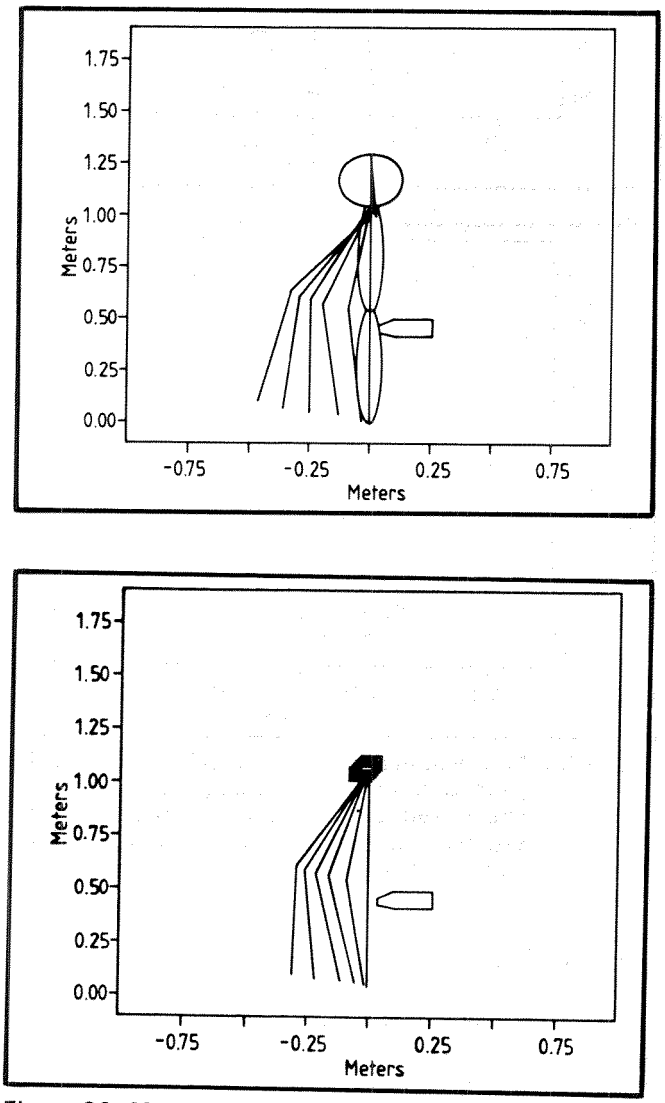

Figure 29. Mathematical and mechanical simulations of pedestrian impact—impact point h = 0.45m above ground (upper segment—body; middle segment—upper leg; lower segment—lower leg; Δt = 10ms)

falling in the region where the chosen approximation of the knee proves insufficient. However, the tendency is quite obvious, and deformation of the knee joint is in the same direction as that of the laboratory experiments. When the first point of impact was near the center of gravity of the lower leg, the knee deformation was low.

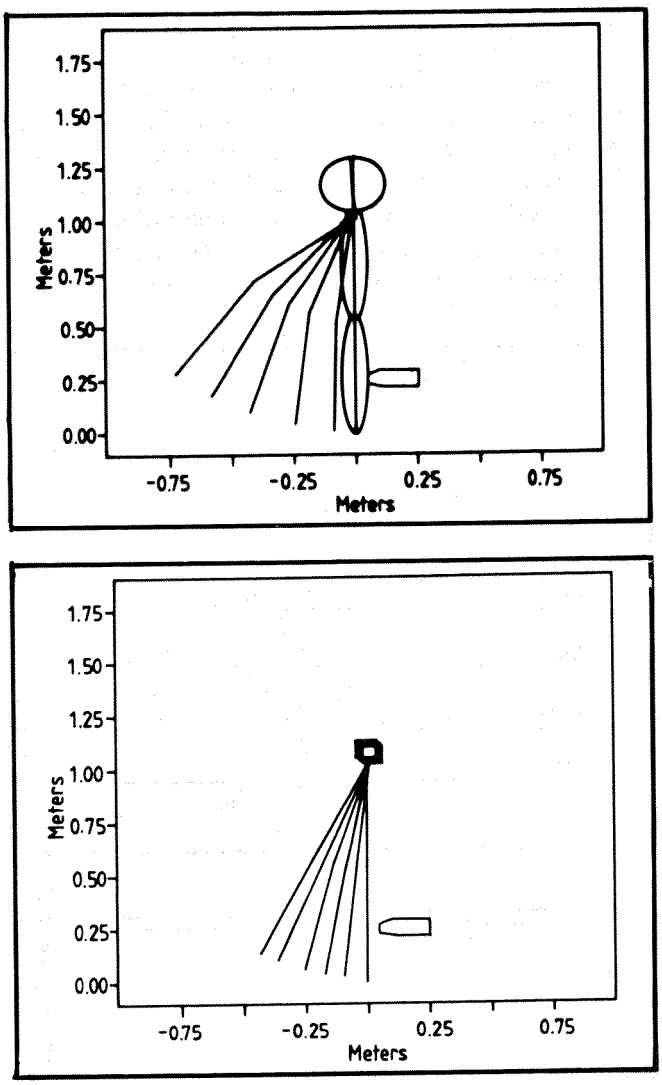

Figure 30. Mathematical and mechanical simulations of pedestrian impact—impact point h = 0.25m above ground (upper segment—body; middle segment—upper leg; lower segment—lower leg; Δt = 10ms)

Discussion

The intention of this project was to simulate the effect of lowering the bumper of a passenger car.

When the choice was made to use the EEVC MDB as a bullet vehicle in the side impact tests, it was obvious this would lead to some simplifications. As the face of the barrier has a defined height, the only way to simulate the different bumper levels was to move the entire block vertically. It is uncertain whether a future car with a lowered bumper will also lower its entire front face in the same magnitude. In spite of this problem, it was decided to use an MDB to enable general conclusions that would have been difficult if a specific car had been used as a bullet vehicle.

It is disappointing the APROD dummy did not discriminate to a higher degree between the different levels of violence. It is clear from the results that the lowest ground clearance produced significantly lower chest deflections than any of the other clearances. These results suggest that the lateral deflection characteristics of the dummy are extremely progressive in the upper half of the 50mm stroke. It could be questioned if this response is humanlike. Another possible explanation could be that the shoulder bottoms out and transfers much of the loading to the spine. This is, however, not

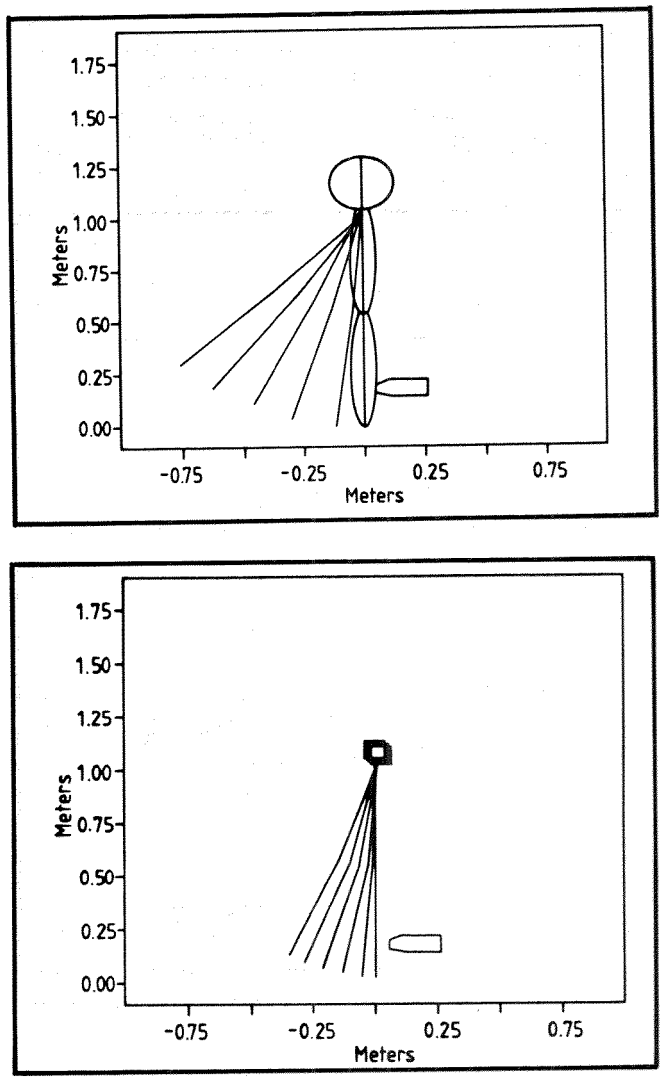

Figure 31. Mathematical and mechanical simulations of pedestrian impact—impact point h = 0.18m above ground (upper segment—body; middle segment—upper leg; lower segment—lower leg; Δt = 10ms)

very probable since the dummy was positioned so that contact between the B-pillar and the shoulder was prevented.

The accelerometer maximum readings in the pelvis show a clear trend toward a decreasing magnitude with decreasing ground clearance. This supports the theory the chest deflection should have had a larger variation for the different test heights.

The high-speed films show the roll angle of the impacted car is influenced by the ground clearance. From this project, it is not possible to quantify the effect of this phenomenon, but it points out the importance of further investigation of this matter.

The velocity profile of the intruding door is known to be an injury-explanatory parameter. The methods used in this project to assess this velocity were not satisfactory and, therefore, these results have been omitted. It is, however, recommended that feasible methods to record this velocity be developed.

This work has shown that changes in ground clearance of 50mm can influence the results. It is uncertain to what degree the nominal ground clearance could be kept at the time of impact in this type of testing. If the barrier is pitching up and down due to irregularities in the paving of the test track, the actual ground clearance at the time of impact may vary within a couple of centimeters. The target cars will also vary in height due to equipment, loading, tire pressure, etc. If entirely controlled test conditions are desired, the parameter that should be defined is the barrier location in relation to the car at impact.

This report shows experiments with a pedestrian dummy leg with sophisticated instrumentation can provide valuable insight into the effect of changing the impact point. It is planned to mount this leg on a complete pedestrian dummy(1). Further testing with this dummy may confirm the findings in this report and also demonstrate the influence of the bumper level on gross kinematics and head and chest impact violence. As pointed out above, the description of the knee in the MADYMO model is not suitable for simulation of the mechanical model of the leg used in this project. It is necessary to change the MADYMO model slightly to develop a versatile tool for engineering pedestrian leg injury mitigating car fronts.

Conclusion and Recommendations

It is evident from these test results there is a correlation between the collision load transfer height and the injury level of the struck occupant in side impacts. The new test methods used, and the limited number of tests that could be made, limit the confidence level of the results.

It is therefore recommended these findings be used to demonstrate the need for further development of test methods and equipment and evaluation of how much lower the optimum bumper or load transfer level should be.

Measurements of present car bumper levels showed that most are at about 450mm. At full braking at urban speeds, this level decreases approximately 90mm after a braking distance of 8m. Consequently, in most urban side collisions, a fully developed dive seems very unlikely.

A general comparison between the EEVC MDB and the Peugeot 305 used as bullet vehicles shows that the EEVC MDB can be used as an acceptable test device even in the crabbed configuration. The value of using the more complex crabbed mode should be investigated further.

Possible problems with the performance of the EEVC front elements at local loads have been observed, as well as problems with the deflection measurements in the chest of the APROD dummy. Further research in these areas is recommended.

The pedestrian impact evaluation part of this project indicates the following:

- For each impact velocity, the soft bumpers caused lower forces than the rigid ones. The bumper forces were highest at impact points near the center of gravity of the lower leg.
- The bending moment about the knee was lowest at impacts near the center of gravity of the lower leg. The use of soft or hard bumpers did not significantly change the maximum value of the bending moment about the knee.
- The shear force about the knee was diminished with decreasing impact height and was lower in collisions with soft bumpers.
- When the first point of impact was close to the knee, the bending moment exceeded the maximum tolerable level. This was true even at very low impact velocities.

The results from both series of tests confirm the previous clinical and experimental observations that there is a correlation between both the level and the compliance of the bumper and the seriousness of the injuries to the knee(12,13).

Problems with the use of conventional mathematical models for the simulation of an advanced leg model have been recognized.

Appendix

Review of the Bibliography Concerning Vehicle Front Structure Characteristics and Their Consequences for Pedestrian Injury Mitigation and for Other Goals

Background and Objectives

This review was made by T.E.A. Benjamin from France during the period 1982-83 and includes 42 technical papers from a total of 72, of which reference is stored in the OECD/IRRD retrieval system.

The objectives of the review were to examine and collate information concerning the scientific methods used and the conclusions reached by the authors of these papers with particular focus on—

- The consequences, in terms of pedestrian injury frequency and severity of various vehicle (essentially passenger car) front structure configurations, special reference being made to bumper height
- The consequences for the occupants of passenger cars laterally impacted by various front structure configurations of the striking vehicle
- Information concerning the possible consequences, in terms of vehicle aerodynamics (with its influence on fuel consumption) of injury-mitigating changes to front structures

The conclusions drawn from this review can be used to improve the relevance of upgrading vehicle structural standards that will reflect the best compromise between requirements that may be conflicting—

- Between road user groups at risk: adult pedestrians versus child pedestrians; pedestrians as a whole versus laterally impacted vehicle occupants
- Between vehicle safety performance goals and other goals: energy conservation (via aerodynamic performance and weight reductions); considerations of production costs and of repair costs

Further, the conclusions can be used to increase the relevance of tests used in research and in vehicle or component type approval by rendering the test conditions maximally representative of real-world accident circumstances and injury mechanism and to establish baseline safety performance data on current vehicles so the consequences of future upgrading can be measured.

Even if one considers solely the problem raised, it can be seen that the range of conditions in which pedestrians are impacted and in which their injuries are produced includes combinations of all the following:

- Different vehicle front structure combinations (especially bumper height width shape deformability, bumper lead angle, bonnet height)
- Various impact speeds
- Various degrees of pitch
- Pedestrians having various (to some extent age-dependent) characteristics (life cycle stage and state of health, overall knee and hip height, mass and mass distribution, bone quality)
- Different postures in relation to the front structure
- Different weight distribution on each leg caused by walking or running
- Different shoe/roadway friction characteristics
- Different body segment kinematics in relation to vehicle zones of different stiffness

Review of Conclusions Concerning Pedestrian Injury Frequency and Severity

Bonnet Height, Leading Edge, and Other Characteristics

In the earliest paper(22), it is stated that the selection of an optimal bonnet height involves a dilemma: a high front may knock an adult under the car at low speeds and throw a child forward at most speeds with a high risk of head-ground impact. A low front reduces these risks but increases the possibility of head-windscreen surround impact (particularly for adults). A long bonnet—1,100mm or more—reduces this latter possibility. The bonnet leading edge should be made of an energy-absorbing material (yield: at least 150mm and preferably much more) that matches adult pelvis and child thoracic tolerance levels.

Optimal bonnet shape is very sensitive to bonnet parameters(40); the principal design problem being that of avoiding head contact (see also below: Devices: Induced Kinematics). Bonnet properties should associate appropriate stiffness with crush depth (idem). It is recalled that head injuries are the main cause of death (N:211), the windscreen frame being the main fatal contact point(8).

The same author(10) found that pelvic fractures were mostly likely to occur when the relative bonnet height was in the range 0.46 to 0.50, and suggested the interesting concept of bonnet effective height: the height acquired by the bonnet due to its deformation during impact. Acting in combination with the bumper, the bonnet leading edge should minimize rotational acceleration and head velocity(16). Bonnet edge height, in cases where bumper lead angle is below 60°, does not seem to influence adult leg injuries, but it may increase risk of injury to children's heads, necks, and torsos(14).

An important feature of the high leading edge profile—tested alongside medium and low variants(41)—is that adult and child head impact velocities are consistently below vehicle impact speed. The child thorax/pelvis contact problem this profile engenders can be reduced by increasing bumper lead. With various medium and high leading edges, further reductions in severity can probably be achieved, but this will call for further study of stiffness and geometry.

Bumpers: Energy-Absorbing; Force-Limiting

As early as 1974(26), it was stated that bumpers should be energy-absorbing, their softening up being agreed to be beneficial(32) but seeming to accentuate the influence of ground reaction in the injuries sustained (net result: injury severity seems not to be reduced). It is suggested(40) that bumper and grille padding significantly reduce lower body injury (pelvis acceleration and knee force) it being considered(2) that while bumper force can be reduced by a deformable bumper structure, not all the knee reaction forces can be so reduced.

One group of papers(17,19), Fifth ESV Conference (various authors)(25,30,33,34,35) is mostly concerned with the U.S. FMVSS 215 standard, that is to say, with very low (up to 8km/h) impacts.

Bumper Height

In the earliest paper(32), attention is drawn to what sometimes seems to be a difficulty. In experiments, the lowered bumper height (from 508 to 355.6mm) reduces adult knee injury and limits pelvic and abdominal involvement—head velocity for the lowered profile, however, being almost twice as high as for the standard profile. In other experiments(13), bumper heights of less than 400mm did not produce head impact more frequently than higher bumpers. The FMVSS 215 standard is stated(7) to require a minimum bumper height of 400mm; it is also being pointed out(36) that adult knee height (500mm) coincides with the top of bumper height standardized by FMVSS 215 and ISO. An upper edge at 400mm would, in that author's opinion, produce a gain of 25 percent.

Looking at Swedish work in sequence, we see(1) that the 450mm bumper caused significantly greater injury than the 250mm version and that injury would be reduced by a bumper lead angle of less than 60° and lowered static level from 450 to 350mm, such a bumper to be energy-absorbing and force-limiting and to strike the lower half of the tibia. This is corroborated(23): The bumper should strike near the tibia/fibula center and well above the ankle joint. There seem to be other advantages: When the

leg is struck at its center of percussion (approximately 317mm for adults and 203mm for a 6-year-old child dummy), negligible forces are generated in the hip but vehicle front and ground contact could still produce high values(11). The same author cites some effects of bumper height extremes: Intolerably large knee bending moments are generated by high (about 508mm) bumpers, and a height of about 254mm reduced this to zero.

The negative effects of high bumpers are cited elsewhere(10). In a subsample of knee injury victims (N:44), 70 percent were struck by bumpers in the height range 450 to 540mm; in only 11 percent of cases was it less than 400mm. The same author(9) reports that 92 percent of knee injuries were caused by bumpers in the relative bumper height range 0.26 to 0.33 (corresponding to 420 to 530mm, taking 1.6m as average pedestrian height) and raises another complicating factor: that lowered bumpers reduce fracture probability but, at a relative bumper height in the range 0.16 to 0.20, ankle injuries—especially at high speed—can occur.

Some of the proposals made are as follows. To reduce adult leg injury severity, a bumper lower than the 380mm knee height (60 percent of a British sample) would reduce leg impact forces and bending moments across the knee(23). A height in the range of 305 to 356mm has been proposed(11). Optimum static bumper height for adults should be 340mm(14). The last mentioned author also reports that in a follow-up of disability, six out of seven cases of walking impairment were due to bumper heights at or above 400mm. In an anthropometry-dependent proposal, it is suggested(26) that the bumper should be below the height of the adult knee and below that of the child's pelvis (6-year-old's height). This indicates the need for anthropometric data on the population at risk (Writer's note).

A height of 375mm from ground to top of bumper in semi-laden conditions is proposed(22). Such a bumper should have energy-absorbing characteristics with a yield of at least 100mm. The same author(24) later suggests, however, that the following configuration (bonnet height: 700mm, combined with either a bumper at 375mm or a bumper lead of about 150mm or more) may allow excessive torso rotation and increasing risk of head-ground impact. It is stated that, in experiments, the 500mm bumper always reduced risk of head-windscreen surround impact. The combination finally proposed is as follows: For thoracic/head impacts to the bonnet, both adults and children would seem to benefit from the 700mm bonnet height, a 50mm bumper lead, and, to reduce leg injuries, a crushable 500mm bumper (combined with a crushable secondary bumper mounted at 300 to 350mm and below and about 50mm behind the primary bumper).

From epidemiological research(13), it was established that the bumper level parameter has no effect on healing time.

Bumper Lead and Lead Angle

Bumper lead cannot be assessed in isolation. Reducing lead benefits the second leg struck, but there is a corresponding increase in the contact loads of the hip and femur with the front end. Bumper lead should mainly be considered as a means for reducing front end contact loads—typically, 127mm dependent on front end height(11).

Decreasing bumper lead (increasing bumper lead angle) is associated with decreased bumper contact fractures and increased leading edge contact fractures. All acetabulum fractures involved elderly adults and vehicles with relative leading edge height in the range 0.45 to 0.51 and short bumper leads(9).

Conflicting goals appear to exist from a reading of the following: While it is stated that risk of knee injury will be reduced if bumper lead angle is below 60° (that is, if bumper lead is long) and found in conjunction with a force-limiting and energy-absorbing bumper(14), it has also been concluded(28) that, independently from bumper height, increasing bumper distance brings head impact areas nearer to the windscreen.

Bumper Width and Shape

Broad, flat-faced, or slightly rounded surfaces with rounded top and bottom edges would reduce bumper leg forces, maximum bending and crushing stresses, and leg rebound velocity(22).

Devices: Head Injury Mitigation

It is stated(29) that pedestrian kinematics can be controlled so impact is as close as possible to the bonnet center, which has a built-in honeycomb structure for impact energy absorption. No results, however, are provided.

Devices: Induced Kinematics

A low-mounted energy-absorbing bumper (yield: at least 100mm) and bonnet leading edge (yield: at least 150mm; preferably much more) would help direct the pedestrian head toward a suitably designed energy-absorbing bonnet(23). A device has been developed to retain adult pedestrians on the bonnet and to help lift a child onto it(22). It is also suggested(40) that a hood with a high coefficient of friction of its surface could increase head protection when the pedestrian's arm or elbow interacted with it.

Epidemiology (Related to Test Conditions)

Impact Direction—Pedestrians are normally struck from the side (79 percent of a sample of 211 at ±22.5° to the vehicle's path(8); almost always laterally(5); laterally in 84 percent of cases (N:87)(39). NB Cadaver experiments indicate(15) that, when laterally impacted, pedestrian head impact speed is approximately the same as car impact speed; when impacted to their front, it is higher.
Pedestrian Pace at Impact—Two epidemiological studies(39,8) provide data: for the former, 42 percent walking, 47 percent running, and 8 percent standing. For the latter, 25 percent of adults less than 60 years old and 76 percent of children were running.
Average Vehicle Profile—In (39) this was unloaded bumper height 420mm, front face upper edge 730mm, and distance from front face to windscreen 1,110mm.

Impact Speeds

It is thought worthwhile to draw up these data in a collated form in spite of the fact the source documents reporting on experimental and epidemiological studies and the data are of different types (based on samples of different size and representativity for the accident data and on different test conditions for the experiments). The following has been noted:

Speed or speed b (km/h)	and Remarks and source
17	AIS 3 injuries occur at speeds as low as this(1)
20	No vehicle contact injuries (N:211) at less than this(8)
20-25	Risk of severe injury exists laterally and frontally(15)
20-35	Ligament strain noted(10)
24.8	Side impact leg fracture threshold(*)(18)
32	Frontal impact leg fracture threshold(*)(18) Speed arbitrarily selected for experiment as being the fatal impact speed threshold(40)
33	In a pedestrian accident sample (N.72) 50 percent were at impact speeds below this(37)
34	Mean impact speed in fatal and nonfatal accidents(5)
35-45	Complete ligament rupture noted(10)
36	Average impact speed(N:87): 29km/h for injured; 51km/h for killed(39)
40	Probable limit to pedestrian protection(24)
50	No adult life-threatening/fatal contact injury at less than this(8)

* No cadaver age or bone condition data were given.

The demographic/anthropometric scatter of the population at risk takes on its full meaning when one reads that at comparable impact speeds vehicle front contact injuries appear to be age-dependent(8). In a later study(9), the same author reported (N:211) assessed impact speeds as less than 20km/h: 12 percent; 21 to 40km/h: 57 percent; 41 to 60km/h: 25 percent; and above 60km/h: 4 percent.

Research Needs

Epidemiological—With so much attention directed at narrowly limited body segments and injury mechanisms, it is not surprising that there is a call(32) for close examination of overall injury potential. A part of this close examination should apparently be long-term effects: Leg injury effects are not well correlated with primary injury severity nor impact speed(13), and more research is needed. The same theme is cited(31) in relation to knee injuries that may lead to degenerative arthritis. He states that recognition and early treatment of extremity injuries should decrease long-term disability.

In another area, it is suggested(7) more data are needed to resolve areas of conflict (quantification of trade-off factors such as those in the field of bumper height optimization for adult versus child pedestrian protection).
Methodological—There is a call for more complex test procedures that take account of hip reaction forces and knee joint angulation(10) and for a more precisely defined injury-scaling method for bumper-leg contact(1).

Test Conditions (See Also Epidemiology)

Dummy/Cadaver Posture—The portion of the walking cycle that gives the most serious impact loading is with 90 percent of body weight on the fully extended leg closest to the vehicle(32). Dummies should be free-standing due to the influence on kinematics of foot friction(11); the reduction of ground contact forces increases angular rotation, which can sometimes lead to greater head impact velocities (idem).
Vehicle Pitch (Influence on Bumper, Etc., Dynamic Height)—The vehicle had started to brake in 54 percent of cases (N:87)(39); in 30 percent of cases (N:363)(10). Bumper mismatch, caused by vehicle pitch, can increase vehicle damage but may mitigate pedestrian injuries(7).
Other Points—In mathematical simulations, the method of modeling joint dynamic and static properties is critical(40).

Vehicle Aggressiveness: Ranking Methods

The mechanical leg model developed(2) can probably become an instrument for ranking bumper aggressiveness. The development is also reported(24) of a local impactor device for use horizontally (bumper-knee) or vertically (head-bonnet).

Vehicle Aggressiveness and Upgrading Priorities

While the bumper has been stated to be the most aggressive zone for adults and the bonnet for child injury(5), the point is made(13) that car front aggressiveness cannot finally be judged without noting long-term effects of injury. In accident samples, the bumper is reported on as follows: Among lower extremity/vehicle injuries, the bumper was responsible for 70 percent and the top part of the front end for 30 percent(N:87)(39). Also, 55 percent of nonminor leg injuries (N:211) were attributed to the bumper and a further 36 percent to the front structure above the bumper(9).

From an analysis (N:292) of accidents, the requirements of the age groups less than 15 years old and 15 years or more were stated(38) to be different and to suggest the need for two levels of reaction forces for some vehicle exterior elements (such as bumper contact stiffness). The same author(37,38) more generally suggests that vehicle features, including their deformation characteristics, should be adapted to the biomechanical load values of victims' body segments contacted and that vehicle layout upgrading priorities should be based on such capacities in an age-dependent way.

The problem is shown as being not only to upgrade vehicle features but also to combat the deleterious effects of some add-on items: Bullbars (as used in Australia)(16) amplify front end aggressiveness and negate the effects of positive design features.

Struck-Striking Car Compatibility in Side Impacts

Two not very recent references make up the sum of data. It is stated(7) that one aspect of the FMVSS 215 standard has been to increase front end aggressiveness, one aspect of this being a mismatch in side impacts between the striking car's bumper and the struck car's side beam. A different view comes from (27), which asserts that the 5mph energy-absorbing bumpers lower the aggressiveness of vehicles fitted with them and do not degrade the small benefits, for unrestrained struck-side occupants, achieved by side door reinforcement beams.

Abstract

Thoracic injury to the near side occupant in a side collision is normally caused from contact with the struck vehicle's crushed side structure engaged by the striking vehicle's front end. Extensive research has already been done to investigate the effect that strengthening and padding struck vehicle side structure has on occupant safety. This study investigated the effect that altering the striking vehicle front end characteristics has on occupant safety in a side impact.

The National Highway Traffic Safety Administration's (NHTSA) moving deformable barrier (MDB) was used to conduct 12 crash tests. Three different types of honeycomb barrier faces were used, each representing a front end characteristic change. These were a reduction in stiffness, a lowering and tapering of the hood profile, and a lowering of the bumper. The alterations were believed to represent achievable production vehicle changes.

Each of the altered frontal designs were tested four times, striking baseline and padded Volkswagen Rabbits at both 60° and 90° configurations. In each case, the simulated striking and struck velocities were 35 and 17.5mph, respectively. The occupant responses and relative benefits from each of these concepts are shown and discussed.

Introduction

In May 1984, NHTSA summarized the results of the near-term research toward improved side-impact thoracic protection(1). This near-term research effort consisted of problem definition, surrogate development, and demonstration of improved performance. The improved performance was achieved by strengthening the side structure and adding interior padding to the side interior.

The effort described here was a first step toward understanding potential alterations to the fronts of vehicles that would reduce the potential for occupant thoracic injury when these vehicles strike other vehicles in the side. It represents a recognition of the long-range nature of the front/side compatibility issue.

Three specific alterations to vehicle frontal characteristics were included for consideration in this research: reduction of the frontal crush strength; lowering the hood height; and lowering the bumper height to allow side sill engagement.

Objective

The objective was to identify which of the three candidate characteristics could provide the most benefit to occupants in side-impact collisions. The characteristic that, when altered a reasonable amount, caused the largest reduction in occupant thoracic injury potential was the one to be recommended for future research.

Background

The research described used a dynamic crash test to measure the level of safety of a vehicle. This type of testing is relatively complex and was performed in an attempt to simulate in the laboratory as many aspects of a highway accident as possible. The test involved the placement of two Side Impact Dummies (SID's) in the struck vehicle (one in the driver and the other in the left rear seated positions). The SID has been documented in other presentations(1,2). Measurements of acceleration and displacement were taken at the following locations in the SID:

- Lateral accelerations—left upper rib, left lower rib, upper spine, lower spine, head, and pelvis

- Longitudinal accelerations—upper spine, lower spine, head, and pelvis
- Vertical accelerations—upper spine, lower spine, head, and pelvis
- Lateral displacement—left ribs relative to spine

All of the lateral accelerations in the thorax were measured redundantly to assure capture of these data. The lateral accelerations of the ribs and lower spine were used to estimate the thoracic injury potential of the test environment using the Thoracic Trauma Index (TTI) criterion presented at the 1984 SAE Government/Industry Meeting(2).

The crash test mode and the severity level were the same as derived for Crash Test Matrix II(1) and will be reviewed briefly here. All conditions were derived from a study of thoracic injury-producing side-impact accidents in the National Crash Severity Study. It was found that for the serious-to-fatally injured cases, roughly the same numbers of oblique and near perpendicular impact orientation were present. Impact angles of 60° and 90° have been used to represent these two groups of impact orientations. An impact area was also derived from the file. Basically, the left edge of the striking vehicle was aligned with a vertical line on the left side of the struck vehicle. The vertical line was 37in forward of the midpoint of the wheel base. The severity level was derived in the form of traveling velocities for the striking and struck vehicle. A 35 and 17.5mph velocity combination was found to be an average among the serious-to-fatally injured cases.

The striking vehicle used for the study was the NHTSA MDB. The barrier design was reviewed in (1). The MDB was configured to a weight of 3,000 lb to represent a median weight of the striking vehicle for injury-producing side impacts in the United States. The wheels of the MDB were adjustable to allow the simulation of two-vehicle-moving collisions when, in fact, the struck vehicle is stationary. A wheel setting of 26° was used in the 90° impact orientation and a wheel angle of 19° for the 60° orientation.

The above test conditions, derived for the Matrix II tests, were used for testing in this effort. Most of the Matrix II tests and all of the tests for this research were performed at the Transportation Research Center of Ohio (TRCO). A test report (available upon request) documenting the conditions and results of each test was submitted by TRCO. These results are summarized in this report.

It was found from the Matrix II testing with VW Rabbits that interior padding alone resulted in a significant reduction of rib accelerations, but that both padding and structural reinforcement were required to significantly lower both rib and spinal accelerations. To allow the results of the previous work to be compared with the frontal modification work, the VW Rabbit was again used as a target vehicle. The relative improvement achieved through modifications to the struck vehicle will be compared with those achieved through changes to the striking vehicle in a later section.

Test Conditions

Selection of Test Conditions

In the previous section, the crash configuration was reviewed. Two angles, 60° and 90°, a speed combination of 35/17.5mph, and an impact area were derived. In formulating the project, it was further decided the testing would be conducted in both padded and unpadded interior conditions. The reason for this was to allow application of these test results as to whether or not future vehicles use interior padding such as that tested in earlier programs. This resulted in 12 tests being planned for the evaluation of frontal characteristics of striking vehicles. The test conditions are shown in Table 1. Note that each test at an alternate level has a corresponding test at the standard level for comparison. The comparison tests were conducted under earlier agency test programs, with the test number shown on Table 1.

Table 1. Test conditions for evaluation of frontal characteristics

MDB Front	60°		.90°	
	Padded	Unpadded	Padded	Unpadded
Reduced Stiffness	840905	840713	840913	840621
Lowered Hood	841008	841001	841015	840919
Lowered Bumper	841204	841109	841120	841026
Standard Matrix II	831013	830505	830930	3144-6

Derivation of Frontal Characteristics

This section describes how the improved levels of each of the three frontal characteristics were chosen and reviews the fabrication procedure used. As stated earlier, it was the intent of the project to use reasonable values for each of the alterations, that is, to attempt to select alternate levels that were believed to be within the present or near future state-of-the-art. It was decided the baseline for comparison of frontal characteristics would be the NHTSA MDB. The primary reasons for this decision were the ease and repeatability of testing. The various types of alterations were then accomplished by the use of various types of honeycomb fronts for the MDB.

The standard front for the MDB is documented in a series of drawings, which are in NHTSA Docket No. 79-04. Figure 1 gives most of the frontal geometry and the

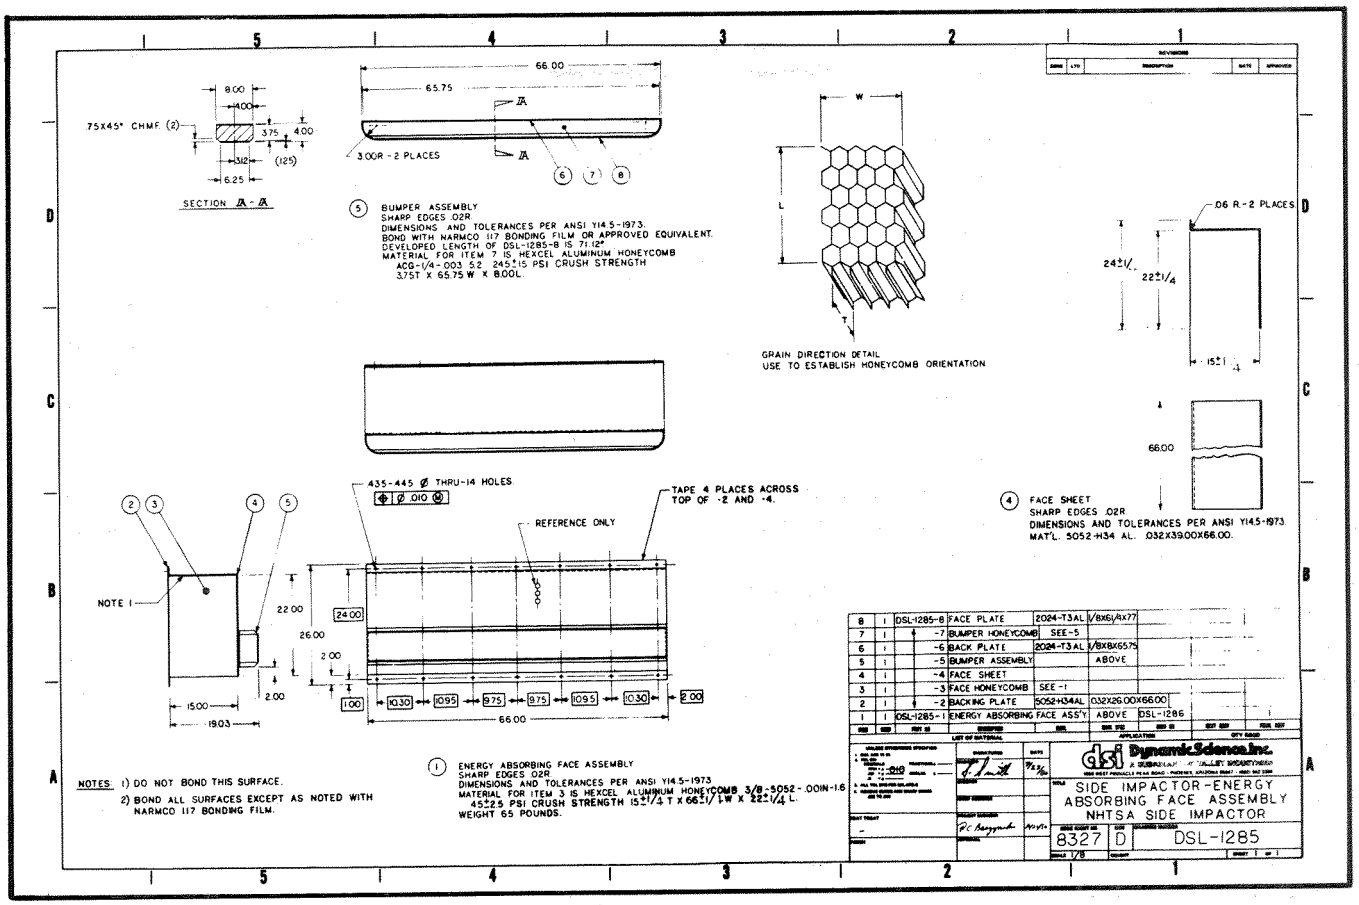

Figure 1. Standard MDB honeycomb face assembly

specified crush properties. The alterations of frontal characteristics will be presented relative to the standard geometry and crush properties.

Frontal Crush Strength

The core material of the MDB is made of aluminum honeycomb and has a specified level of crush strength of 45 ± 2.5psi. It should be pointed out that the term crush strength is used here in the same context that most of the honeycomb manufacturers use it, i.e., an average force level divided by the average area. Thus, it is given units of pressure or stress.

The present barrier face was shown in (1) to represent the stiffness of a vehicle such as the AMC Concord. The Concord was found to be relatively stiff in laboratory crash testing. The Chevrolet Celebrity was found to be one of the softest vehicles. It seemed reasonable, therefore, to select a barrier face stiffness that approximated the stiffness of the Celebrity. One simplified basis for making this selection was to use the energy equation and assume a square wave pulse shape. The average properties for an assumed ramp shape pulse were also computed. They were not used in the selection process but were of interest because the force versus deflection curves were somewhat ramp-like. The relationship used to derive the average "F" for an assumed square wave was as follows:

$$F = \frac{m(v_0^2 - v_1^2)}{2x}$$

x = amount of crush
m = test mass
v_0 = initial velocity
v_1 = velocity at crush x

The relationship used to derive the average "k" for an assumed ramp shape was as follows:

$$k = \frac{m(v_0^2 - v_1^2)}{x^2}$$

These equations were applied to crash test results of the Concord, MDB, and Celebrity. Since the MDB face "bottomed out" beyond 15in of crush, the values for each pulse shape were derived at 15in. The Concord and Celebrity values were also derived at maximum crush. Table 2 contains a summary of this analysis.

An approximation to honeycomb crush strength representative of the Celebrity was obtained by dividing the square wave force value by the surface area of the

Table 2. Front end stiffness analysis

Vehicle	Test Number	Force, based on Square Wave		Stiffness, based on Ramp	
		15″ (lb)	Max Crush (lb)	15″ (lb/ft)	Max Crush (lb/ft)
Concord	Cal-30829470	69,000	78,000	110,000	81,000
MDB	TRC-820528	69,000	N/A	110,000	N/A
Celebrity	DOT-HS-9-02274	27,000	47,000	44,000	31,000

MDB face (1,452in^2). The values obtained for 15in crush and maximum crush were 18.6 and 32.4psi, respectively. (Values representing the Concord, derived similarly, were 47.5psi and 53.7psi, which were close to the specified barrier face crush strength of 45 ± 2.5psi.) A value of 25psi was selected as the crush strength for the reduced stiffness barrier front.

Lowering the Hood Height

A sampling of the front end profiles of 20 passenger vehicles was done(3). The results are given in Table 3. From this, it was judged that a front edge hood height of 25in off the ground would be representative of one of the lowest hood profiles currently produced. In addition, as reported in (3), a striking vehicle with this hood height would contact the door of a VW Rabbit (the struck vehicle in this study) below the ribcage of a normally seated SID dummy.

Many of the vehicles sampled had hood profiles that sloped upward from the front to the rear. This was especially true for vehicles with relatively low front edge hood heights. For this reason, the lowered profile barrier fronts were also designed to slope upward. Over the 15in depth of the barrier fronts, the hood profile would rise from 25 to 29in.

Table 3. Hood profiles

Vehicles	Hood Height* (in)	Distance from Front of Bumper* (in)

Lowering the Bumper

Federal Safety Standard 215 specifies a zone in which an impact surface will hit the front of a vehicle. This has the effect of regulating bumper heights. A sampling of bumper heights is shown in Table 4. This sample placed the center of the bumpers for passenger vehicles between 17 and 18in above the ground. The bottom of the bumpers ranged from 13 to 16in.

Table 4. Bumper profiles

Vehicles	Bumper Height (inches) Bottom	Center	Width
Datsun 280 Z	15.0	16.8	3.6

Ford Bronco	18.5	21.6	6.1
Average	14.6	17.7	6.1
Current MDB	13.0	17.0	8.0

The centerline of the bumper of the MDB is 17in above the ground, which matched well with the vehicles measured. Since there was a 5in offset between the alignment of the MDB bumper and the side sill of the VW Rabbit, the alternate bumper height for the MDB was then set at 5in lower than the standard. The lower portion of the altered bumper was then 8in above the ground.

The hood height was kept the same for these fronts, so as not to confuse the results with the lowered hood height fronts. These fronts were thus larger in cross-sectional area than the standard fronts.

Simulation of Frontal Characteristics

Each of the frontal characteristic alterations mentioned in the previous section was incorporated into the design of an MDB honeycomb face. The surface area of the lowered hood and lowered bumper fronts was different than the standard. Because of this, either the localized unit crush strength or the overall crush force had to be different from the standard front. It was judged more important to maintain the unit crush strength (i.e., use 45psi core material) and let the total load on the struck car vary. The effect of this will be discussed later.

Reduced Crush Strength Barrier Faces

Four faces were constructed that had a crush strength of 25psi ± 10 percent. To accomplish this, the honeycomb material that comprised the main core of the face had this reduced stiffness. The bumper honeycomb material had the standard crush strength of 245psi. Finally, the geometry of these faces had the standard dimensions.

Lowered Hood Height Barrier Faces

The main core and bumper honeycomb materials for these four faces had the standard crush strength of 45psi and 245psi (±10 percent), respectively. Figure 2 shows the cross-sectional shape of these faces compared to those with the standard geometry. Note the bottom edge of the face and the bumper remained the same distance from the ground as the standard. The front hood edge, though, was lowered by 8in and the rear hood height was 4in lower than the standard.

Lowered Bumper Barrier Faces

As with the lowered hood height faces, the main core and bumper honeycomb materials had the standard crush strengths. As Figure 2 indicates, the hood height and profile were also standard. Note, though, that the bottom edge of the face was lowered by 4in while the bumper position was lowered by 5in. The actual dimensions of the bumper did not change.

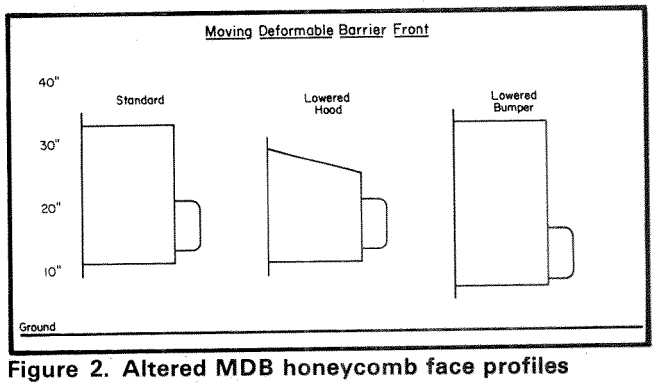

Figure 2. Altered MDB honeycomb face profiles

Crash Test Results

Twelve crash tests were performed to investigate the effect that altering striking vehicle front end characteristics has on struck vehicle occupant safety in side impacts. Each of the three different MDB front designs were involved in four different crash tests. For each test, two SID's were used: one as a driver, the other as a left rear passenger.

Tables 5 through 7 list the lateral rib, spinal, and pelvic accelerations (in g's) as well as the calculated HIC values

for each dummy of each test. Table 8 lists these same results obtained from similar Matrix II tests using the standard MDB fronts.

All tests simulate a 35/17.5mph collision

Several of the pelvic responses were not reported on these tables. The reason for this was that an unexplained rattling occurred on these acceleration signals. This problem was not new to this study for it appeared frequently in crash tests of previous projects. For most of these, it was not possible to estimate a pelvic response as the rattling occurred at the peak. An estimate was possible for a couple of them since the rattling occurred near, but not at, the peak. As can be seen in these tables, the reduced stiffness MDB faces produced peak driver pelvic accelerations that were 0.3 percent higher on average than those of the corresponding standard MDB

face tests. Similarly, the lowered hood fronts produced a 2.2 percent decrease while the lowered bumper fronts resulted in a 19.4 percent decrease.

It is also noted that the driver HIC values listed in Table 6 (lowered hood crash tests) are unusually high. These barrier faces had two effects. The first was that the striking vehicle front end penetrated the occupant compartment further than it did in the other crash tests. The second was that the submarining of the lowered profile front end caused the dummy to rotate, pelvis toward the roof, rather than just pushing the entire dummy across the arc. The result of these effects was that the dummy's head struck the barrier face mounting plate. Although no such structure is present in a real car, the rotation of the dummy did cause the head to contact the hood of the striking vehicle, which was an infrequent occurrence in tests using standard MDB faces. This may indicate that additional head protection would be required if future cars are built with lowered front end profiles.

As mentioned, Matrix II explored the possibility of reducing the thoracic injury to an occupant of a car struck in a side impact collision through structural and padding modifications to the side of the struck car. Figure 3 shows a summary of these tests, averaging 60° and 90° test results. As an average, a 23-year-old driver in the baseline vehicle (VW Rabbit) would have had a 97 percent chance of receiving an AIS 3 or greater thoracic injury. The introduction of door padding alone reduced this average possibility to 82 percent, while the combination of padding with side structural modifications reduced this to 61 percent. All these tests were performed using a standard honeycomb front on the MDB.

Presently, an upgrade to FMVSS 214 is under consideration. Based partially on the results of Matrix II, this upgrade would require a certain level of occupant safety to be maintained in a side impact crash test. Since the future of this upgrade is at this time undetermined, two separate cases are examined. In case A, it is assumed that no FMVSS 214 upgrade has been enacted. Consistent with that assumption, effects of the MDB front alterations have been determined on unpadded baseline cars. In case B, it is assumed that an upgrade to FMVSS 214 is in place. Accordingly, effects of barrier modifications have been determined on cars containing additional interior padding.

Again, averaging the results of the 60° and 90° tests, Figure 4 presents the results of the tests done with no additional padding (case A). In this and the following figure, the Matrix II results from structurally modified and padded struck cars are shown on the left of the figure, while the results of the frontal alterations are shown on the right. This provides a direct comparison of benefits

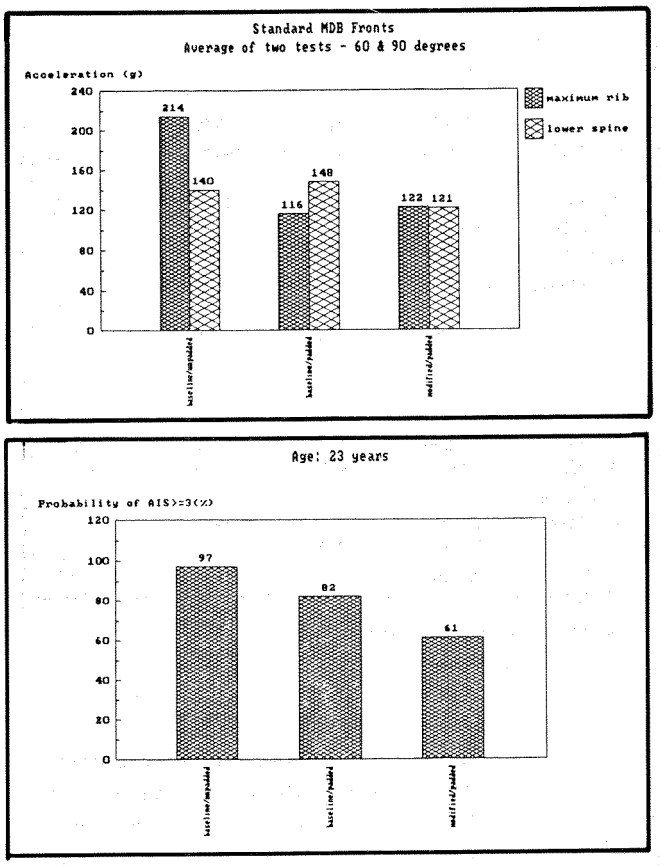

Figure 3. Struck vehicle study—matrix II results—driver

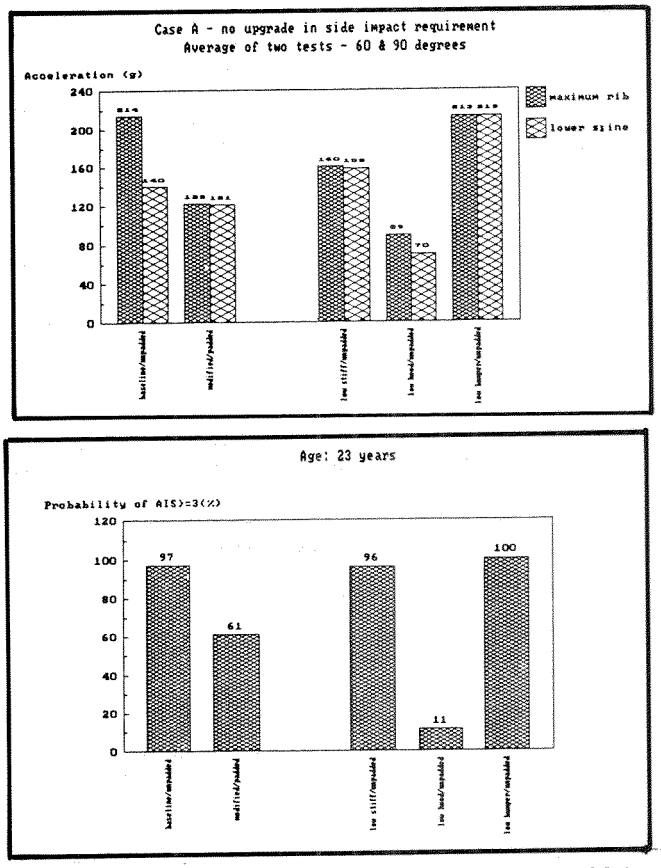

Figure 4. Comparison of striking and struck vehicle studies—driver—case A

derived from altering the front of the striking vehicle with those derived from modifying the struck vehicle. The reduced stiffness and lowered bumper tests showed little change in the thoracic injury probability from the baseline tests done with standard MDB fronts. However, the lowered hood tests produced a large reduction in injury probability. For a 23-year-old driver, the average chance of receiving an AIS 3 or greater thoracic injury went from 97 percent for the standard MDB front to 11 percent for the lowered hood MDB front. This was an even lower injury potential than that from the least severe tests of Matrix II (modified structure and additional padding—61 percent).

Case B is presented in Figure 5. The altered MDB front test results represented here are the average of the 60° and 90° padded tests of each type. Again, based on average thoracic injury probabilities, the reduced stiffness and lowered bumper tests did not perform as well as the modified vehicle tests of Matrix II (64 percent and 73 percent versus 61 percent). Although no vehicles with structural modifications were tested in this project, it is reasonable to assume that the addition of such modifications for the reduced stiffness and lowered bumper tests would further reduce the above injury potentials. The extent of this is not known.

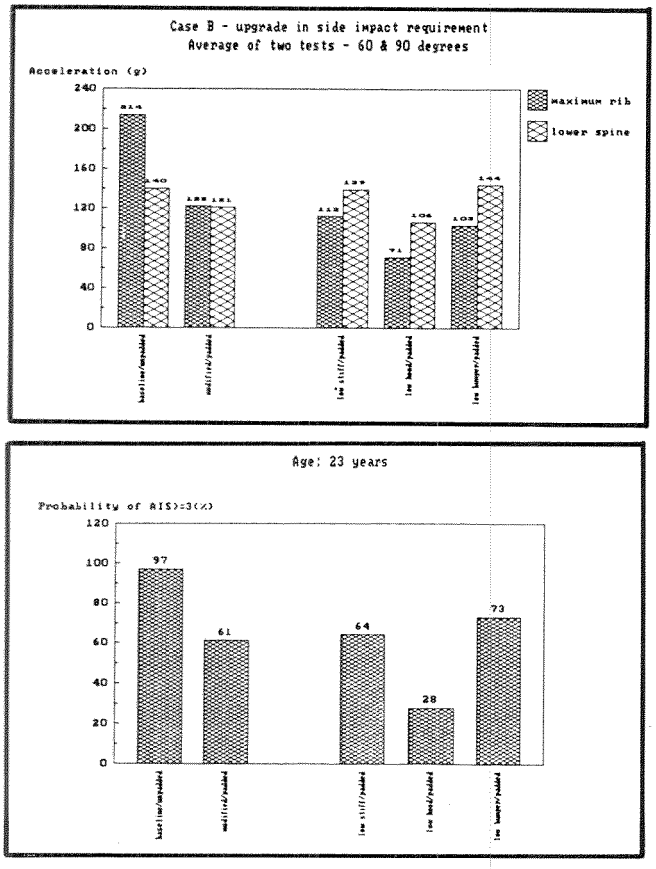

Figure 5. Comparison of striking and struck vehicle studies—driver—case B

The most important portion of Figure 5 deals with the lowered hood tests. Even without structural modifications, these tests produced a much lower thoracic injury potential than the fully modified vehicle tests of Matrix II. For a 23-year-old driver, the probability of an AIS 3 or greater thoracic injury fell from 61 percent to 28 percent. The effect of the addition of structural modifications, although not known, would probably be to reduce this injury potential further.

The appendix contains complete listings of the probabilities for receiving an AIS 3 or greater, 4 or greater, and 5 or greater thoracic injuries for both 23- and 41-year-old drivers and passengers.

From these results, it appears that since the lowering of the striking vehicle hood height reduced the dummy thoracic responses substantially, the injury an actual occupant receives should also be reduced. While it is likely this is true, there was an oddity in the data that merits discussion. The following addresses this point.

Table 9 lists the lateral chest deflections for the 12 crash tests performed for this investigation as well as for the 4 comparable tests from the Matrix II study. A standard deflection ranges from 1.8 to 2.0in. The reduced stiffness and lowered bumper tests resulted in chest deflections that were within this range. The lowered hood tests, though, had much lower values for this measurement. Particularly low was that from the 60° baseline test.

One explanation for this was that the thorax may not have been loaded directly due to the submarining action described previously. This could have reduced deflection and acceleration of the ribcage and spine. In this case, the actual thoracic injury an occupant would have received would indeed have been reduced.

Another possibility was that the lowered hood MDB fronts caused an unusually large amount of nonlateral loading on the SID ribcage and spine. Since the chest deflection potentiometer and rib accelerometers were not omnidirectional, they may not have measured a significant portion of the total responses.

Nonlateral accelerations were measured at the upper and lower spine locations. Table 9 lists the lateral and resultant peak accelerations (in g's) for the upper and lower spine of the driver dummy for each of the tests. As an indication of the magnitude of the effect of the nonlateral responses, the percentage increase of the resultant as compared to the lateral peak is also included.

This table would seem to indicate, with one exception, the effect of nonlateral loads on the spine was no greater for the lowered hood crash tests than they were for the others. This exception was the baseline 60° test, which, as mentioned previously, also had a very low chest deflection.

In the lowered hood crash tests, there was no structure immediately contacting the upper door as there was in the tests involving the other MDB fronts. Since the thorax of the dummy contacted this portion of the door, the door-to-thorax impact caused the door to indent around the

thorax. As is often the case for 60° impacts, the hinges tore away from the A-pillar in both the padded and unpadded 60° lowered hood tests. The combination of the door being bent around the thorax and the loose door being forced rearward may have caused the unusually high amount of nonlateral loading on the thorax for the unpadded test. Although the damage to the doors was similar in the two tests, the additional padding may have lessened the effect of this indentation to cause nonlateral loads on the thorax. If this was true, the lateral results of this test do not give the complete picture. Even if this were so, the overall findings of this study would not change.

It is also possible, however unlikely, that nonlateral loading occurred on the ribcage, not measured by the chest potentiometer or the rib accelerometers, that did not translate through to the spine. Since the ability of the SID to measure nonlateral loading on the ribcage is uncertain, no judgment was made as to which of the preceding explanations is correct. A further investigation would be necessary to make this determination.

Since the passenger dummy responses are generally used less frequently than those of the driver, these results are only summarized here. Complete responses are listed in Tables 5 through 8 and in the appendix.

Similar to Figures 4 and 5, Figure 6 shows the probability that a 23-year-old rear left seat occupant would receive an AIS 3 or greater thoracic injury in both this study and in the Matrix II study. As before, 60° and 90° tests are combined and two cases are considered. In case A, the lowered hood MDB fronts produced the most benefit to the occupant as compared to the other MDB faces. Thoracic injury probability was reduced from 82 percent for the standard front to 15 percent for the lowered hood front.

In case B, the reduced stiffness MDB faces produced the lowest chance of serious thoracic injury for the vehicles without structural modifications (13 percent). The lowered hood fronts were only slightly higher (17 percent). Both of these MDB fronts performed better than the standard front did under the same level of struck vehicle modification (22 percent). If these tests were repeated using structurally modified cars, it is reasonable to assume that these probabilities would be reduced further. The extent of this reduction is not known.

Finally, the results of the reduced stiffness tests helped to evaluate the decision to use 45psi honeycomb in the lowered hood and lowered bumper MDB faces (see previous section). The 25psi fronts used for the reduced stiffness tests represented a 44 percent reduction in both overall and localized (adjacent to occupant) stiffness. The response changes due to this reduction were minimal. The lowered hood profile tests and lowered bumper tests

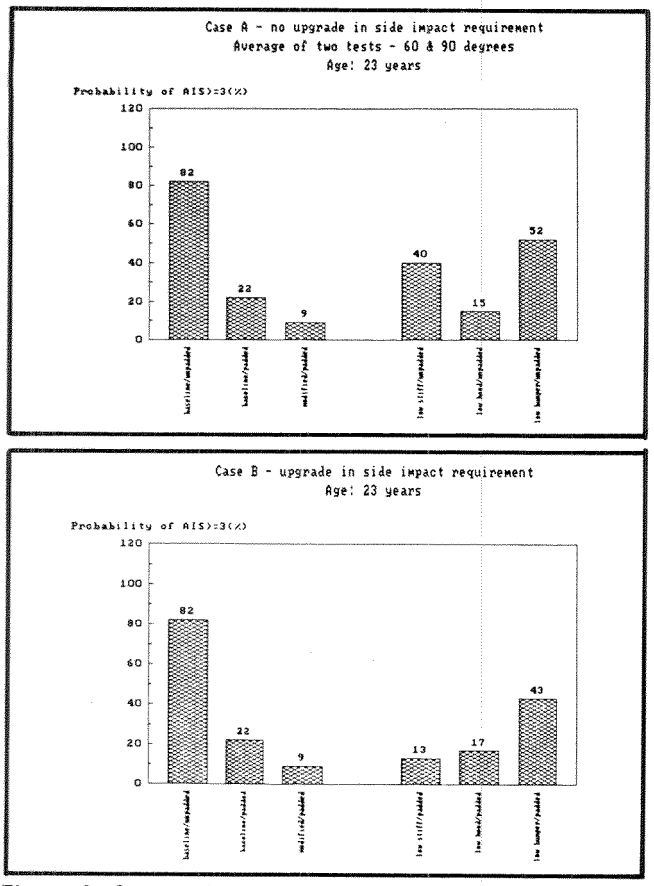

Figure 6. Comparison of striking and struck vehicle studies—passenger

resulted in a 36 percent decrease and an 18 percent increase in overall stiffness, respectively, due to the differences in impacting surface area. Since a 44 percent decrease in overall stiffness did not significantly reduce occupant responses, the large reduction in thoracic responses in the lowered hood tests was judged to be due primarily to the lack of localized external structure at the thoracic level. It was not believed to be caused by the reduction in overall stiffness. It was also judged that the 18 percent increase in overall stiffness for the lowered bumper tests did not significantly affect occupant response.

All aspects considered, the concept of lowering the striking vehicle's hood shows much promise as a means to reduce struck vehicle occupant thoracic injury in side impacts.

Conclusion and Recommendations

NHTSA has completed a preliminary study of the effects that altering the front end characteristics of striking vehicles has on the safety of an occupant of a vehicle struck in a side-impact collision. The following are conclusions from this investigation. Each injury potential listed here is the average probability of a 23-year-old occupant receiving an AIS 3 or greater thoracic injury from the 60° and 90° tests of each type.

1. When considering thoracic injury to a driver in a subcompact car, when struck in the left side, there appeared to be more potential benefit in altering the front end characteristics of the striking vehicle than in modifying the side of the struck vehicle. The best performing vehicle of the Matrix II tests, which had both structural and padding modifications, resulted in a thoracic injury potential of 61 percent. This compared to 11 percent for baseline vehicles struck by the MDB with lowered hood fronts.
2. For the three types of MDB fronts tested in this project and the standard fronts tested previously, the lowered hood MDB fronts produced the least severe thoracic injury environment for the driver of a subcompact vehicle struck in the left side. The injury potentials were as follows:

   For unpadded tests:
   - Standard—97 percent
   - Reduced stiffness—96 percent
   - Lowered hood—11 percent
   - Lowered bumper—100 percent

   For padded tests:
   - Standard—82 percent
   - Reduced stiffness—64 percent
   - Lowered hood—28 percent
   - Lowered bumper—73 percent

3. Of the three types of MDB fronts tested in this project, the lowered bumper fronts showed the largest improvement in the peak lateral driver pelvic responses as compared to the standard front. The average driver peak pelvic acceleration from three lowered bumper tests was 19.4 percent lower than that from the same three standard MDB front tests of Matrix II. Similarly, the reduced stiffness fronts showed a 0.3 percent increase, while the lowered hood fronts produced a 2.2 percent decrease.
4. If lowered front end profiles were required on vehicles, additional protection for the head may also be needed. The submarining of the lowered hood MDB fronts caused the driver dummy to rotate, pelvis toward the roof, much more than did the other three MDB fronts. This rotation caused the head to contact the hood of the striking vehicle, thereby increasing the risk of serious head injury.
5. The lowered hood MDB fronts produced the lowest thoracic injury potential for a left rear occupant in the unpadded tests, while the reduced stiffness fronts resulted in the lowest for the padded tests. These injury potentials were as follows:

For unpadded tests:
- Standard—82 percent
- Reduced stiffness—40 percent
- Lowered hood—15 percent
- Lowered bumper—52 percent

For padded tests:
- Standard—22 percent
- Reduced stiffness—13 percent
- Lowered hood—17 percent
- Lowered bumper—43 percent

Based on the results presented in this paper, it is recommended that future aggressiveness studies focus on the relative placement of the striking vehicle hood to the occupant thoracic region. This should include an investigation of the SID thorax dynamics in this type of testing as well as an attempt to determine an optimum hood design, considering all factors. Finally, an investigation should be done to determine whether the findings of this study apply to other vehicle size/weight categories.

Volvo Side Impact Testing

Mats Nilsson,
Kjell Andersson,
Johnny Korner, and
Anna Nilsson-Ehle
Automotive Safety Centre, Volvo Car Corporation

Abstract

The improvement of side impact protection is today a major concern to the crashworthiness community. A prerequisite for making this development possible is the establishment of a common side impact test method, representative of several traffic environments.

Volvo has made a study aimed at determining the suitability of a moving barrier test as a tool for the development of side impact protection. Traffic accident data from car-to-car accidents have been used as references to full-scale tests. Certain test parameters have been varied to find out if an improved correlation is possible between real-world accidents and laboratory collisions. To further understand the interaction between the occupant and the car structure, sled testing has been used as a complement.

The conclusion of the study is that a suitable side impact test method is a moving deformable barrier (MDB) impacting in a 90° noncrabbed configuration. A good resemblance to real-life accidents is achieved with a CCMC MDB 76, mass 1,400kg, ground clearance 250mm, and impact speed 35mph.

Future work at Volvo will include further accident investigations, improvement of measurement techniques, development of subsystem testing, and evaluation of different MDB front faces in terms of force-crush characteristics.

Background

Volvo strives to continuously improve the crashworthiness of Volvo cars by a conscious development and design strategy, the Volvo Safety Design Philosophy(1,2).

In short, this means the experience from traffic accident studies is used as an important source for establishing crashworthiness requirements, which, in combination with other requirements, form the input to the establishment of laboratory test methods. Requirements on performance in these tests are established and further developed into requirements on systems and subsystems in the car. These requirements provide the basis for the actual design work of the car structure and the interior safety systems.

Side impact collisions have been focused on for several years, and a broad analysis of the Volvo accident material was published in 1982(3). Here the complexity of the problem was enlightened, for instance, the varying injury patterns due to different collision objects, and it was recommended, to cover different types of side impacts, that a car-to-car simulating full-scale test should be accompanied by complementary subsystem testing.

Since then, further in-depth studies of side impact accidents have been conducted to improve the input data for the development of test methods.

This paper focuses on the simulation of car-to-car accidents and the establishment of a corresponding test method. Irrespective of the severity of lateral collisions with poles and trucks, car-to-car side impacts still constitute an essential problem to be dealt with.

Volvo has followed the development of the CCMC moving deformable barrier, the MDB 76(4). This barrier is thought to be a good representative of modern cars, not only European but also American(5). It has a good repeatability and makes a suitable substitute for actual cars. However, comparisons with struck Volvo cars in real-life accidents have shown certain discrepancies that have initiated part of the Volvo study presented here.

The objective of the study has been to find the effect of variations of certain test parameters and to establish a test configuration corresponding to real-life experience.

Side Impact Accident Studies

The side impact test procedure described in this paper has partly been chosen on the basis of a comparative analysis of Volvo 240 field accidents and laboratory collisions in corresponding crash configurations.

Two different investigation levels were used in the accident sample. From Volvo's statistical accident material (large number of accidents, limited investigation depth), 645 car-to-car side impact cases were chosen for analysis, the selection criteria being that the occupant compartment was impacted and an occupant was seated nearside.

To these accidents were added 23 side impact cases investigated by Volvo's multidisciplinary in-depth study team and chosen to insure accident conditions comparable to the laboratory crash tests. The selection criteria were: Volvo 240 accidents where the compartment was run into by a medium-size car or a van at 60° to 120° (orientation angle) and with an occupant seated on the near side. The in-depth study cases were analyzed thoroughly with a view to the degree and shape of deformation (B-pillar intrusion) and the degree of injury severity (MAIS) to the near side occupant.

In spite of the absence of reliable crash severity calculation methods for side impacts, it has been possible

to establish a fairly reliable assessment of the connection between the degree of deformation, the impact speed (for a homogenous group of specified striking cars), and the resulting injury to occupants, since laboratory crash tests corresponding to the field accident conditions were available.

The results are shown in Figures 1, 2, and 3.

Both the accident statistics (Figure 1) and the analysis of the in-depth study cases (Figure 2) show that serious injuries (AIS 3+) start to occur more frequently at deformations corresponding to impact speeds exceeding 30 to 35mph. This does not mean that AIS 3 injuries necessarily occur in such collisions. Occupants sometimes escape with minor or moderate injuries (AIS 1 to 2) at B-pillar intrusions corresponding to approximately 35mph (see Figure 3).

It should be pointed out the deformation pattern analysis described here does not necessarily imply that a mere reinforcement of the side structure—and consequently a reduced deformation—would reduce the severity of injuries.

The deformation shape of a Volvo 240 run into by the CCMC barrier does not satisfactorily correspond to the deformation shape in the field accidents investigated. The barrier causes a considerably greater deformation at shoulder/head height, (see Figure 2).

Full-Scale Tests

The traffic accident experience shows the necessity of improving the resemblance of today's laboratory tests to actual side impacts. The basis for this study has been the CCMC test method(4). At present, the CCMC test configuration and barrier are felt to be the most representative setup. Volvo cars have also been tested earlier according to this.

Test Matrix

Six full-scale tests were conducted in Volvo's crash testing facility, (see Table 1).

In all tests, the target was standing still and was run into by the bullet vehicle on the driver's side. In tests 1 to 5, the bullet hit the target perpendicularly with centerline in bullet at SRP-position in target. Test 6 was conducted in a 90°/27° crabbed configuration. The varied parameters were—

- Type of bullet
- Mass of bullet
- Ground clearance of barrier
- Structural reinforcements and padding
- Crash configuration

Based upon experience from a previous side impact study of the Volvo 240, the Volvo 760—the most recent production car—was chosen as the target vehicle in this study. In tests 5 and 6, the target was an experimentally reinforced Volvo 760 (see Table 1).

Choice of Varied Test Parameters

Type of Bullet

The comparison between cars and MDB's as bullets was made to give an idea of the difference between a mid-size car with US-bumper system, such as a Volvo

Table 1. List of conducted full-scale tests

Test No.	Bullet Type	Bullet Mass (kg)	Bullet Ground Clearance (mm)	Target Type	Target Mass (kg)	Test Type	Impact Velocity (mph)
1	Volvo 240	1400	—	Volvo 760	1690	90°	35

240, and an MDB 76(4) regarding intrusions, wall speeds, and dummy responses. The bullet had a mass of 1,400kg in both cases (tests 1 and 2 in Table 1). A comparison was also made with the previous study of the Volvo 240 as target and with field cases.

Mass of Bullet

The mass was varied to ascertain the effect on wall speeds and dummy responses. The levels chosen were 950kg in accordance with CCMC specifications and 1,400kg, a typical medium-size car mass close to the NHTSA barrier(6). Ground clearance in the compared tests was 300mm (tests 2 and 3 in Table 1).

Ground Clearance of Barrier

The barrier's ground clearance was reduced in test 4 to 250mm, as the basic MDB 76 ground clearance of 300mm turned out to give greater loads on the structure and the dummies at chest height as compared with the Volvo 240, and poor resemblance of intrusion profiles in the field cases. The bullet in the full-scale tests compared had a mass of 1,400kg (tests 1, 2, and 4 in Table 1). A comparison was also made with the earlier tests where the target was a Volvo 240.

Structural Reinforcements and Padding

The target was reinforced primarily to permit investigation into how an MDB 76 reacts, regarding its resistance to bottoming out when put up against a test object that is essentially stronger (test 5 in Table 1). The target vehicle was also equipped with padding.

Crash Configuration

It was also decided to study the effect of testing in crabbed configuration, as it is generally considered this type of test better simulates side impacts in the field. The same test configuration was chosen as is used in the joint NHTSA and VW(5) project MIV, i.e., a 90° / 27° crabbed configuration.

Nonvaried Test Parameters

MDB

No comparative testing was made on the different deformable fronts available. The CCMC MDB 76 was chosen as the bullet due to its force-crush characteristics and good repeatability.

Test Speed

The speed of the bullet at right angles to the target was, in all cases, 35mph. The reason for this is that severe injuries (AIS 3+) in the Volvo 240 field accidents start to occur more frequently at impact speeds exceeding 30 to 35mph. To improve side impact protection, the relevant test criteria, therefore, must be met at an impact speed of 35mph).

Choice of Structure-Related Evaluation Parameters

In the full-scale tests, a large number of parameters were measured with the aid of accelerometers and high-speed cameras. Some of the relevant structure-related

parameters were chosen for a comparative analysis of the various tests.

The injuries affecting the nearside occupant in a side impact depend to a large extent on the speed of the intruding side structure. It is therefore essential that intrusion speeds are correctly simulated. In traffic accidents, only postcrash data are available. A comparison between laboratory tests and traffic accidents must rely on such data, e.g., residual deformation. For the evaluation of the full-scale tests, comparison is made for—

- Wall speed at chest height
- Wall speed at pelvis height
- Residual internal deformation of B-pillar

A further indication of the fundamental side impact mechanisms is also the velocity increase to which the target is exposed in relation to the velocity increase of the side structure, i.e.—

- The target's rigid body movement pattern
- The movement pattern of the side structure
- The relation between these two

The velocity, in chest- and pelvis-level, of the intruding side structure is graphically established from high-speed film of the B-pillar at the time of dummy impact. This method of measuring the wall speed is more reliable than using accelerometer readings from the structure that actually impacts the dummy. The wall speed is looked upon as a structural parameter since its importance as an injury-producing parameter is reduced when padding is introduced. The time of dummy impact is assessed by using the chest acceleration resultant graph.

Since this is a comparative analysis, the different evaluation parameters are normalized so that values in one test are set to 1.0. The values in the tests to which the first test is compared are all in relation to this.

Comments

The wall speeds must be interpreted with care due to both the inaccuracy of the measuring method used and the fact that the dummy responses are not only dependent on wall speed at the time of contact, but also on the wall speed history during the total period of contact. Thus, wall speeds and dummy response in some cases may appear to be contradictory.

Choice of Dummy-Related Evaluation Parameters

The APROD-81 dummy has been used as a measuring device. This dummy is basically a Part 572 dummy with a special chest designed to measure chest deflection at two levels(7).

This dummy was preferred to the American SID dummy because the deflection and deflection rate are biomechanically better related to injury than acceleration is. However, during testing it was found that imperfect design of the chest, especially the shoulder part, has reduced the information from the chest deflection readings and the reliability of these measurements.

The following parameters are used for the evaluation of test results:

- Maximum head acceleration (>3ms)
- Maximum chest acceleration (>3ms), center of gravity
- Peak resultant chest acceleration
- Peak acceleration upper rib
- Peak acceleration lower rib
- Maximum hip acceleration (>3ms)

Sled Test Method

As a complement to full-scale testing, a test method is required for studying the interaction between the car side interior and the occupant. This test method must simulate the desired dummy contact speed and also provide further acceleration for the dummy as long as it is in contact with the wall.

In the sled test, a test rig is mounted on an HYGE crash simulator. Padding is fastened to two steel plates attached to the rig by six load transducers. Two bars project from the rig, and the seat with the APROD dummy moves along these (see Figure 4).

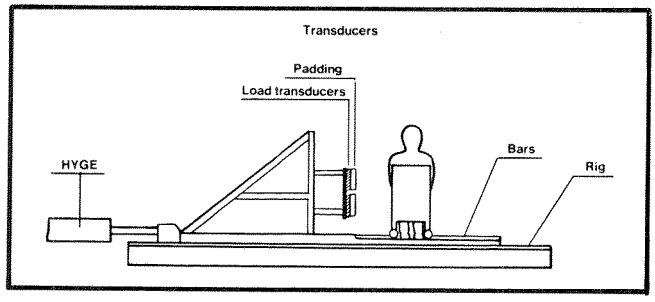

Figure 4. Side collision rig mounted on HYGE

The rig is geared to the desired impact speed and acceleration after dummy impact. The dummy seat remains still until the wall hits the dummy.

Three load transducers and an accelerometer are mounted on each steel plate to which chest padding and pelvis padding are fastened (Figure 5). They measure the load and rate of acceleration at pelvis and chest when the dummy is hit. Impact times for chest and pelvis padding are recorded by means of two zero triggers. The accelerometers on the steel plate and on the far side of the ribs record the intrusion in the padding after two integrations. As an extra check on the padding intrusion, a sliding potentiometer is also used. With a few additions, the rig can easily be adapted for simulation of B-pillar impact.

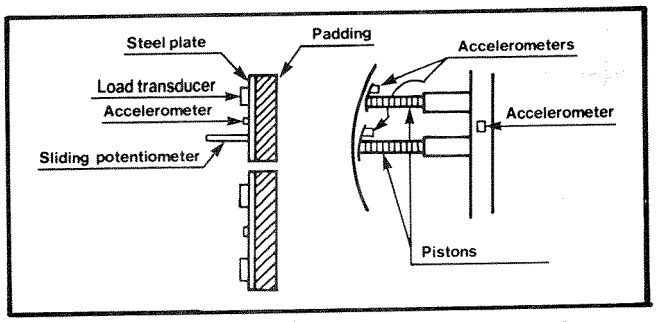

Figure 5. Transducer positioning in wall and dummy chest

Results of Full-Scale Tests

Type of Bullet

Structure

Tests 1 and 2, i.e., Volvo 240 versus Volvo 760 and MDB versus Volvo 760 (see Table 1), show the residual deformation is considerably greater at chest height in the case of an MDB 76 than in that of a Volvo 240. At pelvis height, on the other hand, the deformation is greater for the Volvo (Figure 6). The same results are obtained using

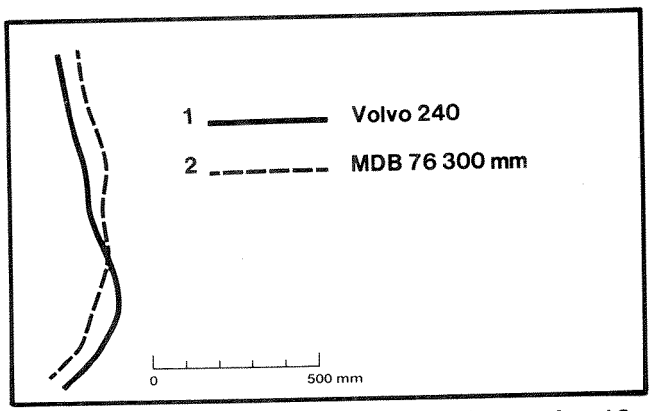

Figure 6. Internal deformation of B-pillar in tests 1 and 2

a Volvo 240 as target in the 90° test configuration (Figure 7). The Volvo 240, however, is relatively rigid in the bumper region compared with other car models, which can also be seen from the field accidents that have been analyzed.

The field cases (Figure 2) also show the residual deformation of the B-pillar caused by the MDB 76 is greater at chest height, the difference being equivalent to that in Figure 6.

Figure 8 shows the wall speed on impact with the dummy is the same both at chest and pelvis height in test 2. It can also be seen that vc (wall speed at chest height) and vp (wall speed at pelvis height) are somewhat lower in test 1, and also that vc $<$ vp. This suggests that the MDB

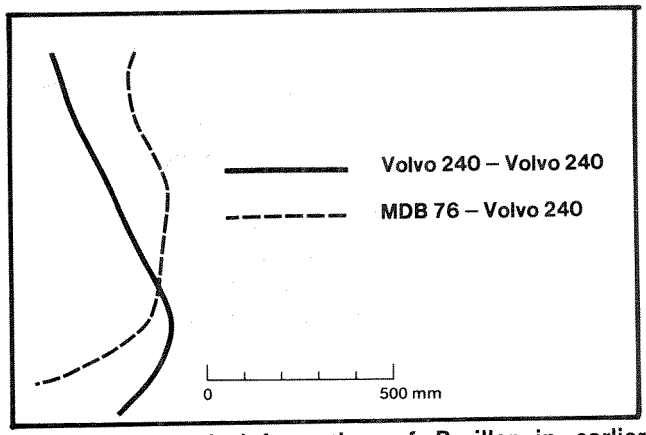

Figure 7. Internal deformation of B-pillar in earlier Volvo test series

76 loads the target's side structure more than the Volvo 240, and the load is more evenly distributed.

The dynamic intrusion process illustrated in Figure 8 shows there is no difference, at the time of dummy impact, between the Volvo 240 and MDB 76 at the point in the structure where measurement was made.

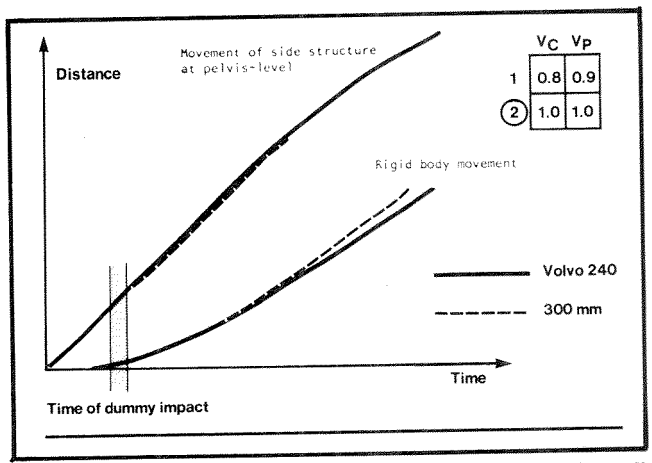

Figure 8. Comparison of intrusion patterns and wall speeds (v) in tests 1 and 2

Interior

The load on the dummy, like the residual deformations, varies greatly regarding chest and pelvis from test 1 to test 2 (see Figure 9).

The different evaluation parameters are for the comparative analysis normalized so that values in test 2 are set to 1.0, and the values for test 1 are given in relation to this.

The level of acceleration at the ribs depends on the impact speed, and maximum acceleration occurs soon after the dummy is hit. Max Cr occurs when the dummy's deflection pistons bottom out, since the dummy is relatively compressible to begin with before going too rigid. The Cr level is thus extremely dependent, at a later stage, on the intrusion speed.

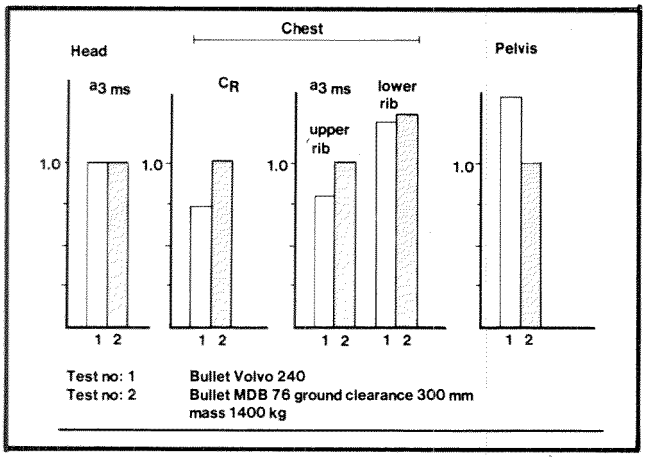

Figure 9. Dummy response in tests 1 and 2—normalized values

Figure 9 shows that the Cr in the dummy is higher with an MDB 76 with a ground clearance of 300mm as the bullet than for a Volvo 240, while the acceleration levels at pelvis height are lower.

Comments

It is clearly unsuitable to model a car's side impact protection on the basis of a specific car model as the bullet. The above results suggest, however, that the MDB 76, 300mm, does not satisfactorily represent either the Volvo 240 or the colliding vehicles in the field accident analysis. It is our opinion tests should be carried out with a bullet that, in respect of the decisive criteria, is more representative of the average car. Certain modifications to improve the resemblance of the CCMC barrier to the average car are discussed further on.

Mass of the Bullet

Structure

A reduction of 450kg in the mass turned out to have little effect on wall speed at chest and pelvis level on impact with the dummy (Figure 10).

Figure 10 shows that dynamic intrusion is not affected appreciably until after impact with the dummy, when the greater kinetic energy in test 2 results in a greater acceleration and, in the end, a greater residual deformation (Figure 11).

Interior

The speed of the intruding wall at chest and pelvis height at the time of impact is the same in both tests (see Figure 10). However, in the case of the lower barrier mass, the speed of the intruding wall at the time of head

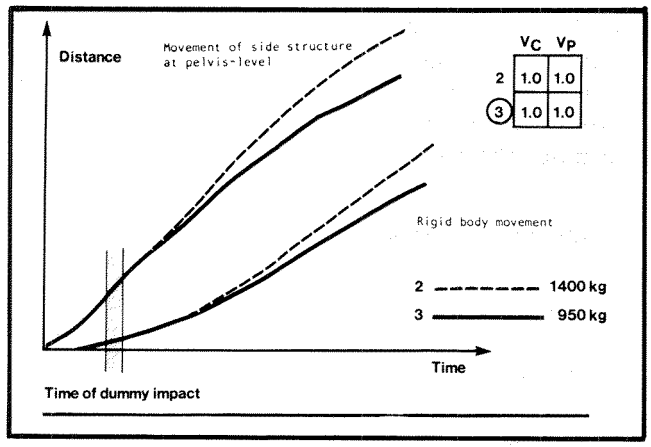

Figure 10. Comparison of intrusion pattern and wall speeds (v) in tests 2 and 3

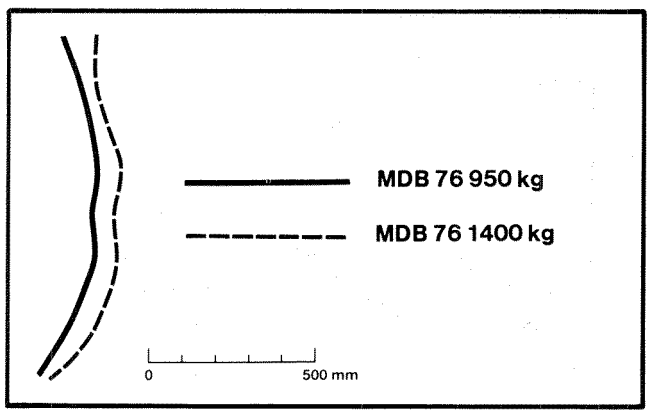

Figure 11. Internal deformation of B-pillar in tests 2 and 3

impact is lower, thus giving less severe head impact (see Figure 12).

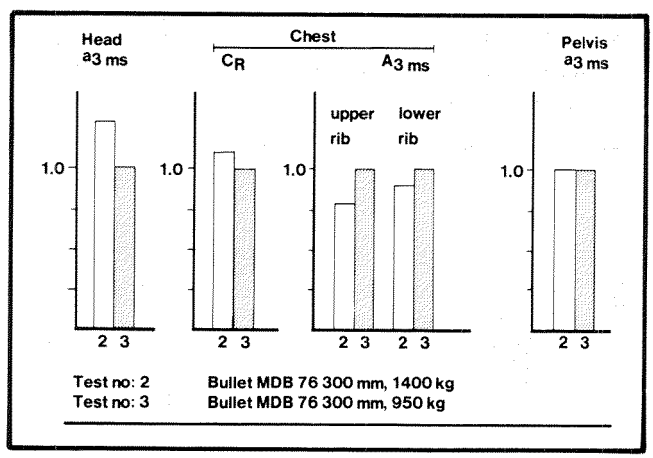

Figure 12. Dummy response in tests 2 and 3—normalized values

Comments

Greater mass means greater deformation of the target but no decisive difference in the loading of the dummy.

We find it preferable, for development reasons, to maintain a high mass in the bullet: first, to cause greater deformation in the target enabling us to pinpoint weaknesses in the structure, and, second, to take into consideration the heavier vehicles in the field.

Ground Clearance of the Bullet

Structure

Lowering the ground clearance from 300 to 250mm means the overlap of the deformable foam front over the door sill structure of the target is bigger. This, however, has little effect on the wall speeds at chest and pelvis height on impact with the dummy (see Figure 13).

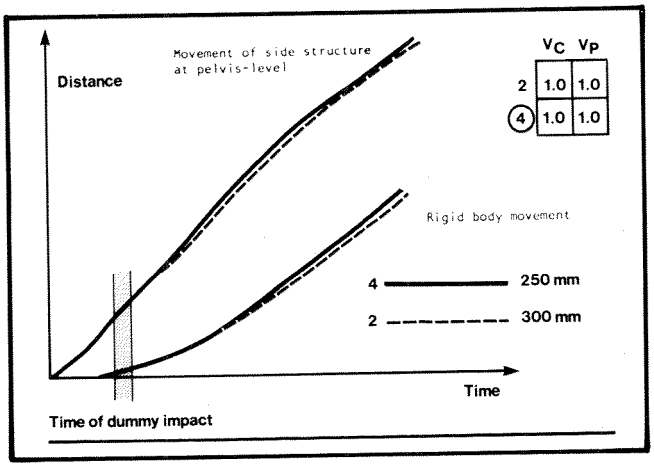

Figure 13. Comparison of intrusion pattern and wall speeds (v) in tests 2 and 4

The residual deformation of the B-pillar at chest height is less than the intrusion caused by a barrier height of 300mm. Thus, the 250mm barrier height better resembles the situation for a Volvo 240 (see Figure 14).

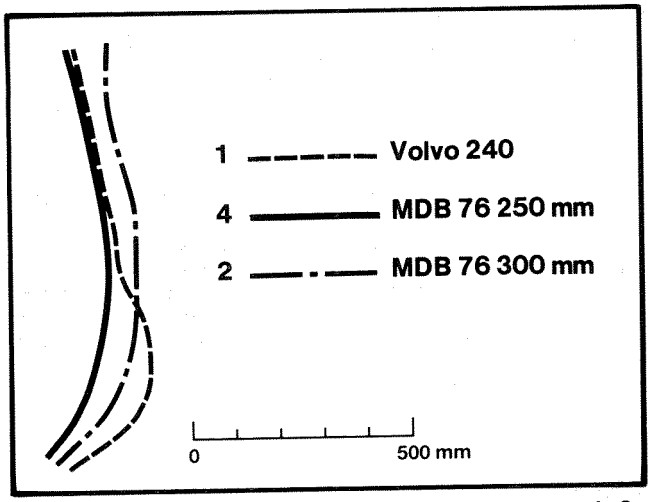

Figure 14. Internal deformation of B-pillar in tests 1, 2, and 4

Intrusion at pelvis height is, however, considerably greater with the Volvo 240. This car is stiffer than average in the bumper region, as was mentioned above, and this is also shown in Figure 15.

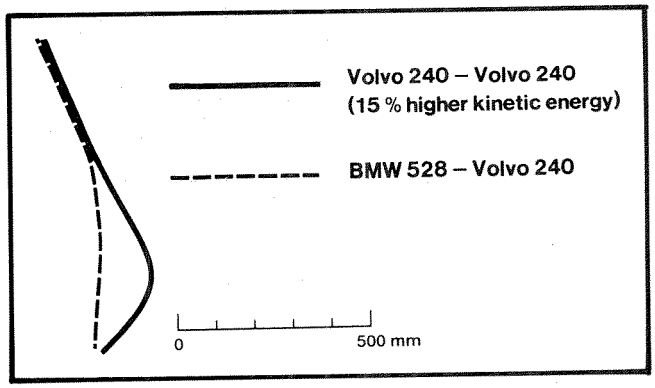

Figure 15. Internal deformation of B-pillar from Volvo test series in 1978

Interior

Lowering the ground clearance by 50mm resulted in a lower load on the chest. The load on the pelvis, however, was a little higher than with a 300mm barrier (see Figure 16). The chest value shows a good resemblance with the Volvo 240 as a test bullet, but the difference at pelvis height still remains. It should be pointed out the Volvo 240 is representative of the average car at chest height but is more stiff in the bumper region (see Figures 2 and 15).

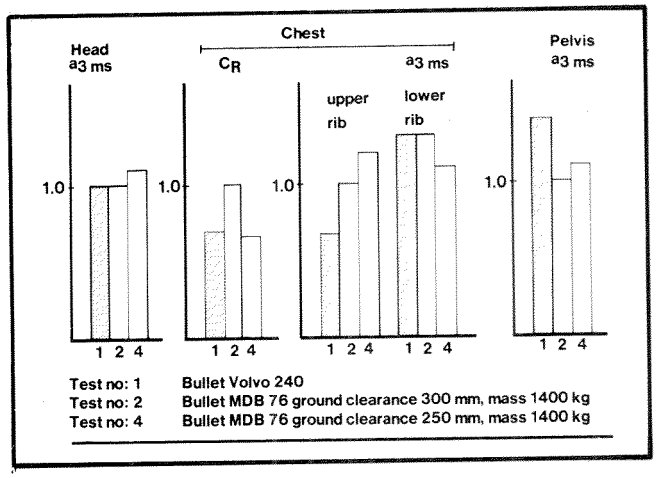

Figure 16. Dummy response in tests 1, 2, and 4— normalized values

Comments

Figures 2, 14, 15, and 16 together indicate that lowering the ground clearance to 250mm provides a more realistic load on the target's side structure and therefore a more realistic dummy response.

Structural Reinforcements and Padding

The residual deformation is appreciably less in test 5 than in test 4, which means the bullet must absorb more deformation energy (Figure 17). Despite this, the MDB 76 functions well and shows no tendency to bottom out. It should be mentioned that the target's mass, which amounts to 1,690kg with the two dummies, is considerably greater than that of many car models on the market.

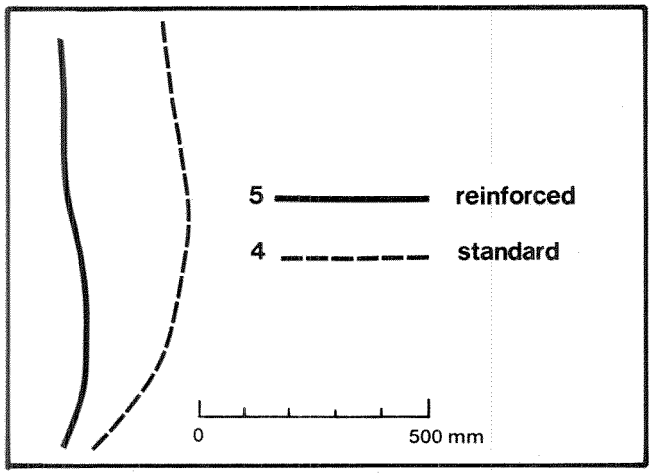

Figure 17. Internal deformation of B-pillar in tests 4 and 5

Comment

A structural reinforcement as extensive as that in test 5 considerably reduces wall speeds on impact with the dummy (Figure 18). This reinforcement leads to an increase of the velocity in the nondeformed parts of the target, which, in general, causes an increase in the relative velocity of the occupant's body as compared with that of the intruding side structure. The result of this could be a reduced effect of the reinforcement. However, this increase of velocity is very small at the moment the dummy is hit, and the reduction in velocity of the intruding side structure predominates, as can be seen from Figure 18.

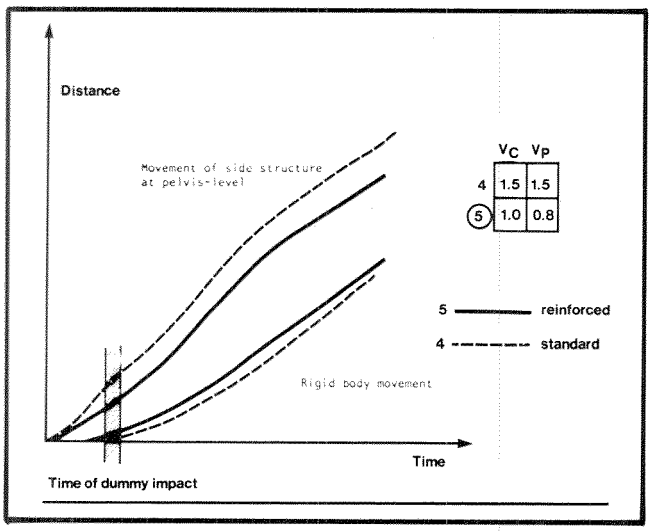

Figure 18. Comparison of intrusion pattern and wall speeds (v) in tests 4 and 5

The dummy response in Figure 19 shows the acceleration levels in the chest are considerably lower when padding is added together with a substantial reinforcement of the body structure.

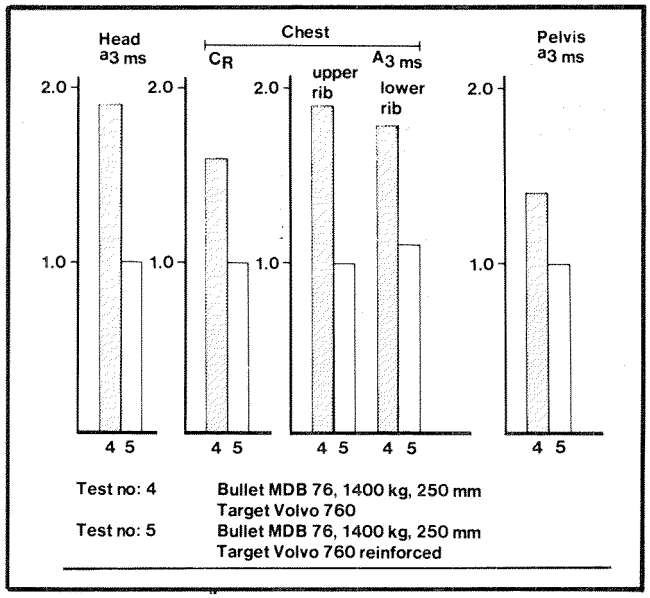

Figure 19. Dummy response in tests 4 and 5—normalized values

Crabbed Configuration

Test 6 was carried out in a 90°/27° crabbed configuration(5). Compared to test 5, the wall speeds with this configuration are affected to the extent that a small increase occurs at chest height and a slight decrease at pelvis height. Impact with the dummy takes place at about 20ms. Figure 20 shows no appreciable rotation of the target occurs until after about 40ms. However, the target is moved in parallel along a line about 10° from its lateral direction. This means that during the first 40ms, the target is exposed to a load that is almost the same as with a perpendicular configuration at 35mph.

The residual deformation of the B-pillar is slightly less than in the corresponding 90° collision, due to the fact that a large proportion of the bullet's kinetic energy is transformed into rotational energy throughout the system (see Figure 21).

Taking the cross sensitivity of the accelerometers into account, it is a very difficult task to plot the intrusion process and target acceleration laterally, since the target and the bullet do not move in the rectilinear manner throughout the process of deformation as in the case of the 90° configuration.

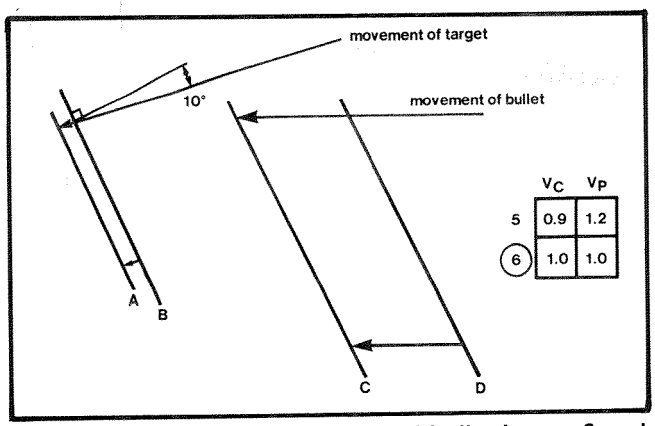

Figure 20. Movement of target and bullet in test 6 and wall speeds (v) in tests 5 and 6 (lines B and D—center line of target and rigid part of bullet at 0ms respectively; lines A and C—center line of target and rigid part of bullet respectively at around 40ms)

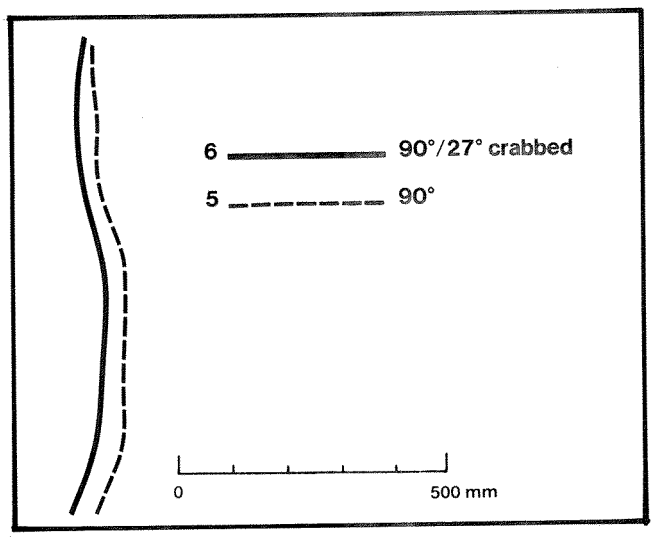

Figure 21. Internal deformation of B-pillar in tests 5 and 6

Interior

The effect of a 90° / 27° configuration on the response of the dummy is that the dummy does not impact the B-pillar of the Volvo 760. The head at 3ms is lower and the Cr increases, since no load is transferred through the shoulder part of the dummy but is entirely directed to the chest. The greatest difference concerns the load on the head, while the difference regarding chest and pelvis acceleration is fairly small (Figure 22).

Comments

The test in crabbed configuration showed the load on the car body is less severe laterally compared to the 90° configuration, and the dummy moves somewhat differently. The latter difference can, in development testing,

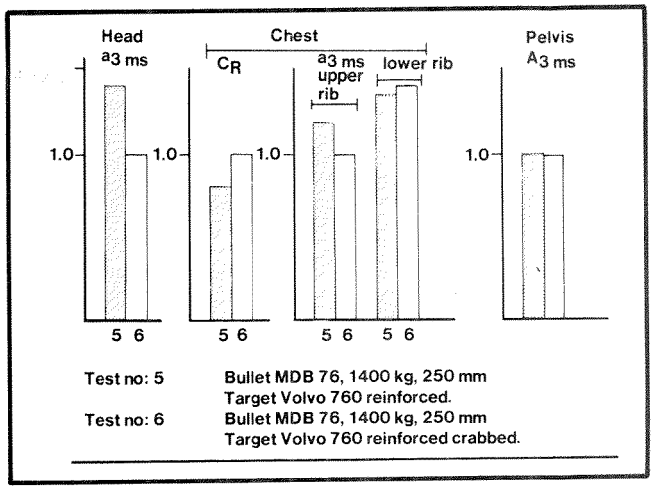

Figure 22. Dummy response in tests 5 and 6—normalized values

be obviated by altering the position of the seat so the dummy does not impact the B-pillar in case of a perpendicular configuration.

The perpendicular situation leads to greater lateral load on the structures added to improve side impact protection, as most of the kinetic energy is used for the deformation of the deformable front, deformation of the target's side structure, and acceleration of the target, without any significant amount transformed into rotation in the system. The perpendicular situation is thus more severe than the crabbed one, as far as the structure is concerned, when the impact speed normal to the side is the same. Even if the judgment is that field accidents are simulated more realistically by a crabbed configuration, there is, with the discussion above in view, still reason to let the main part of the development tests be conducted in the 90° perpendicular configuration.

Conclusion

The conclusion from this study is that a suitable side impact test method is a moving deformable barrier impacting in a 90° noncrabbed configuration. A good resemblance to real-life accidents is achieved with a CCMC MDB 76, mass 1,400kg, ground clearance 250mm, and impact speed 35mph. The motives for this are discussed above and briefly summed up below.

A moving deformable barrier was chosen as the bullet, since it is unsuitable to model a car's side impact protection on the basis of a specific car as the striking vehicle. The MDB 76 used with its standard ground clearance of 300mm did not satisfactorily represent the striking cars in the field accidents investigated, nor in the laboratory tests. Lowering the ground clearance by 50mm gave good results, however, in terms of car resemblance. Reduction of the mass to 950kg did not appreciably affect the dummy response, so the mass 1,400kg was chosen for development reasons to cover

also the American medium-size cars as striking vehicles and to pinpoint weaknesses in the side structure.

The chosen impact speed, 35mph, is in the upper range of the speed interval where severe and more serious injuries (AIS 3+) start to occur more frequently in Volvo 240 side impact accidents today. Therefore, this level must be kept if the object of future car designs is to improve side impact protection.

The differences, in terms of dummy response, between a crabbed configuration and a noncrabbed one were small. The advantage of a greater field accident realism, when conducting the tests in the crabbed configuration, were found to be overruled by the disadvantage of an increased test complexity. Thus, for development work, it is believed the noncrabbed configuration is more suitable. For the evaluation of certain design solutions, the performance in the crabbed situation must, of course, be checked at regular intervals.

Volvo will continue to work with the improvement of test methods for side impact testing. Some steps in this process will be—

- Further accident investigations and development of methods to assess side impact crash severity as a basis for improvement of the resemblance between real-life accidents and laboratory tests
- A complete evaluation of the different MDB's in terms of force-crush characteristics
- Testing with the NHTSA honeycomb MDB in different crabbed configurations
- Development of an MDB, based on the MDB 76, that measures deflection and force in several sections of the front
- Further development of the MDB front face based on experience from both field accidents and laboratory testing
- Extending the test methods with supplementary subsystem testing
- Further development work on side impact dummies
- Extending the test methods to cover accident types other than car-to-car impacts

Side Impact Testing

J. Gratadour
P.S.A.

Abstract

Basic parameters that determine the occupant injury gravity, in a side crash are speed and the hit sidewall hardness. These two parameters are intimately linked together, and a full-scale reconstitution of a lateral collision does not permit their separation easily.

A method is presented in this paper that uses a subsystem-type test arrangement, reproducing the physical lateral shock sequence while having the two parameters separated. It then becomes possible to show the role played by different elements involved in a real-life impact:

- Impacting vehicle deformable front end part
- Impacted vehicle structure at the door inner panel, where deformability plays an energy-absorbing role

- Impacted vehicle structure at the body side, where side speed is rigidity-dependent

As a result of these tests, a subsystem test procedure should take into account the impacted vehicle side structure rigidity, and use a flexible prop fixed to the body, for the impact phase with a side impactor.

Introduction

Accident statistics generally show that lateral shock is the secondmost cause of injuries and fatalities, coming immediately after frontal shocks. The case of shock, vehicle against vehicle, is of great importance in side collisions. These well-established facts are acknowledged all over the world and will not be discussed further in this paper.

Due to its importance, side impact is the objective in numerous studies, be it at the level of accident study, biomechanics, representative dummies definition, or test methods.

As to vehicle evaluation test methods, three main directions are possible. In conformity with ISO-adopted terminology, they are—

1. Full-Scale Tests—Full-scale testing is a test or set of tests performed on the vehicle as a whole with anthropomorphic dummies, and chosen as a reference because of its representativity for a range of actual accidents (front or side collisions, for example).
2. Subsystem Tests—Subsystem testing consists of a test or set of tests sufficiently sophisticated to represent the important interactions between intervening parts. A test or set of tests will be qualified as subsystem testing if the following conditions are met:
   - The assembly includes a sufficient part of the complete vehicle tested to emphasize the interactions between various components of the vehicle.
   - The test equipment allows reproduction of those phenomena that contribute to injuring road users, in particular by taking into account interactions of body segments.
   - The test results are expressed in terms that can be correlated to the performance criteria of a given full-scale test, i.e., criteria based on human tolerance of impact (protection criteria).

   The fundamental basis of the subsystem concept is the concept of a system that permits a representation of the interaction between vehicle elements and the implicated road user. Only satisfactory representation of these interactions can lead to an optimization of the technical solutions.
3. Component Tests—Component testing is a test or set of tests of specific vehicle elements that provide a sufficient evaluation of the ability of these elements to provide road users protection without reproducing interaction of elements not included in the test.

Component tests are, in fact, used by all car builders for vehicle development and are obviously of primary importance for that purpose, while standard testing has to insure an effective level of passenger security and even to progress faster in it.

Component tests, however, used in the spirit of regulation, would not yield this true level of security. As a consequence, they would not permit whole vehicle optimization and could even block new and efficient systems applications if the latter do not enter in the regulation frame. This is not to the benefit of users and should be excluded.

The only regulation tests having some value are the full-scale and subsystem tests. The full-scale tests' advantage is due to their holding close to reality and thus they are easily justified; they are cumbersome, costly, and some improvement in their repeatability is desirable.

Hence the idea of defining the subsystem-type tests. Tests described in this paper bear the ambition to become, in their final definition, tests of the subsystem type. As of now, certain details need to be improved, and a more complete valuation must be achieved.

Notions of Wall Speed and Hardness

The basic idea of the work presented in this paper is that "the higher the speed of blow, the higher its hardness" and consequently "the greater one's injury." This is conducive both to the definition of wall speed and to body-side hardness, this being said for the case of lateral shock.

These are simple notions in appearance, but in reality they are very subtle to understand and should be handled with caution.

Wall Speed

Let us consider a collision of two objects, the following assumptions being accepted:

- The impact can be considered as a unidimensional phenomenon, forces and inertia forces being distributed well enough to ignore balance conditions in all but impact direction.
- Forces related to the masses located in the deformation zones are negligible in regard to deformation effects.
- Deformation effect laws in the zones where deformations occur are linear or at least, in all cases, equivalent in the two objects.

We consider the contact surface behavior of the two objects (Figure 1) at any time the following equation is true:

$$x_2 = x_o + l_o - v_o = x_o + l_o - \frac{F}{k_o}$$

$$x_2 = x_\Lambda - l_\Lambda + y_\Lambda = x_2 - l_\Lambda + \frac{F}{k_o}$$

$$x_2 = \frac{k_o}{k_o + k_\Lambda} x_o + \frac{k_\Lambda}{k_o + k_2} x_\Lambda + \frac{k_o l_o - k_\Lambda l_\Lambda}{k_o + k_\Lambda}$$

The speed of the contact surface is thus equal to:

$$V_\xi = \frac{k_o}{K_o + k_\Lambda} V_o + \frac{k_\Lambda}{k_o + k_\Lambda} V_\Lambda$$

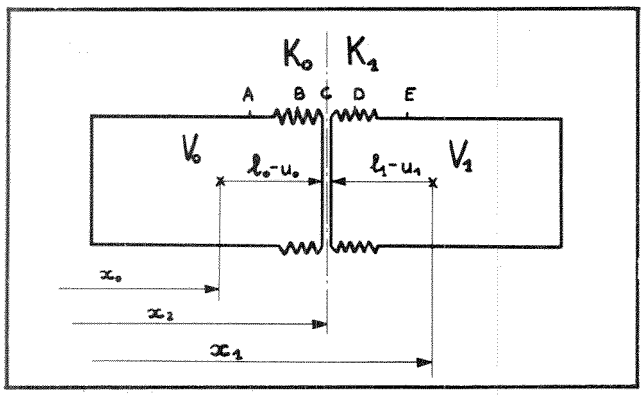

Figure 1.

This is conducive to the laws of velocity of the type illustrated in Figure 2.

The same theory is applicable to any other part of the contact zone (B or D). If the rigidity repartition in the impact zone is homogenous, the fact is conducive to the speed laws shown in Figure 2 relative to points B and D.

Now let us consider what is happening in a lateral crush where object 1 is the impacting vehicle and object 2 is the impacted. The occupant hits a sidewall, side of the body, the thickness of which is small and the speed practically uniform throughout the thickness. The speed is that of the body side, and its value can be evaluated using the above-described method.

Sidewall Hardness

The sidewall that is hit by the occupant is composed of the side of the vehicle body and also by the front face of the impacting vehicle in its crushing action. Its hardness will be a function of its building materials (influence of speed of shock on its rigidity) and also of its mass effect. To evaluate it realistically, it is necessary to come nearest to the true conditions of impact.

Test Method

The test method described in this paper consists of separating the analysis of the body-side speed, and consequently of the rigidity of the body side, from its hardness.

Body Side Rigidity

To study this rigidity, we use a rigid punch, the outer configuration of which reproduces that of a 205 front section after it has hit the side of a 205 body (Figure 3). More precisely, the shape is that of a 205 front section, carried out to fit the shape of a 205 panel after a lateral impact.

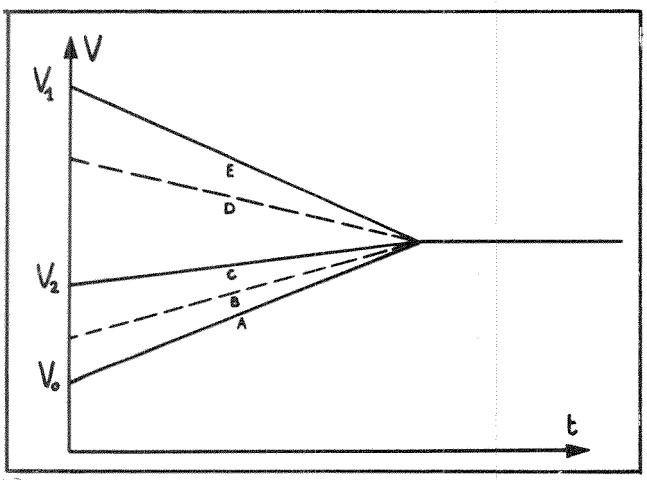

Figure 2.

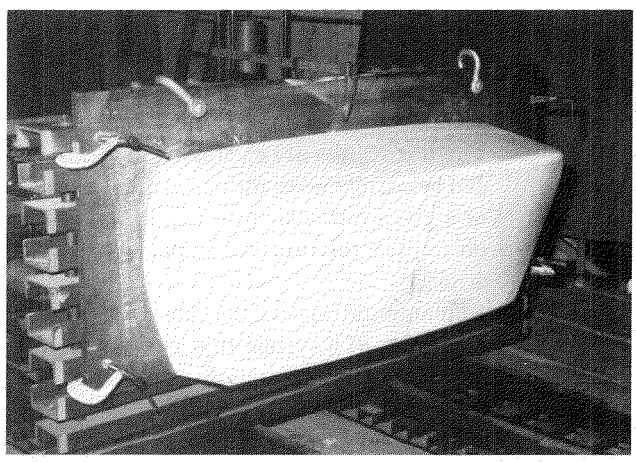

Figure 3.

This punch is fitted into a dynamometric movable wall (or barrier) facing the body being tested (Figure 4).

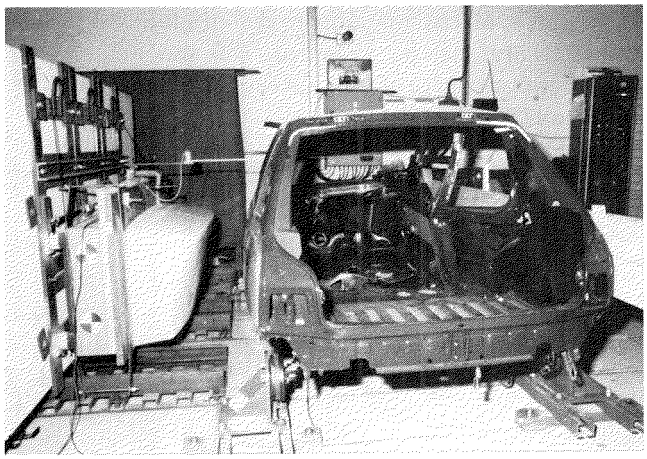

Figure 4.

The latter is fixed securely to the ground through its suspension system and moreover is buttressed on the opposite side by a prop. height; both the punch and side panel facing it are adjusted to the relative lateral post-impact positions 205 against 205 (Figure 5).

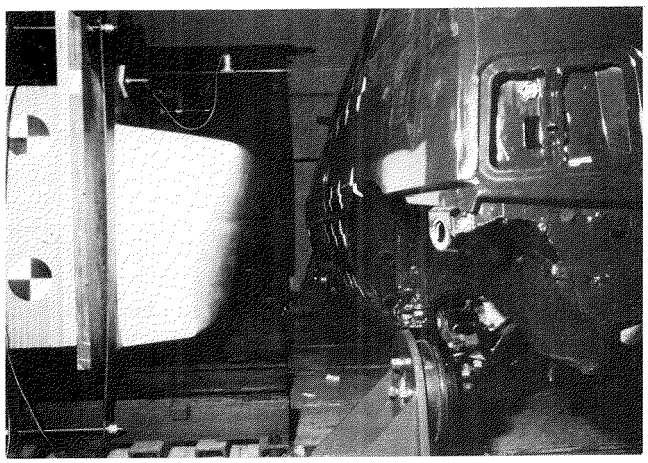

Figure 5.

This requires a slight engagement on a frame member. The punch is centered on point H of the driver as it is in a full-scale lateral impact test (Figure 6). The body is then crushed in a pseudo-static operation until the global shock deformation is obtained (Figure 7).

The applied force is measured and also the deformation of the body part facing the punch. The latter measurement is performed relative to the wall (to eliminate parasitic deformations of fixing bracings). Analysis of applied forces versus deformation curves permits the evaluation of the first parameter: speed of body sidewall.

This first operation being achieved, the crushed side of the body is recovered by cutting it out and will serve next for the second parameter evaluation, namely, the sidewall hardness.

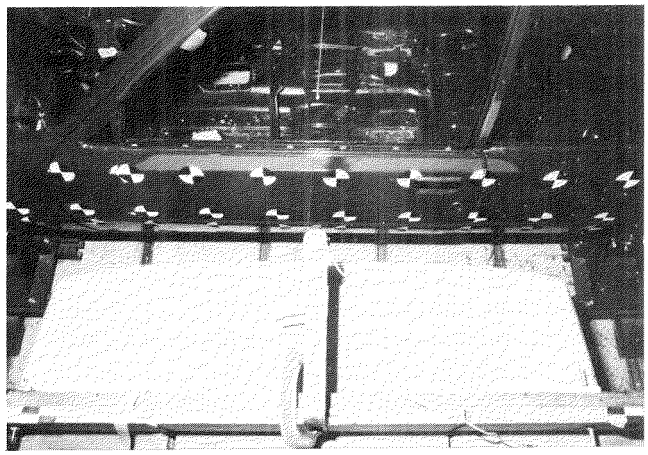

Figure 6.

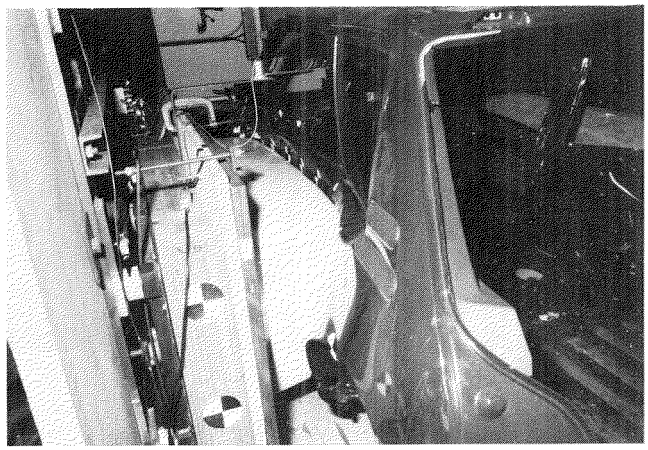

Figure 7.

Sidewall Hardness

The evaluation is performed dynamically (Figure 8). The impactor is a dummy APROD-82 (the same as used in full-scale reference tests).

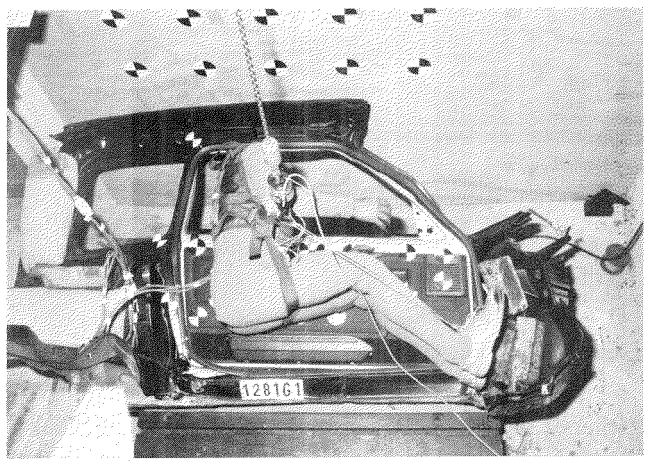

Figure 8.

Impactor (Figure 9) speed is obtained by dropping the dummy (free chute) from the height necessary to duplicate at arrival the body-side speed observed in the full-scale tests. In future tests, speed will be determined from the results of body-side crush tests. Impact configuration is selected to have different dummy body segments hit the same zones as in the full-scale test.

There will be no problem at this level if the dummy sensor wiring is correctly located so as not to interfere with anything during the drop, and if the dummy is kept motionless prior to its drop. Thus, it lands on the sidewall having the anticipated configuration.

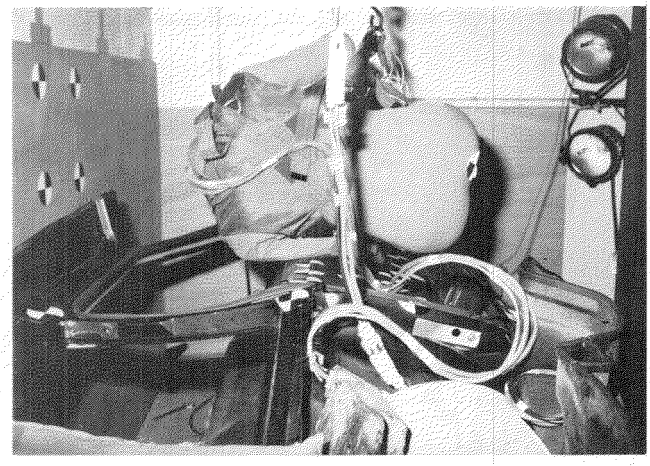

Figure 9.

Installation of the predeformed body-side panel requires a few precautions. It is installed on a foot base having the predeforming punds shape (Figure 10). This furnishes an excellent support to the body-side panel on the foot base: the body side bears on the entire impact zone of vehicle versus vehicle full-size collision.

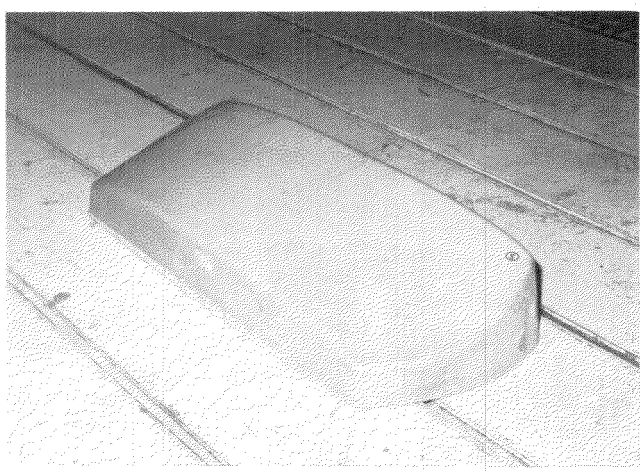

Figure 10.

The foot base used is constituted, according to the case, either by the punch itself or by polyurethane foam blocks. For future tests, the retained solution will be that of foam blocks.

In course of the impact dummy versus body-side panel, the contact effects between the body side and foot base may vary and even get inverted. To obtain a linear behavior, or at least one close to that of a full-scale test, a ballast charge has been applied. This was obtained by distributing a charge of 130kg at each end of the body side (Figure 11).

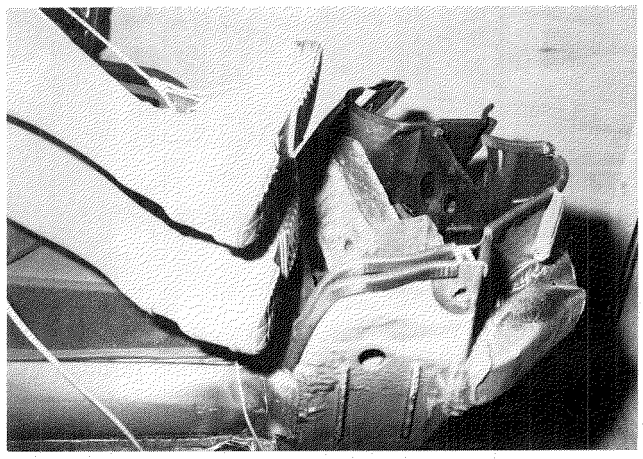

Figure 11.

Tests Performed

The above-described method has been applied in different configurations. The first aim was to validate the method relative to the full-scale testing.

Validation

The aim was to evaluate the correlation between this test and the full-scale test, in the case of the 205 car, for which a number of full-scale test results are available (3- and 5-door versions: car against car or with moving deformable barrier CCMC).

For dummy/sidewall impact, the chosen speed was that measured with the full-scale test, that is, 10m/s (corresponds to a fall from about 5m high). The only unknown parameter being the rigidity of the support simulating the full-scale test impactor, various configurations have been tested, either with a rigid support or a support made of polyurethane foam of various rigidities.

Although the speed of body side chosen was that of the full-scale test, its measurement is not immediate, and it was of interest to check the impact speed validity by means of some other parameter: the maximum ΔV of the occupant (Figure 12) for one.

At this level, an acceptable concordance has been observed. One can now examine the results (Figures 13 and 14). These figures represent the pelvis and thorax accelerations for different tested supports and full-scale collisions. What appears most clearly is the aberrant

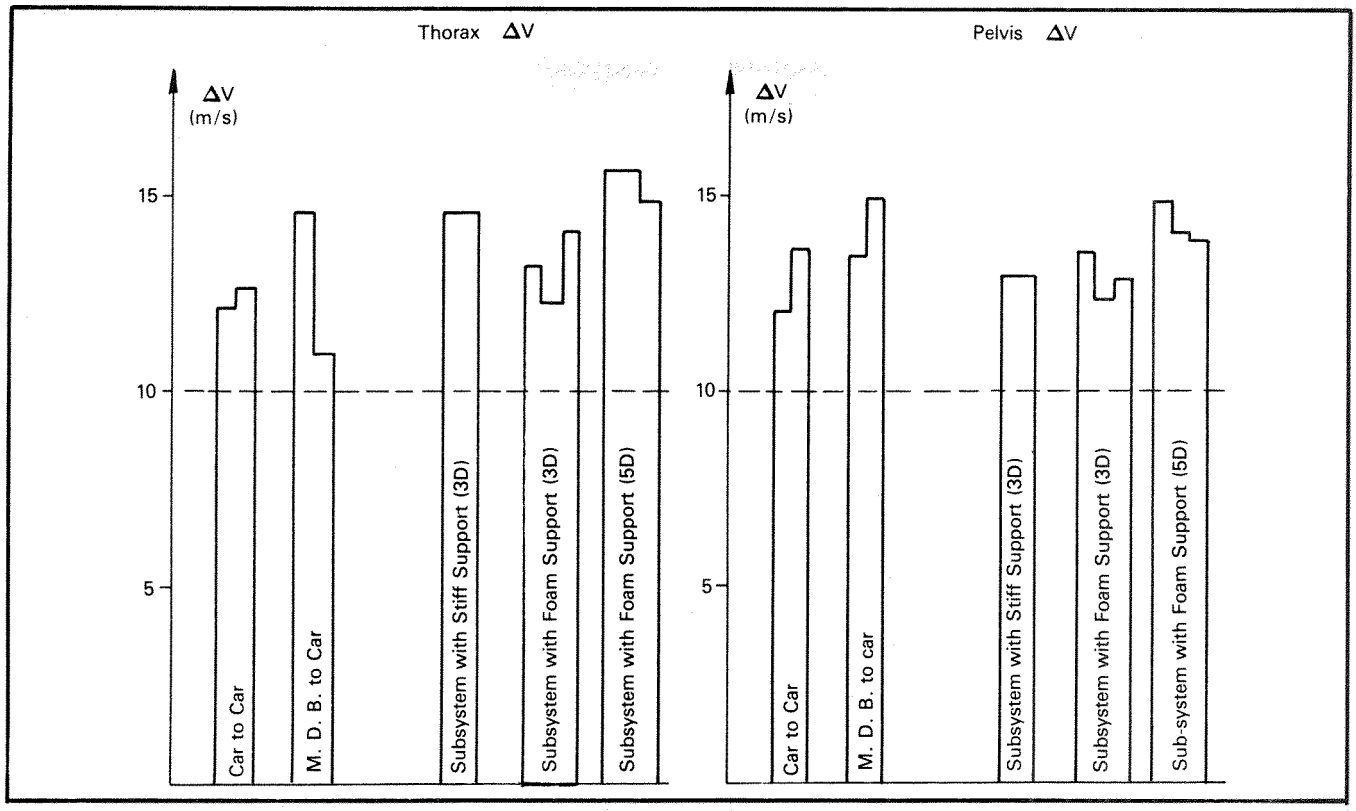

Figure 12.

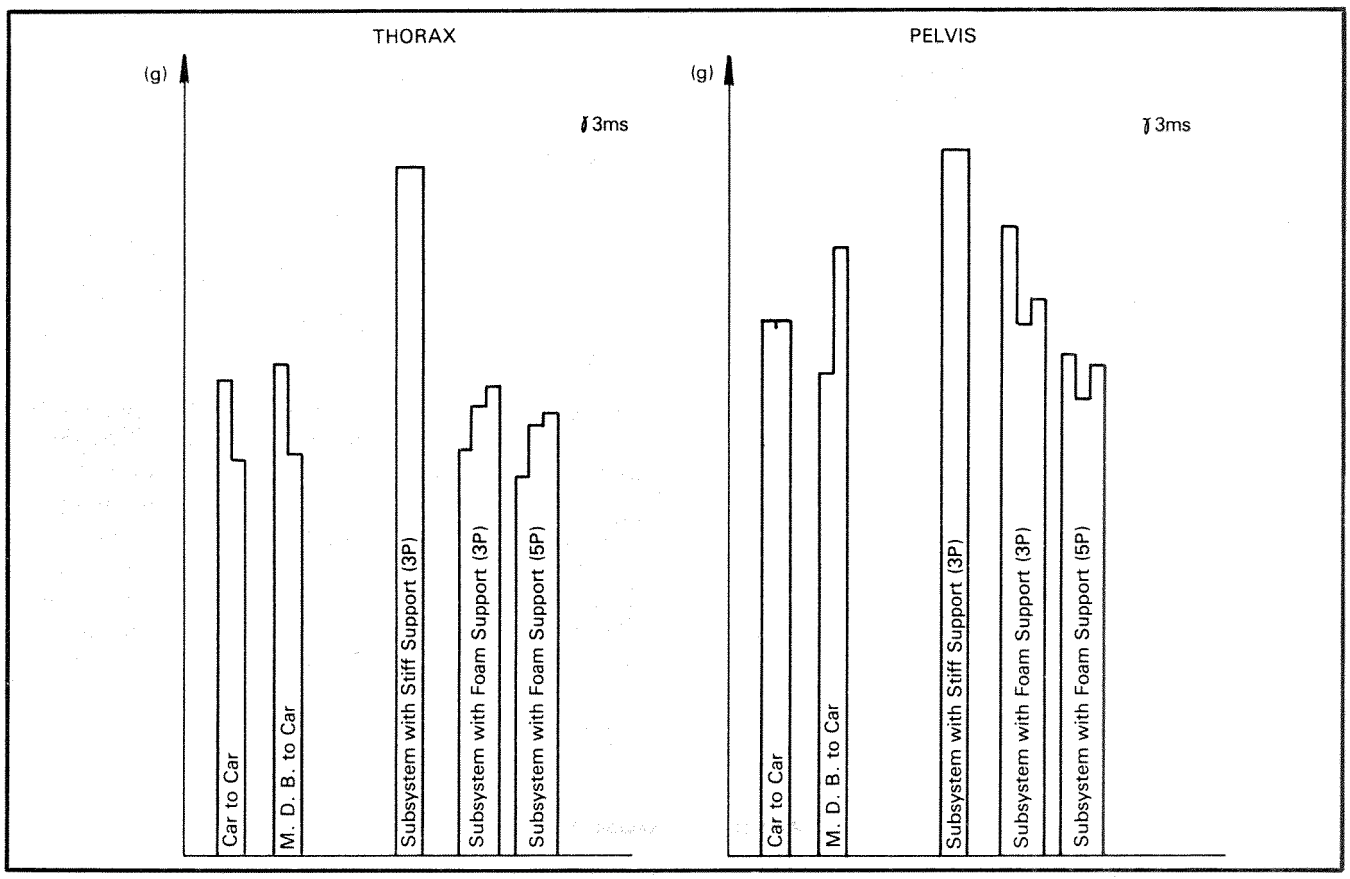

Figure 13.

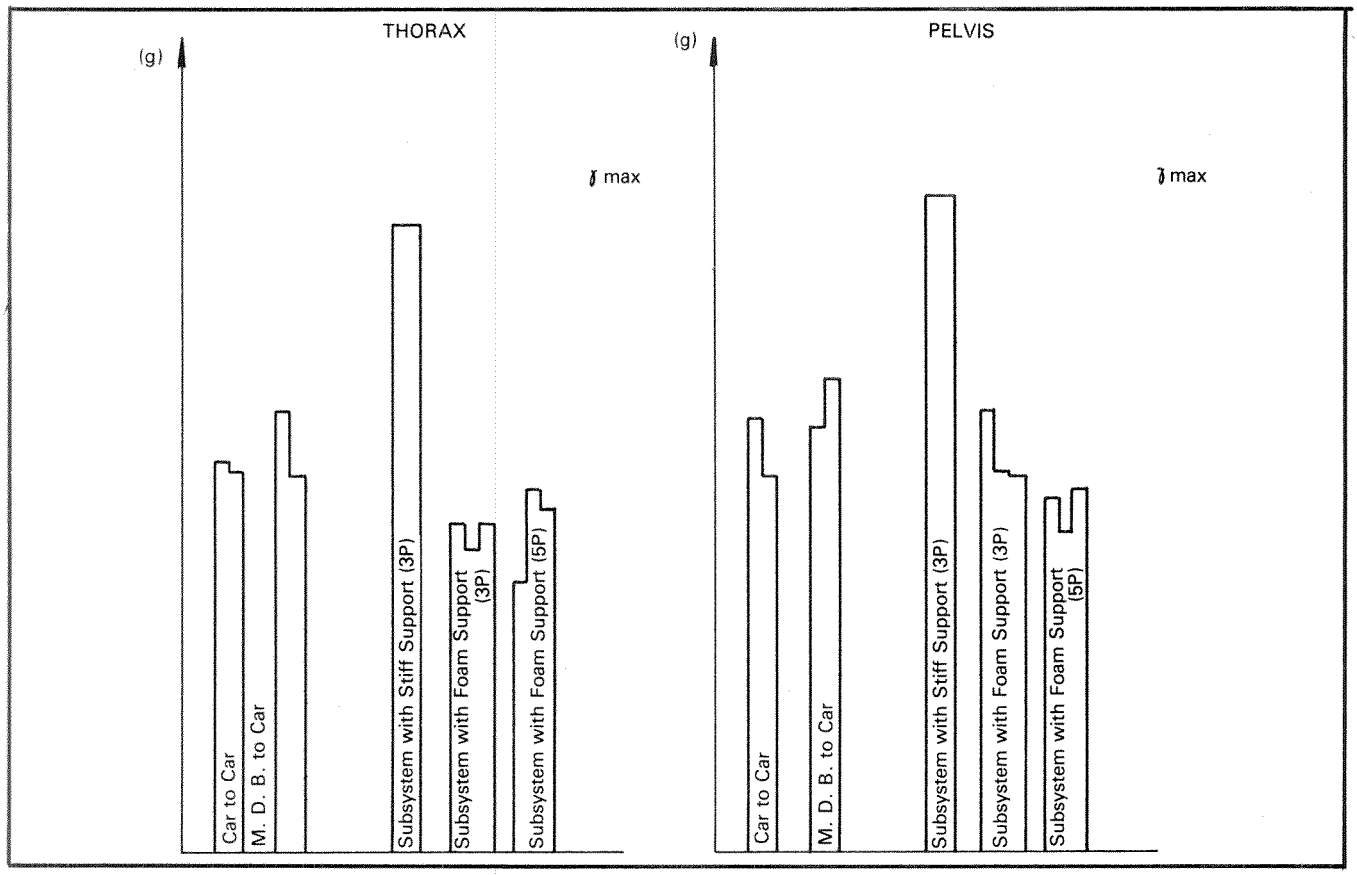

Figure 14.

characteristics of the test carried out with a rigid support. This test is of such violence that we have refused to reproduce it, so as to not destroy the dummy.

Values obtained with foam support are contained inside the full-scale test data dispersion.

At this stage of tests, the conclusions are as follows:

- In a test of the subsystem type, a rigid support against the body side does not permit a correct full-scale test simulation.
- A foam support of convenient rigidity permits an acceptable full-scale test simulation.

Influence of the Body-side Rigidity

The influence of body-side rigidity on occupant injury severity is a very controversial topic. This seems due to the fact that it is difficult to act on the wall speed without acting on its hardness, which generally reacts in opposite directions.

To clarify the problem, a reinforcement, which, in principle, should eliminate it, has been defined (Figure 15). To cope with this, no reinforcement has been added to the zones of impact with the dummy. Supplementary cross members were used—

- Behind the dashboard
- At the bottom of the A-pillar
- Under the seat
- On the rear floor

We also have reinforced the B-pillar and fixed a cross member between the two B-pillars at the height of body waistline, in order to have the opposite side work. It is to be underlined again that reinforcements are used only to demonstrate the principle of increasing body-side rigidity without increasing its hardness.

These reinforcements are absolutely not optimal, nor are all of them even useful. A body reinforced in this

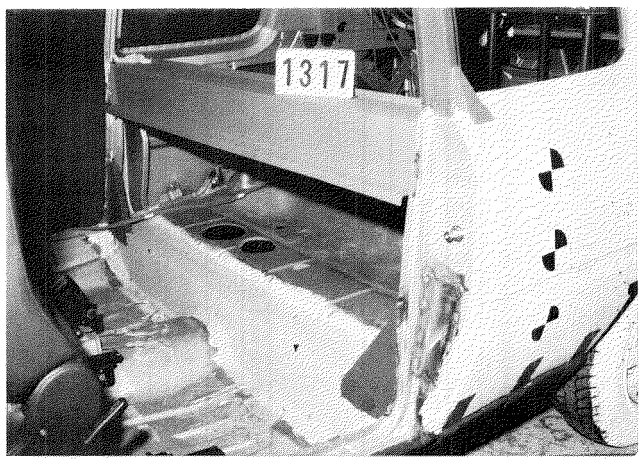

Figure 15.

manner has undergone a static crash test. The result is shown on Figure 16, compared with a vehicle from the production line. The maximum force level shows an increase (about 40 percent), but, more importantly, the mean rigidity at the start of crushing is practically doubled.

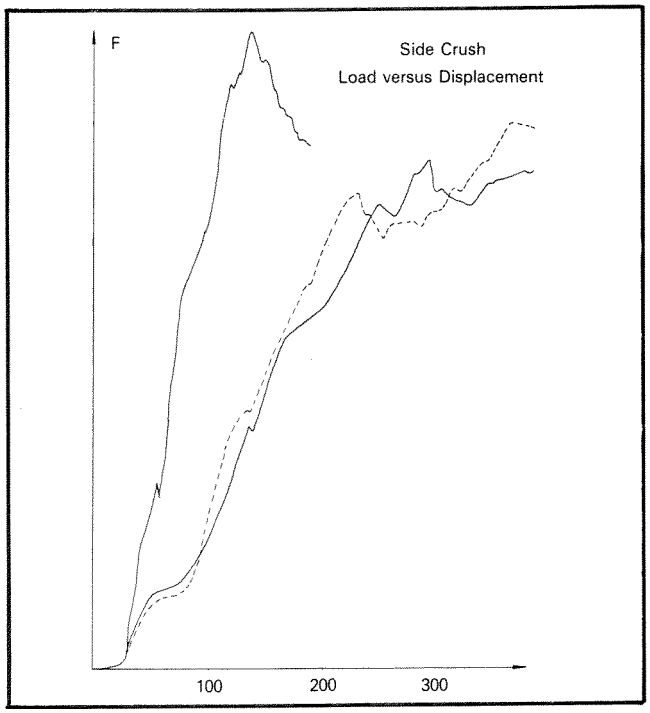

Figure 16.

A vehicle equipped with an identical reinforcement was submitted to the full-scale test with a CCMC mobile deformable barrier (Figure 17).

Figure 17.

Figures 18 and 19 show the results obtained at the thorax and pelvis levels. Thorax improvement is quite clear, on the order of 30 percent, but, for the pelvis, the improvement is less apparent. We feel two reasons clarify the phenomenon at the pelvis level. The CCMC mobile deformable barrier hardly hits the sill. Due to the great difference in rigidity between the body understructure and the door, the barrier overrides the sill, and the body understructure reinforcements do not perform their work. In spite of this, according to the measurement, the wall speed has notably diminished; consequently, it may seem that test dispersion played a false role here.

At this point of testing, the following conclusions have been made:

- Structural reinforcements are capable of having an important influence on the results, by means of wall speed.

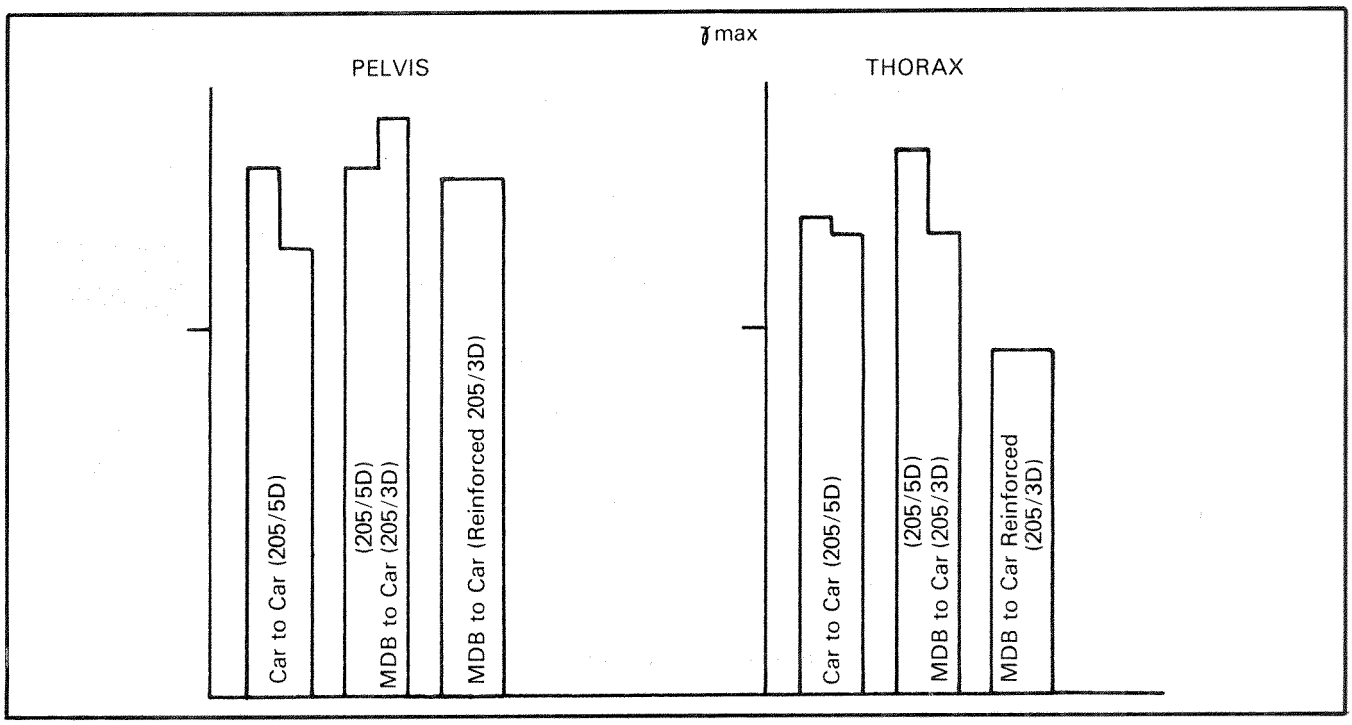

Figure 18.

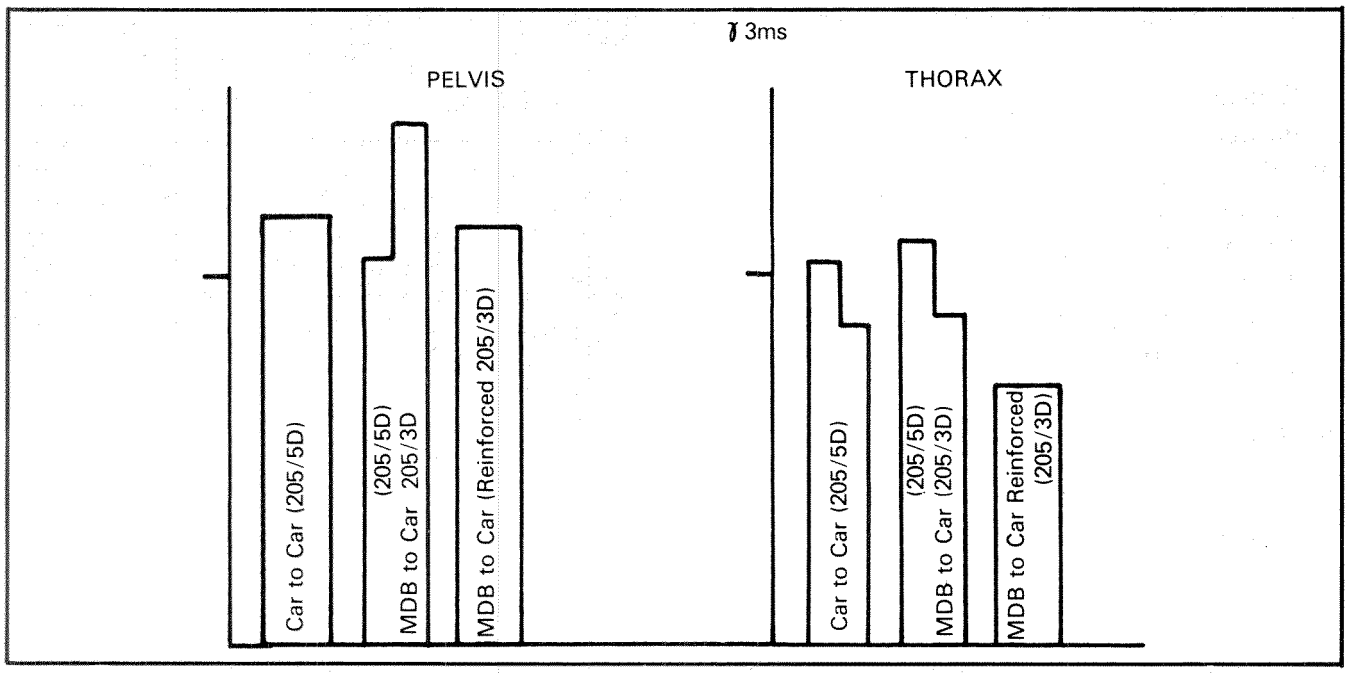

Figure 19.

- Interactions between elements (sill overridden by the barrier) are multiple, and for any simplified test it is hardly possible to take them all into account.

Conclusion

As stated in the introduction, component tests are not adapted for regulation purposes. The possibility of choice remains between full-scale tests and subsystem tests.

The above-described method is intended to enter the latter category. To become a true subsystem test method, it should be refined, particularly in what concerns the relationship between structure rigidity and wall speed. Once this is accomplished, the method will still remain cumbersome, and it is not clear whether it will have much to offer compared with a full-scale test.

One possible way to simplify it consists of a separate testing of different body segments. This has already been initiated by certain laboratories, but it is of absolute necessity to verify whether this method still permits body segment interactions. The problem of the abdomen, which has not been examined due to lack of adequate instrumentation, should not be forgotten.

Of some points brought to light in this paper, two at least are important:

- In a subsystem test, the support to be placed behind the body side for the test with an impactor must not be infinitely rigid.
- The influence of structural rigidity is an important factor and should not be neglected.

Testing the Side Impact Tests: Method and Some Initial Results

Abstract

This paper addresses the general problems of selecting an impact test method. A test method must produce results that (a) are repeatable, (b) can distinguish between tested items that are of different design, and (c) predict real-world performance of the tested item.

The paradigm employed here is based on the notion that to identify the most appropriate test method among a set of candidate methods, one must compare the results of laboratory testing over a wide range of products with the results of actual field use of the various products.

This is difficult in a case where a new test procedure is to be evaluated and actual field data and laboratory data may not yet exist. This paper provides a methodology for assessing alternative test device concepts by means of simulation and applies it to the side impact test situation. This is done by (1) simulation of field accident experience of vehicles involved in side impacts, and (2) the simulation of test devices and procedures. Simulated test results can then be compared with simulated field accident data. This study shows some interim results for several impact test device design variations.

The principal tasks of this study were to: develop a vehicle occupant dynamics model suitable for estimating field results in side impacts; develop a test device dynamic model; select a range of alternative hardware configurations for both the simulated vehicle and the simulated test device; and develop random variable exposure distributions of accidents, vehicles, and occupants so the simulated "field" accidents cover a broad spectrum of exposure conditions. Approximately 90,000 simulations are run, using a Monte Carlo procedure, to estimate the distribution of outcome over the range of exposure conditions.

Introduction

This paper is the second in a series of side impact simulation papers. The first paper(1) given at the 1985 Government/Industry Meeting & Exposition described the project background and methodology. The current paper provides more detail.

Despite the exploratory nature of this study and the assumptions and simplifications embodied in the mathematical solutions, we believe the results show the substantial potential for test concept exploration this simulation methodology can provide. Two test procedures were chosen for simulation: the first, a simplified simulation of a mobile deformable barrier-type test; and the second, an early version of the MVMA Side Impact Test Development Component Procedure.

In the moving deformable barrier simulations, the results were not very sensitive to such things as the moving barrier weight, moving barrier face, or whether it was a SID or APR side impact dummy. While changes in the test parameters may make substantial differences in a single test, they did not seem to change the overall correlation of test results with simulated real-world performance.

The predictive power of the test procedure, in these results, was sensitive to impact severity. There appeared to be an optimal test severity, above or below which the predictive power of the test is diminished.

The comparisons between real performance and test performance on the component test procedures also showed a sensitivity to test severity. There was some small amount of variation in the predictive power of the test procedure as a function of the size of the test device (i.e., 40th percentile male, 50th percentile male, etc.). The results were somewhat similar among the model configurations that simulated the MVMA test device and variations thereon as well as the simulations of a rigid impact. The component test results were rather sensitive to car mass/stiffness, thus corroborating the frequently voiced expectation that such tests need to have an adjustable speed to account for variations in door gap and side structure stiffness.

In any case, the results presented are tentative and intended to serve as an exposition of the overall methodology. Future work will develop the speed compensation formula for the component test, expand the test parameters studied, and introduce the effect of test-to-test variability in test procedures into the model.

Correlation Coefficient Measures Test Performance

How do we measure the performance of a car safety test? We could draw a graph with the real-world injury rates of cars on the vertical axis and the test performance of cars on the horizontal axis as shown in Figure 1. For each car tested, we could plot a point on this graph representing the real-world injury rates and the test results of that car. We might expect to see a scatter of

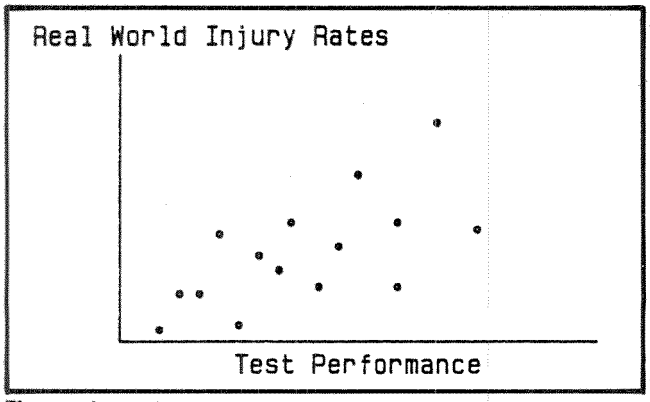

Figure 1. Validation plot—low correlation example

points if we plotted data for a number of different car designs. The scatter would come about because the test cannot possibly take into account all the different accident conditions represented in the real-world performance. If the test were a perfect linear predictor of real-world performance, then the points for different cars would all fall on a line (Figure 2). The correlation coefficient is a measure used by statisticians of how closely these points are to forming a line. If all the points fell on a straight line, the correlation coefficient would be one. If the points formed a completely random pattern, the correlation coefficient would be zero. So the correlation coefficient can be used as a measure of how well the test predicts the real-world performance—the higher the correlation coefficient, the better the test.

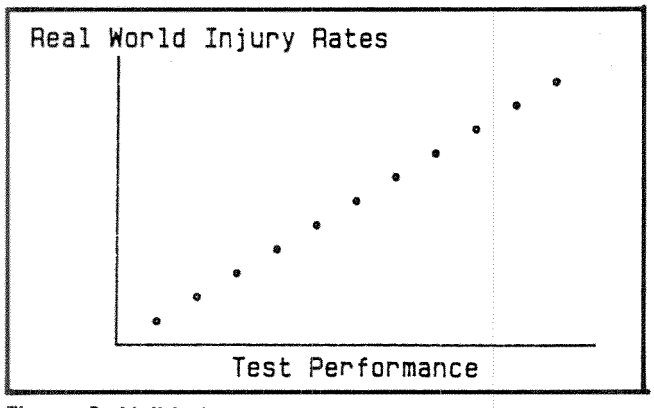

Figure 2. Validation plot—high correlation example

A Data Analysis Approach

How would one actually go about testing the predictability of a side impact test? One way might be through accident data analysis. Several vehicles could be chosen that are thought to have a range of side impact performance and have been in service long enough to have been in a large number of accidents. A measure of performance for these cars would have to be chosen, such as the total number of injuries, total number of fatalities, or some weighted measure such as harm. Because different vehicles experience different exposures to accidents, the measure of performance would have to be adjusted to take into account the different exposures. For example, the number of injuries or fatalities might have to be divided by the number of vehicles of each type in operation or by the number of miles driven annually by each vehicle. Also it may be necessary to adjust for demographic variables such as the age of the driver. The next step would be to test the individual vehicles with each proposed test. Plots of the injury measure versus the test performance could be made as shown in Figure 1. The calculated correlation coefficients would then be used to compare the tests—the closer the correlation coefficient is to one, the better is the test.

There are some problems with this procedure. Large variations in human tolerance and crash conditions will make it necessary to have a large number of accidents for each vehicle to show that the performance of one vehicle is actually different from that of another. Over the period of time needed to collect the number of accidents necessary, one or more of the vehicles may not remain in production unchanged from earlier models. Design changes could add to uncertainty in the results.

Another problem is in identifying and properly accounting for all the demographic factors such as driver age, which could influence the results. Many unaccounted-for demographic factors may be interpreted as a change in vehicle performance rather than a difference in accident involvement rates.

Also, it would be necessary to test several samples of each vehicle to account for test-to-test variability in test performance. The large number of tests required could economically limit the number of alternative candidate test procedures that could be included in the study.

Finally, there may not be vehicles currently in production with a wide enough range of side impact performance to allow discrimination among the vehicles in injury rates or in test performance. In that case, correlation coefficients for different tests would be effectively zero, and the performance of one test would be no different than another.

All things considered, the data analysis approach would be expensive, time-consuming, and would produce uncertain results. If vehicles are expected to be substantially changed by a new side impact standard, then results obtained from cars already on the road may not apply to these new vehicle designs.

Computer Simulation Is More Practical

Rather than actually performing the data analysis just described, we decided to simulate the data analysis approach on the computer. The computer simulation required four major steps:

1. Simulate a large sample of accidents for several different vehicle designs as if the accidents were randomly drawn from today's accident data.
2. Establish a measure of vehicle performance in the simulated accidents.
3. Test the different vehicle designs using a variety of computer-simulated tests.
4. Plot the scattergrams and calculate the correlation coefficients for the simulated real performance versus the simulated test performance for the individual vehicle designs.

A flow chart of the simulation is shown in Figure 3. We start with 105 distinctly different cars—15 cars in each of seven weight classes. Within each weight class, the 15 cars are made up of unique combinations of the following variables:

- Side structure strength
- Door interior padding thickness
- Door interior padding stiffness

The description of the hardware variables and the 15 experiments are presented in Appendix A.

For each of these 105 car designs, a crash model simulates a representative sample of 850 side impact collisions. The collisions differ in the following ways:

- Striking vehicle size and front structure stiffness

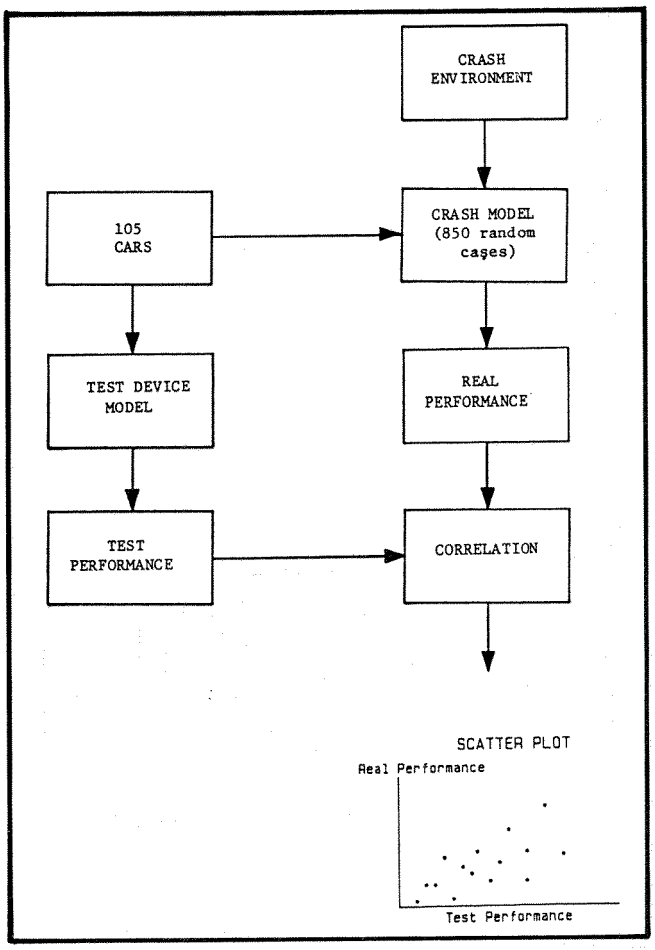

Figure 3. Flow chart of side impact simulation

- Striking vehicle speed and weight
- Driver size
- Driver gender
- Driver age

The crash model uses statistical distributions drawn from the National Accident Sampling System (NASS)(2) of these random collision variables.

In the real world, the safety performance of a vehicle is judged by the number of fatalities and injuries occurring to occupants of that vehicle. Since there are more of some vehicles on the road than others, the fatalities and injuries must be adjusted according to some measure of exposure to accidents. Common measures of exposure are the number of vehicles produced or the number of miles driven by a vehicle in a year.

There is an element of uncertainty in predicting fatalities and injuries from a computer model of crashes. The transformation to injury from the model output of such things as chest acceleration or chest deflection is not known with a great deal of accuracy. To avoid the extra complication of an uncertain biomechanical transformation, we decided to use the following outputs as measures of injury and accident severity for each of the 89,250 (105 $\times$ 850) side impact simulations:

- Rib acceleration
- Chest acceleration
- Chest force
- Chest deflection
- Thoracic Trauma Index, TTI(3)
- Bolster force
- Bolster deflection
- Door intrusion (for the full-vehicle tests)

Once the performance criterion levels were established, the performance of the 105 cars was calculated by finding the percentage of crash simulations for each car that was above the performance level. In this manner, the performance of the 105 cars was calculated for each of the six outputs of the crash model.

Each of the 105 cars was also tested using a test simulation model. The test simulation model simulated a component impactor-type test and a moving barrier full-vehicle-type test. For each of the 105 cars tested in the test model, five chest injury parameters were determined:

- Rib acceleration
- Chest acceleration (spinal acceleration)
- Chest deflection
- Thoracic Trauma Index

Since the study uses the Monte Carlo Method, the output of the model is a collection of 850 answers for each car design studied—a total of 89,250 results. Since we looked at four response measures, there was a total of 357,000 results. If the results are grouped into ranges and the count of the number of results falling into each range plotted as a bar chart for each vehicle design, the results form a statistical distribution as shown in Figure 4. We defined the measure of performance to be the number or

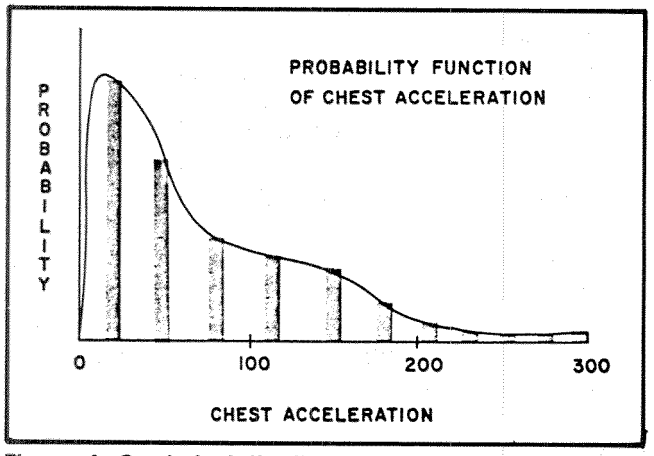

Figure 4. Statistical distribution—frequency counts

percentage of occupants who fell above an optimal cutoff value of the injury indicator. The performance measure is the area of the distribution curve above the cutoff limit. For example, the fewer the percentage of occupants receiving chest acceleration greater than 50, the better the performance of the vehicle.

The remaining question then is: "How do we pick the cutoff limit?" The cutoff limit was chosen to give the greatest difference in performance for a range of different vehicle designs. Choosing the cutoff limit in this way insures that the test procedure will have the best chance of discriminating among vehicle designs. For example, a different vehicle design might produce a different distribution of chest accelerations on the vehicle occupants when exposed to the same representative crashes (Figure 5). For any cutoff limit, the percentage of occupants above the cutoff level for Vehicle A will always be greater than the percentage of occupants above the cutoff for Vehicle B (Figure 6). However, as the cutoff limit increases from 1 to 2 to 3, the difference between Vehicles A and B becomes less and less clear (Figure 7). We chose the cutoff levels after the simulation results for all 105 vehicle designs were completed. We tried cutoff limits at small intervals across the whole range of occupant response until we identified the cutoff limit for each occupant response that made the standard deviation of the performance measure the greatest for the 105 vehicle designs simulated. The resulting cutoff limits are shown in Table 1.

The outputs of the test device model and the crash model, the test performance and the real performance,

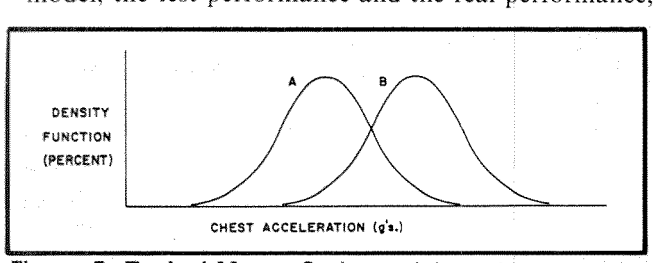

Figure 5. Typical Monte Carlo model results

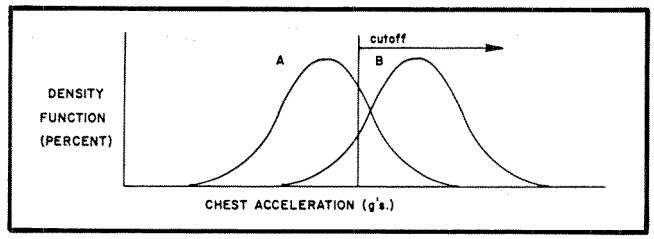

Figure 6. Monte Carlo model results—cutoff effect

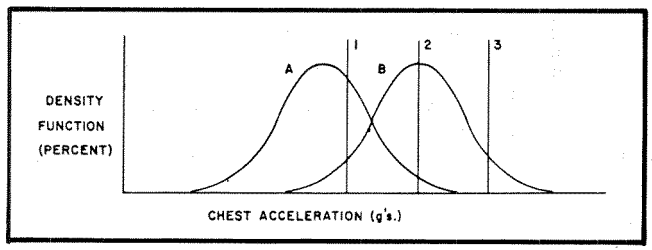

Figure 7. Monte Carlo model results—effects of various cutoffs

were compared for all combinations of responses by plotting the scatter plots of the real performance versus the test performance (Figure 3). Scatter plots and correlation coefficients were used to judge which test procedure and test readings best predicted the simulated real performance.

The individual elements of the model will now be discussed in detail.

A Computer Model of Side Crashes

The computer simulation used in this study was a lumped mass model very similar to others that appear in the literature(4). Six masses (Figure 8) and six energy absorbers are used to simulate a perpendicular car-to-car side impact. Table 2 lists the physical interpretation of each mass, energy absorber, and of the torso-to-pad clearance. Mass 1 represents the weight of the striking car, while energy absorbers 1 and 2 are used to simulate the striking car's crushable structure. The struck vehicle is represented by masses 2, 3, and 4, which are the door

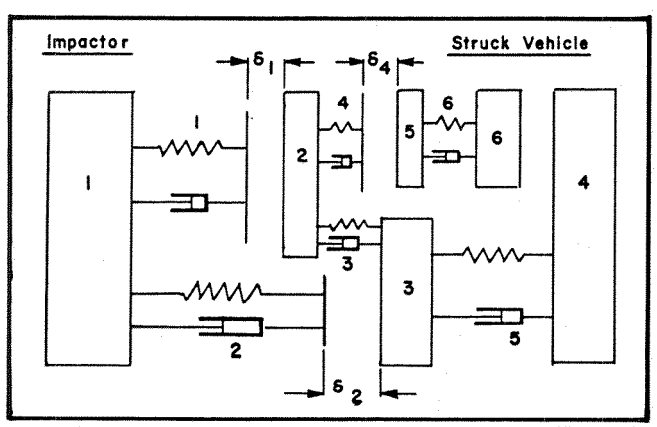

Figure 8. T-type side impact model schematic

Table 1. Optimal cutoff value, range and increments of side impact response variables

Variable	Range Lower	Range Upper	Increment	Optimal Cutoff
Rib Acceleration	0	290	10	90
Chest Acceleration	0	145	5	50
Thoracic Trauma Index	20	310	10	120
Chest Force, Kip	0	2.9	.1	1.4
Chest Deflection, in.	0	2.9	.1	0.6
Padding Force, Kip	0	5.8	.2	2.2
Padding Deflection, in.	0	5.8	.2	2.2
Door Intrusion, in.	0	8.7	.3	6.0

Mass 1	—	Impactor Body
Mass 2	—	Door (Fender or Quarter Panel in L-Type)
Mass 3	—	Sill, A and B Pillars
Mass 4	—	Struck Vehicle
Mass 5	—	Rib Cage
Mass 6	—	Torso
EA 1	—	Impactor Front End
EA 2	—	Impactor-to-Sill
EA 3	—	Door-to-Sill (Side Panel-to-Sill in L-Type)
EA 4	—	Door Pad (Bolster)
EA 5	—	Sill-to-Struck Vehicle Compartment
EA 6	—	Torso-to-Rib Cage
δ 4	—	Torso-to-Pad Clearance

and side pillars, sill, and main car body, respectively. Energy absorber 3 represents the door-to-vehicle connection and the A- and B-pillars. Energy absorber 5 is the car underbody. A deformable occupant upper torso is represented by masses 5 and 6, with an initial gap, Delta 4, between the occupant and the energy-absorbing inner door surface, energy absorber 4.

In the study, masses 5 and 6 increase with occupant size. Energy absorber 6, the thorax stiffness, depends on occupant age and weight. The value of energy absorber 4, the energy-absorbing characteristics of the door inner surface, depends on the contact area of the occupant, which increases with increasing occupant size.

The occupant size being simulated affects many of the other variables in the simulation. It was found that chest stiffness is related to chest girth, so that larger occupants have stiffer chests. Since larger occupants are also wider, the gap between occupants and the door is smaller for larger occupants. These effects are accounted for in the model. The gap between the occupant and the door, Delta 4, depends on the car size as well as the occupant size. The relationships among all of these variables will be discussed more completely in the next section.

Input data for the model were gathered from crash test results of various size cars. Side impact models were defined for the seven car-size categories used in this study to represent the passenger car population. A set of baseline input data can be found in Appendix B.

The model was exercised over a range of collision speeds, and results were compared to side impact tests and the results of other computer model simulations. The model generally agreed with the trends and response levels found in the tests and other model results (Figure 9 and Appendix C).

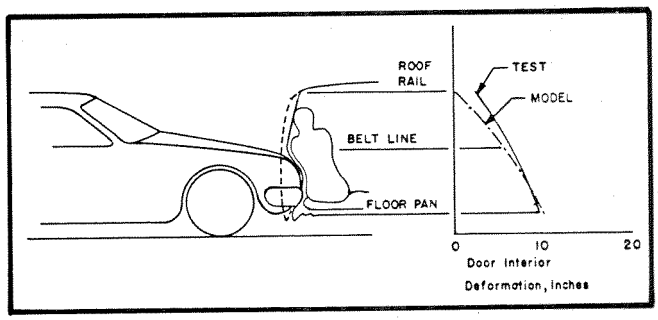

Figure 9. Comparison of side crushes between crash tests and the side impact model

The model was revised to simulate car-to-car collisions in which the impact point is near the front or the rear of the car (Figures 10 and 11). These collisions, called L-type, have little or no intrusion of the side structure into the occupant compartment and, due to the impact point, have a lower speed change at the center of gravity, and higher rotational velocity than the impacts to the occupant compartment, called T-type. The L-type collisions were modeled by exposing the occupant to the acceleration of the whole vehicle rather than the door and by softening the inner door stiffness since the door is not precrushed in the L-type collision. It was our judgment that the L-type model would produce a reasonably accurate simulation of the crash event while avoiding unnecessary complexities involved in a two-dimensional model with vehicle rotation. It is believed most of the occupant loading from the side structure in the L-type collision takes place before significant vehicle rotation has occurred. We also had to keep the models simple so it would be practical to run the tens of thousands of simulations necessary for this type of study.

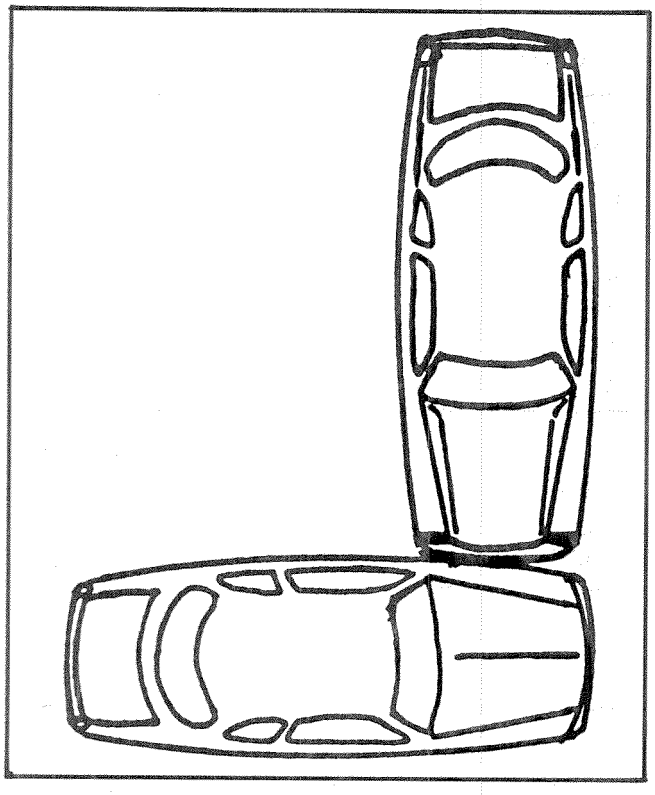

Figure 10. L-type collision

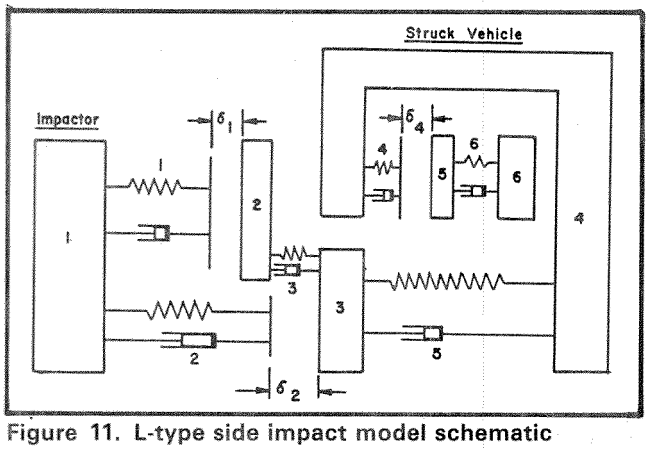

Figure 11. L-type side impact model schematic

Many Variables Considered

Car design can affect occupant dynamics in various ways. Our model considered cars with varying amounts and stiffnesses of energy-absorbing material on the inside of the door and several levels of side structure rigidity, which influences the speed of collision between the occupant and the side of the vehicle. A more detailed description of the study variables follows.

Injuries to occupants in car crashes can also vary widely from crash to crash because of the individual circumstances of each crash. The outcome of the collision is influenced by such randomly occurring variables as collision speed, car sizes, occupant size, occupant gender, and occupant age. There are many other variables that influence the outcome of a car crash, but the foregoing list was believed to be important enough to be included in this study. The effects of these random variables can be either direct or indirect. Variables such as vehicle speed and vehicle weight have an obvious direct effect on the severity of the collision. However, variables such as occupant size can have an indirect effect since larger occupants are closer to the door, and the occupant dynamics are known to be affected by the distance from the occupant to the door.

Door Gap

The definition of the door gap is shown schematically in Figure 12. The procedure used to determine this gap was based on the driver's elbow-to-elbow breadth, Society of Automotive Engineers (SAE) vehicle dimensions, and car size. The derivation of elbow-to-elbow breadth is discussed in a subsequent section, Occupant Size. Car size is defined as subcompact, compact, intermediate, and full size. The car size categories were determined based on wheelbases. These car size categories are discussed further in a subsequent section, Car Size. A range of cars was surveyed from 1978-82 model years to determine the Motor Vehicle Manufacturers Association (MVMA) shoulder room (W3) and centerline of driver (W20) for each car size. The cars used were not weighted for units in operation, UIO's (i.e., each car counted as a weighting factor of one). The space available between the interior of the door and the centerline of the driver for the cars surveyed was determined by—

space available = .5 * W3 - W20.

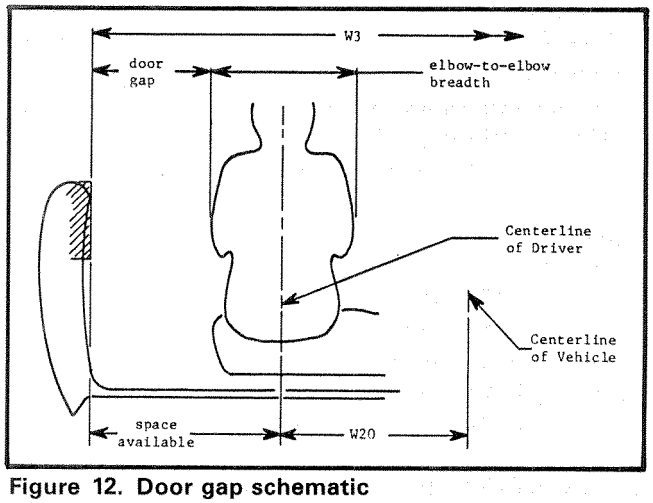

Figure 12. Door gap schematic

The means and standard deviations from the data were calculated. Table 3 presents the results of this analysis and the sample sizes used.

Using the statistical data from Table 3, the space available can be randomly determined from the following equation:

space available = mean + (number of standard deviations) * (standard deviation)

Table 3. Space available versus car size

Wheelbase (in)	Space Available (in) Mean	Standard Deviation	Sample Size
80-100	12.76	.44	11
101-111	14.00	.42	20
112-117	14.60	.68	12
118+	15.43	.77	8

No imports were included in the calculations with the exception of captive imports (e.g., Ford Fiesta).

The gap between the driver's torso and the interior door panel was determined for each car and driver combination.

gap = (space available) - .5 * (elbow-to-elbow breadth)

In the simulation, the struck car was widened or the occupants were moved closer together to account for the addition of the side bolster. Thus, the gap was kept the same as different size pads were simulated. However, no vehicle weight penalty was assessed for the side bolster or for widening the car.

Chest Stiffness

A stiffness parameter was calculated(5) from the thoracic force and deflection measurements made on 14 subjects reported by Tarriere(6) at the Seventh ESV Conference.

Linear correlations of this stiffness parameter with seven primary factors (age, sex, chest depth, chest circumference, subject weight, impact surface padding, and impact velocity) and the secondary factors, consisting of all two-at-a-time combinations of the primary factors, were calculated. These indicated that stiffness was most highly correlated with age and that the inclusion of chest circumference in the regression model improved the correlation (R^2 increased from 0.17 to 0.31 (while slightly improving the confidence level (85.2 to 87.2 percent).

To improve the correlation of the model without degrading its confidence level, a logarithmic transformation was tried. It resulted in a 3-term model, which, when compared to the 2-term model, had a greatly improved correlation (R^2 = 0.43, rather than 0.31) as well as a slightly improved confidence level (probability (of model being applicable) = 88.2 percent, rather than 87.2 percent). This regression accounts for about 43 percent of the variation of the data. The remainder, about 57 percent of the total variance of the data, is relegated to so-called unexplained variance.

This regression equation, relating the calculated chest stiffness (N/m) to the subject's age (years) and chest circumference (m) is given by:

$$\log_{10} \text{Stiffness} = K_1 * \text{Age} + K_2 * \text{Circumference} + K_4 + K_3 * \text{Circumference}^2$$

K_1 = -.014
K_2 = +33.4
K_3 = -18.4
K = - 9.1

The calculation of chest circumference will be discussed in the next section, Occupant Size.

Occupant Size

The driver's anthropometric data were based on the distribution of U.S. adult population age 18 to 79 as documented in the 1960-62 Health Examination Survey (HES)(7). The driver's age and weight were randomly determined using bivariate frequency distributions. The driver's gender was randomly chosen based on a 69/31 male/female mix. These characteristics were based on the 1979-82 NASS data base.

The anthropometric measurements used in developing the driver's profile are shown schematically in Figure 13.

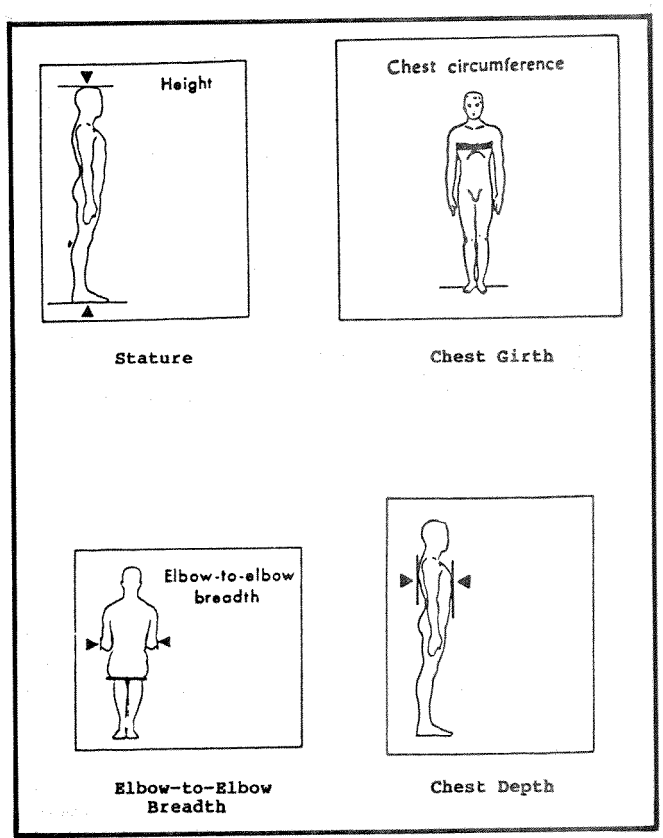

Figure 13. Anthropometric measurement definitions

Using the driver's age, weight, and gender, the driver's stature was based on bivariate data from HES(8). The height was randomly determined based on the distribution within each gender, age, and weight cell. Once the driver's height was determined, the chest girth and elbow-to-elbow breadth were determined. Multiple regression equations for these measurements as a function of height, weight, and age for men and women were derived from the HES data(9). The regression equations used are shown below.

Chest Girth (used to calculate chest stiffness):

- Male: chest girth = 33.206 - .201 * height + .114 * weight + .015 * age
- Female: chest girth = 30.321 - .150 * height + .094 * weight + .020 * age

Elbow-to-Elbow Breadth (used to calculate door gap):

- Male: breadth = 17.283 - .169 * height + .061 * weight + .017 * age
- Female: breadth = 14.060 - .148 * height + .060 * weight + .022 * age

where:

height in inches
weight in pounds
age in years
calculated quantities in inches

A correlation matrix is presented in Table 4. Eighty to 90 percent of the variation in these measurements are accounted for by the driver's weight.

Table 4. Anthropometric measurements correlation matrices

Male:

	Age	Height	Weight	Chest Girth	Elbow Breadth
Age	-				
Height	-.270	-			
Weight	-.058	.394	-		
Chest Girth	.062	.189	.885	-	
Elbow Breadth	.156	.069	.804	.833	-

Female:

	Age	Height	Weight	Chest Girth	Elbow Breadth
Age	-				
Height	-.270	-			
Weight	-.058	.394	-		
Chest Girth	.062	.189	.885	-	
Elbow Breadth	.156	.069	.804	.833	-

The driver's chest girth (chest circumference) and age were used as inputs to the chest stiffness regression model. This model was discussed in the section titled Chest Stiffness.

The last anthropomorphic measurement modeled was the driver's chest depth. Chest depth is used to estimate driver's contact area with door to calculate the interior door stiffness. The HES survey did not record this measurement. Since the correlation of chest girth with weight was high (approximately 90 percent), the assumption was made that the chest depth would be the same percentile as the weight. Using the data from HES(7) of percentiles versus weight, the driver's weight percentile was determined. This percentile was transformed into standard deviation. The data from the Henry Dreyfuss Human Scale Manual(10) for male and female chest depth gave means and standard deviations. The following equations present the chest depth data used.

Chest Depth (used to calculate driver contact area):

- Male: chest depth = 9.0 + .7653 * (standard deviation)
- Female: chest depth = 6.5 + .7143 * (standard deviation)

where the standard deviation is the same as for the driver's weight.

Car Size

The car size algorithm for determining struck car weight versus struck car size was based on the CRASH3 program(11). The algorithm had seven vehicle categories versus a range of wheelbases. These CRASH3 wheelbases were needed to allow using the National Vehicle Population Profile (NVPP) data for determining the frequency of vehicle size versus vehicle weight in the real world. The CRASH3 vehicle categories were also needed for obtaining basic structural characteristics of the struck car and striking vehicle during the side impact simulation. To facilitate using the NVPP data, the CRASH3 wheelbases were rounded to whole numbers. The CRASH3 categories were then combined into the more traditional car sizes to develop the gap between the driver's elbow and the interior door trim. The gap categories were based on an algorithm of car size used by NHTSA and MVMA for the MDAI (Multidisciplinary Accident Investigation Data File)(12). Table 5 shows the relationship of these categories.

Accident and Vehicle Exposure Variable Distributions

Data Base

NASS data files from 1979 to 1982 were used for the accident and vehicle crash exposure variables. The NASS data are a probability sample of each year's nationwide

Table 5. CRASH3 category wheelbase comparisons

CRASH3 Category	CRASH3 Wheelbase (in)	Rounded Wheelbase (in)	Traditional NHTSA & MVMA Category	Wheelbase (in)
1	80.9 - 94.8	81 - 95	Subcompact	80 - 93
2	94.8 - 101.6	96 - 102		94 - 100
3	101.6 - 110.4	103 - 110	Compact	101 - 111
4	110.4 - 117.5	111 - 117	Intermediate	112 - 117
5	117.5 - 123.2	118 - 123	Full Size	118+
6	123.2 - 150	124+		
7	109 - 130	Lt. Truck	Lt. Truck	Lt. Truck

motor vehicle accidents for which candidate accidents were chosen with varying probabilities. The selection of the final side impact data base was made by applying the following filters to NASS data files.

- Accidents involving two vehicles
- Struck cars—direction of force (highest) 2 to 4 o'clock or 8 to 10 o'clock
- Striking vehicles—either cars or light trucks

The detailed NASS vehicle selection criteria are given in Appendix D. Unless stated otherwise, the analysis of each NASS variable was performed on weighted data by using National Inflation Factors as weights. Background information on the NASS files is given in Appendix E.

NVPP data files from 1979 and 1980 were used to obtain the distribution of vehicles in use by weight and size (wheelbase). The NVPP data are compiled by R.L. Polk from State registration files as of July 1 of each calender year for model years back to 1966.

Exposure Variables

The following variables described the individual accident simulations:

- Weight of struck car
- Weight of striking vehicle
- Vehicle wheelbase
- Delta V of struck car and striking vehicle—used in estimating impact speed of striking vehicle
- Driver's age
- Driver's height
- Driver's weight

Method of Establishing the Collision Sample

The NASS and NVPP data were analyzed to establish the frequency distribution of each variable. Some of the variables were believed to be correlated, that is, certain combinations of their frequency distributions would occur more often than others. To determine the degree of their dependence on each other, the correlation coefficients between them were estimated and tested for their being different from zero. The analysis was performed by using the Statistical Analysis System (SAS), a highly flexible statistical package. SAS has been implemented for NASS files by storing each year's NASS file as a SAS data base. When the side impact study was launched in early February 1984, SAS was implemented for 1979 and 1980 NASS files only. So, the first estimates of the correlations were made from 1979 and 1980 NASS files. These estimates were twice updated since then, once in June when the NASS 1981 file was added and again in July when the NASS 1982 file was added.

The analysis of NASS 1979 and 1980 data was performed on the combined sample of male and female drivers. The results of their analysis are shown in Table 6 (raw data) and Table 7 (weighted data). They include the summary statistics and the correlation coefficients. When more data were added from NASS 1981 and 1982 files, the analysis was also performed by driver's gender, in addition to the analysis of the combined sample of male and female drivers. The results of the analyses by driver's gender are shown in Tables 8A-8B (raw data) and Tables 9A-9B (weighted data).

The results from NASS 1979 through 1982 weighted data showed some degree of dependency between driver's age and weight parameters. The correlation coefficients for male and female drivers were 0.13 and 0.30, respectively.

Bivariate Frequency Distributions

- Bivariate frequency distributions of driver's age*weight were generated separately for male and female drivers (Tables 10 and 11).
- Struck passenger cars' wheelbase*weight distribution (Table 12) was obtained from NVPP passenger car units in operation data. The data showed a high correlation between car weight and car wheelbase ($r = 0.93$).
- Striking vehicles' (cars + light trucks) wheelbase*weight distribution was developed by adjusting the Polk passenger car data distribution downward by an estimated truck portion of it. The truck portion for each weight group was estimated from NASS 1979-1980 data (Table 13). Truck portion for each weight group was then assigned to one category of wheelbase.

Vehicle Speed

The sum of CRASH3 delta V's for the striking vehicle and struck car were used as an estimate of impact speed for the striking vehicle. The speed distribution was obtained by type of vehicle damage: occupant compartment (T-type) and nonoccupant compartment (L-type). The T-type is defined as P + Y + Z + D, while the L-type is B + F using the Collision Deformation Classification (CDC)(13) Specific Horizontal Damage Area.

Collision theory shows that for pure one-dimensional impacts (no rotation), the sum of the speed changes of two vehicles is equal to the closing speed of the vehicles prior to the collision. Since the struck car in a side impact collision essentially has a zero velocity relative to the direction of travel of the striking vehicle, then the striking vehicle speed at impact should be equal to the sum of the speed changes of the two vehicles, provided the impact is at or near the center of gravity of both vehicles. Comparing the speed distributions of the T- and L-type collisions shows that the delta V sum for the L-type is less than the delta V sum for the T-type. This is consistent with collision theory, which indicates that for the same vehicle striking speeds, the delta V at the vehicle center of gravity will be less in the L-type collision than in the T-type collision due to vehicle rotation. The difference in the means of the two speed distributions was found to be consistent with collision theory when the amount of offset of the impact point from the center of gravity in the L-type collision was taken into consideration. Therefore, it was decided to use the 1979-82 NASS distributions for the T- and L-type impact speeds.

The cumulative percentage distribution of striking speed of NASS data (unweighted) were compared with that of Highway Safety Research Institute CPIR3 accident data files as of September 1974. The results were consistent (see Figure 14).

Sample Selection From Two Correlated Variables

A sample selection of pairs of two correlated variables can be made by using the matrix of random numbers constructed from the bivariate frequency distribution. A method of constructing such a matrix and its use in sampling procedure is outlined in Appendix F.

Sample Size To Validate Vehicle/Occupant Model

The exposure variable set developed above was input into the preprocessor computer program (discussed in section, Monte Carlo Method) to exercise the vehicle/occupant model of an impact test method. For bivariate variables, the sample selection of random pairs was made by employing the sampling method outlined in Appendix F. The preprocessor generated two sets of univariate and bivariate frequency distributions using sample sizes of 400, 600, 850, and 1,000 cases. The results of each sample were compared with those from the NASS data. The results of the chosen sample size were then compared with the second sample of the preprocessor output for the reliability, that is, the repeatability of the results based on the same sample size.

Method of Comparison

NASS Versus Preprocessor

The percents of cell frequencies of the driver's age*weight distribution generated by the preprocessor were compared with those of the NASS data. Table 14 shows the summary of these results. The results showed a

Figure 14. Cumulative percentage distributions—striking speed by type of vehicle damage

good convergence for the samples of 850 cases and higher. For female drivers, 94 percent of the cell differences had a magnitude of 2 percent or less, and the maximum difference for any cell was 2.8 percent. For male drivers, the differences were even smaller, and the maximum difference was 1.2 percent. The comparison of 1,000 cases with NASS data showed only slight improvement, and, because of computer core limitations, a sample of 850 cases was considered adequate.

Preprocessor Sample 1 Versus Sample 2

Table 15 shows the comparison between two samples of preprocessor results based on 850 cases each. It shows that for female drivers, 86 percent of the differences were of magnitude 2 percent or smaller (maximum 2.9 percent). For male drivers, 97 percent of the differences were of magnitude 2 percent or less (maximum 2.2 percent).

Also, a nonparametric test procedure called a sign test was employed to the differences of the paired cell percents of driver's age*weight distributions of the two samples. If the two samples are similarly distributed, then the number of positive and negative differences are divided evenly. Table 16 shows the results of sign tests. No significant difference is found, that is, repeated samples of the same size produce similar results.

The Monte Carlo Method

The Monte Carlo Method was used in this study to select a sample of representative side impact accidents to simulate. Several of the key elements in our study vary randomly in accidents—collision speed, car sizes, occupant age, and occupant size, for example. In the Monte Carlo Method, information about the frequency of occurrence of values of the random variables is gathered,

and statistical distributions are constructed. Values of the variables are then randomly chosen according to each variable value's probability of occurring. A set of variables is randomly chosen for the first simulation, then another randomly chosen set is used for the second simulation, the third simulation, and so on. In the Monte Carlo Method, hundreds or even thousands of simulations are done in this manner, and the results of the simulations may be grouped into statistical distributions. So instead of saying that the outcome of a simulation is a chest acceleration of 60, one would say that the probability of a chest acceleration of less than 60 is, say, 35 percent.

One of the difficulties in using the Monte Carlo Method is in knowing how many simulations using random inputs need to be run for the results to be representative of the entire population of simulations that could have been run. For a number of practical reasons, we chose a sample of 850 simulations of side impact traffic encounters for one vehicle design.

Structure of Preprocessor Model

The side impact simulation model preprocessor was developed to provide the random inputs for the side impact simulation. The preprocessor program is run using a random seed for the random number generator or a set of previously determined uniform or normal random numbers. The random seed is based on the time and date of the program execution.

The uniform and normal random number routines are general computer system functions. The uniform random number distribution (integer values) ranges from 1 to 100 with equal probability. The normal random number distribution ranges from -6.0 to 6.0 with a mean of 0.0 and a variance of 1.0.

The preprocessor starts randomly determining driver's gender and whether the impact was a T- or L-type. A 61/39 mix of T- or L-type impacts was used, based on the 1979-82 NASS weighted data base. It then randomly determines driver's age versus driver's weight. The preprocessor model source code is written in Fortran 77 for the Ford Honeywell Multics operating system(14). The program can determine up to 1,000 random sets of side impact simulation inputs. Table 17 shows the output format of the preprocessor and briefly defines each variable. A sampling of the side impact Monte Carlo input data from the preprocessor is presented in Appendix G.

A Test Device Model

A simple component test device was modeled using two masses and energy absorbers (Figure 15). For validation purposes, the parameters of the model were adjusted to produce force-time responses that were within the response corridors developed by MVMA for a

component test device(15,16). These corridors were developed from human cadaver drop test data(6) and are believed to be representative of living human dynamic response. The test device response fell within the MVMA corridors when the cadaver drop tests were simulated with the model. Figures 16 and 17 show the validation responses for a lateral rigid impact at 16km/h and a lateral padded impact at 22.5km/h, respectively.

The model of a full-vehicle test procedure was also developed from the computer model used to simulate car-to-car collisions. Since the test tries to duplicate a typical car-to-car crash, the model of the full-vehicle crash described earlier was altered to include the stiffness of the NHTSA and CCMC moving deformable barrier (MDB) face and the effect of mass and stiffness of the SID and APR side impact dummies.

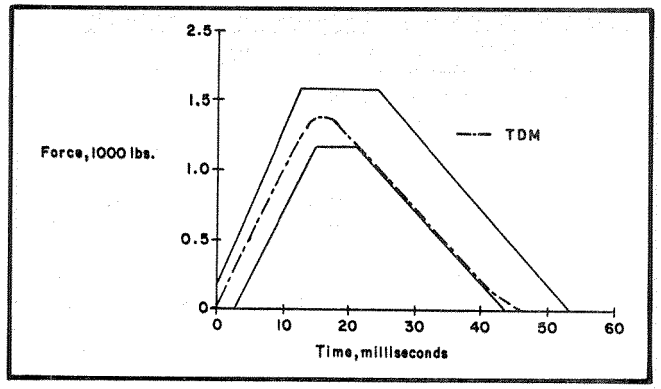

Figure 16. Lateral rigid impact test corridor with test device model response at 16km/h

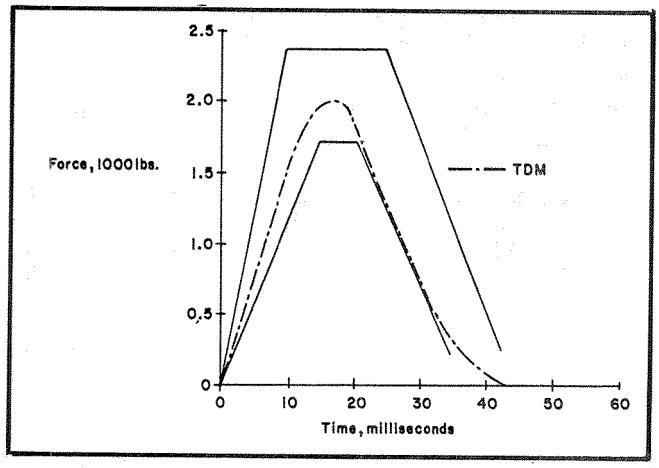

Figure 17. Lateral padded impact test corridor with test device model response at 22.5km/h

Initial Results

We simulated both component and full-vehicle type tests. The component tester was similar to the one developed for MVMA by MGA, Inc.(17), and the full-vehicle tests were patterned after those proposed by NHTSA and the Committee of Common Market Automobile Constructors (CCMC). In this initial study, we did not attempt to investigate fully the effect on test predictability of all the possible changes in test design parameters. Instead, we chose to look at a few plausible test procedure variations.

Component Tests

In the component test, we varied the size of the impactor from a 40th percentile male to a 60th percentile male, and we also varied the impact speeds from 16km/h to 32km/h to study the effect on test predictability of changes in these parameters. We also looked at the effect of using a rigid component test impactor rather than an impactor with realistic thorax stiffness. All component test simulations were run with the door precrushed. A table of the component test runs is shown in Table 18.

Table 18. Test procedure variations—component test runs (precrushed door)

Procedure	Impactor	Occupant	Impact Speed
1	MVMA	50% Male	22km/h
2	MVMA	40% Male	22km/h
3	MVMA	60% Male	22km/h
4	MVMA	50% Male	16km/h
5	MVMA	50% Male	32km/h
6	Rigid	50% Male	22km/h

For the component tests, we measured Thoracic Trauma Index (TTI), chest acceleration, chest deflection, and rib acceleration on both the component test device and the vehicle occupant. We also looked at how well TTI on the occupant is predicted by chest acceleration on the test device and how well chest acceleration on the occupant is predicted by TTI on the test device. Validation plots were made for each of these seven possibilities, and correlation coefficients between test results and real-world simulation results were calculated.

Generally, the component tests have relatively low correlations between real performance and test performance due to the following:

1. The component test model has only a 2-mass and 2-energy absorber.
2. The door gap is not taken into account following the precrushed door. However, the precrushed door stiffness of the struck vehicle was considered.
3. The component test speeds (16, 22, and 32km/h) are the contact speeds between the dummy and door interior.

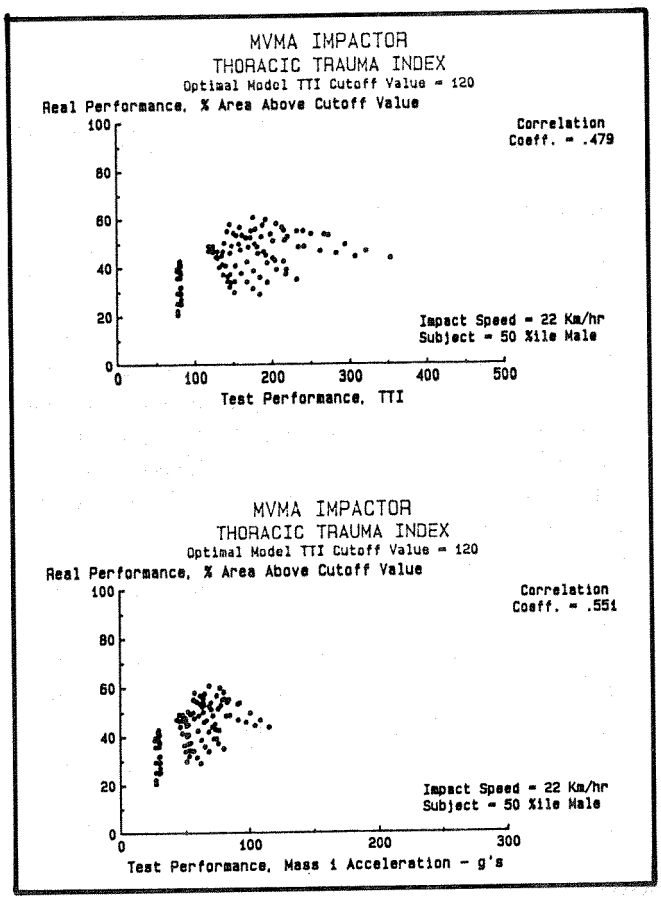

Figure 18. Validation plots—MVMA baseline impactor—thoracic trauma index

MVMA Baseline Impactor

Validation plots for the baseline impactor are shown in Figures 18 through 21. All of the seven response combinations show similar scatter and similar correlation. Note that there are 105 points (15 experiment designs × 7 vehicle sizes) in each validation plot. The highest correlation for the baseline impactor at 22km/h is found with chest acceleration. Note that TTI on the occupant is better predicted by chest acceleration on the impactor than by TTI on the impactor.

Size Variations

Different sizes of the MVMA impactor were also simulated. Validation plots for all of the responses are shown for the 40th percentile and 60th percentile male

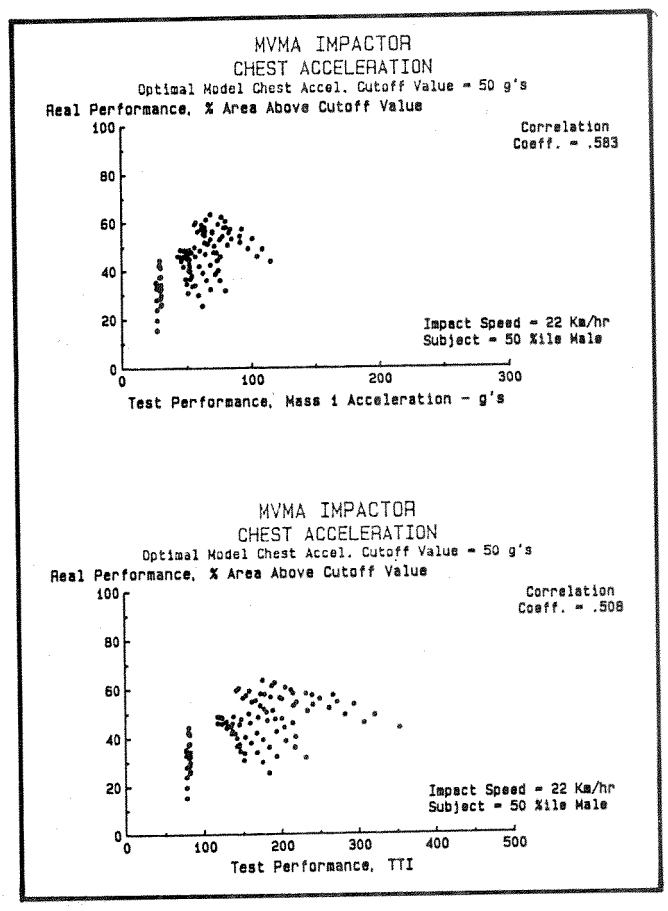

Figure 19. Validation plots—MVMA impactor—chest acceleration

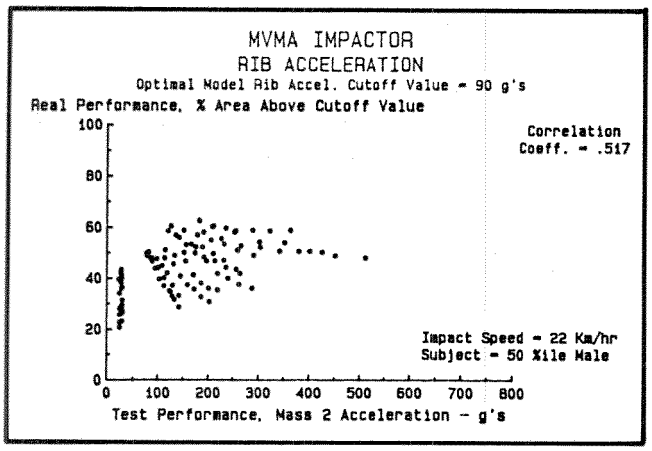

Figure 20. Validation plots—MVMA impactor—rib acceleration

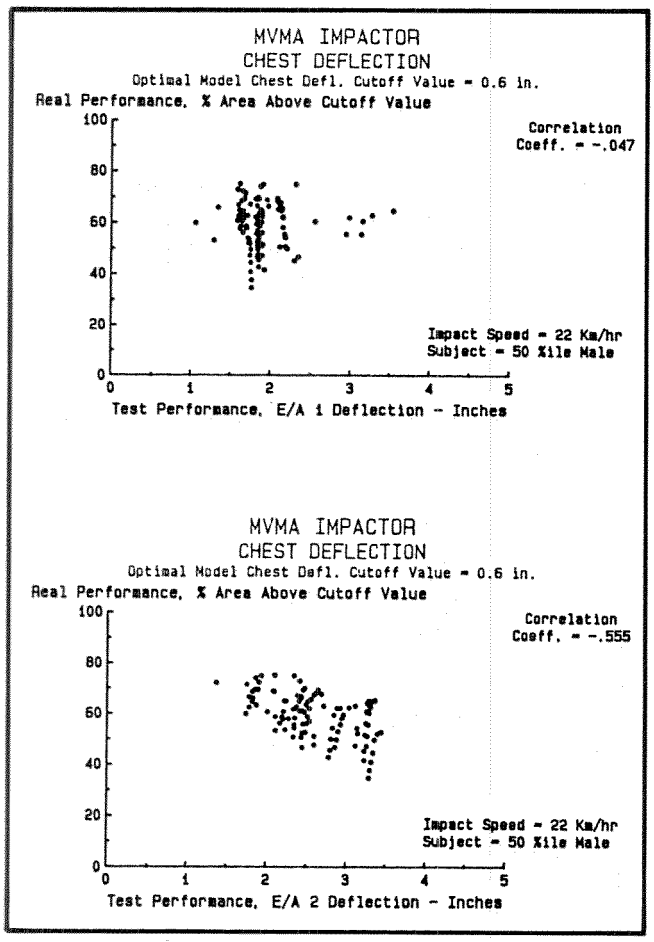

Figure 21. Validation plot—MVMA impactor—chest deflection

sizes in Figures 22 through 25. The different size impactors were simulated by scaling the weight and stiffness values of the 50th percentile impactor in proportion to the change in total body weight. In general, the 40th percentile size impactor correlates slightly better with all the responses than either the 50th or 60th percentile impactor sizes. The correlation coefficients are shown in Table 19.

Speed Variation

The 50th percentile MVMA impactor was also tested at 16 and 32km/h to investigate the effect of different test speeds on the correlation between test results and real-world performance. Validation plots for these tests are shown in Figures 26 through 29. The highest correlations of all the component tests resulted from the MVMA 50th percentile impactor run at 16km/h while the poorest correlations were with the MVMA 50th percentile male impactor at 32km/h. The correlation coefficients for these tests are shown in Table 19. At least in these simulations, the selection of test speed is a critical item in the predictability of a test procedure.

Rigid Impactor

Questions have arisen about just how biofidelic a test device needs to be. Does the impactor need to have exactly the same compliance as a human? To explore this notion of biofidelity, we simulated a component test device that had no compliance. In all other respects, it was the same as the 50th percentile male MVMA impactor simulation. The validation plots for the rigid impactor are shown in Figures 30 through 33. Note, there is very little difference in the validation plots between the rigid impactor and the MVMA 50th percentile male impactor. Does this mean a component test device does not need to be compliant like a human? This issue needs further research to answer the question. The correlation coefficient for the rigid impactor test simulations are shown in the last line of Table 19.

Full-Vehicle Tests

The full-vehicle test simulations investigated the NHTSA MDB(18) and SID dummy(19,20) combination, as well as the CCMC MDB barrier(21) and APR dummy(22,23) combination. We also looked at the effect of changing the weight of both barriers to 1,100kg, the effect of raising the impact speed from 32km/h to 40km/h, and the effect of using the SID dummy with the CCMC barrier. The full-vehicle test simulation plan is shown in Table 20.

Figures 34 and 35 show the force-deflection relationships of the NHTSA and CCMC barriers, respectively. The NHTSA MDB at 0° impact angle approximates the front end characteristics of a typical AMC Concord(18), while the CCMC MDB approximates that of a CCMC average European car(21). Note, a power curve has been used to fit each test curve.

The SID and APR dummy force-deflection characteristics are shown in Figure 36. The lateral stiffness of the HSRI SID is shown compared with that of the APR. The

dummy weights used were 174 lb and 166 lb for the SID and APR dummies, respectively.

The T-type side impact model schematic shown in Figure 8 is used for the full-vehicle test procedure. Energy absorbers 1 and 2 of the impactor are assumed to represent the barrier front end structure and are equal in stiffness. Masses 6 and 5 represent the torso mass and the rib cage mass of the dummy, respectively; energy absorber 6 represents dummy chest stiffness. The door gap, delta 4, is between the 50th percentile dummy and the door interior of a given vehicle. The door gap values used are shown in Table 21.

The correlations between the real performance and the test performance for the seven full-vehicle test procedures are shown in Table 22. These seven test procedures have impact speeds of 32 and 40km/h (or 20 and 25mph). In

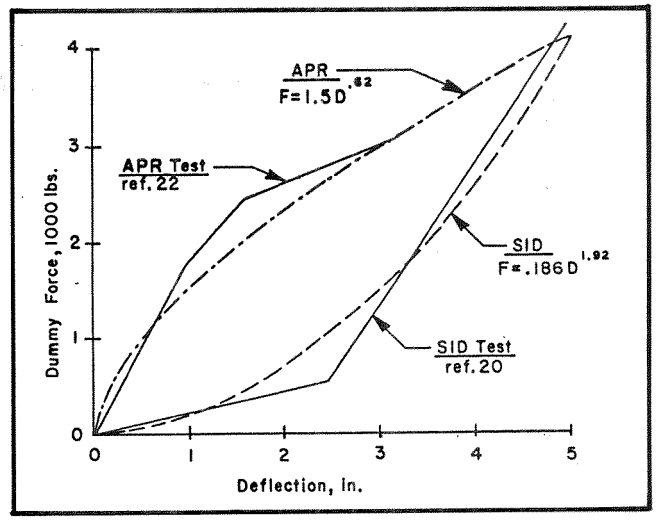

Figure 36. SID and APR dummy chest force-deflection characteristics

Table 22, masses 6 and 5 accelerations represent the torso and rib cage acceleration readings of the struck dummy in the full vehicle.

NHTSA Impactor Speed Variation

As shown in Table 22, test procedures 1 and 2 used the NHTSA MDB impactor weighing 1,361kg at 32 and 40km/h, respectively. Both procedures assume a SID test dummy in a struck vehicle. In general, test procedure 1 at lower speed exhibits higher correlations for most of the responses than those of test procedure 2 at the higher speed.

Figures 37 through 40 show the validation plots of real performance versus test performance for the seven major response correlations in the two test procedures.

Note that the real performance of TTI is predicted better by the mass 6 acceleration (torso acceleration) than by the TTI in the full-vehicle tests. This is true throughout the seven test procedures shown in Table 22.

CCMC Impactor Speed Variation

Test procedures 3 and 4 show the effect of test speed using the CCMC MDB weighing 950kg on the correlation

between the real performance and test performance. The two test speeds are 32 and 40km/h, and the dummy used in the struck vehicle was the APR.

In the seven response correlations, test procedure 4 at 40km/h produces consistently higher correlation coefficients than test procedure 3. The main reason is that to produce the impact severity observed in the real world, the impactor speed would have to be higher, if the impactor weight is less than the mean striking vehicle weight, which is about 1,500kg.

Figures 41 through 44 illustrate the correlations between the real performance and the test performance for the seven responses in the two test procedures.

CCMC Impactor at 1,100kg—Dummy Variation

Test procedures 5 and 6 have the CCMC MDB impactor weighing 1,100kg at 32km/h with the SID and APR dummies, respectively. Test procedure 6 with the APR dummy yields a slightly higher correlation between real performance and test performance than procedure 5 using the SID dummy. However, the difference in correlation due to dummy type is not as significant as that due to speed, as shown by test procedures 3 and 4 in Table 22.

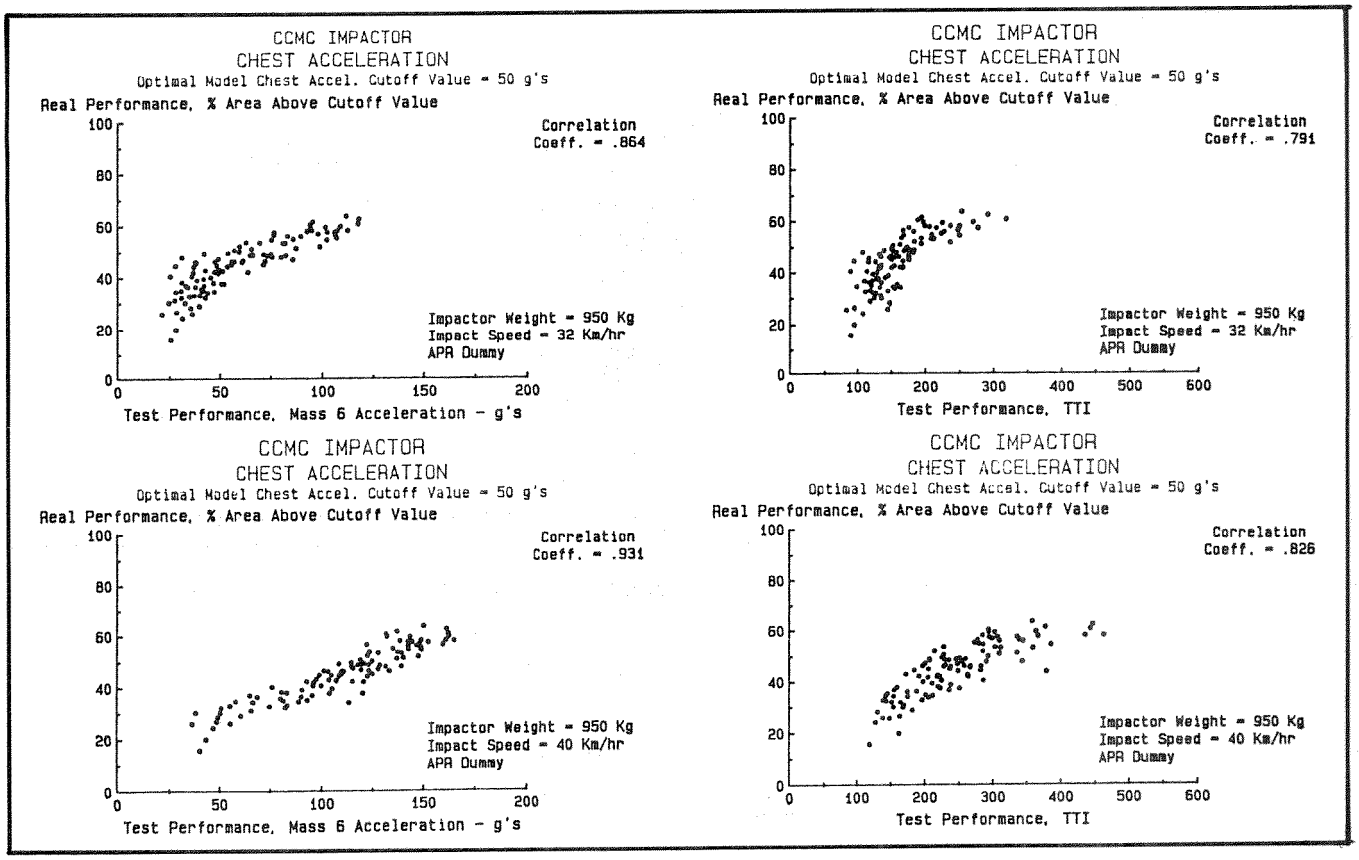

Figure 42. Validation plots—CCMC MDB impactor, speed variation—chest acceleration

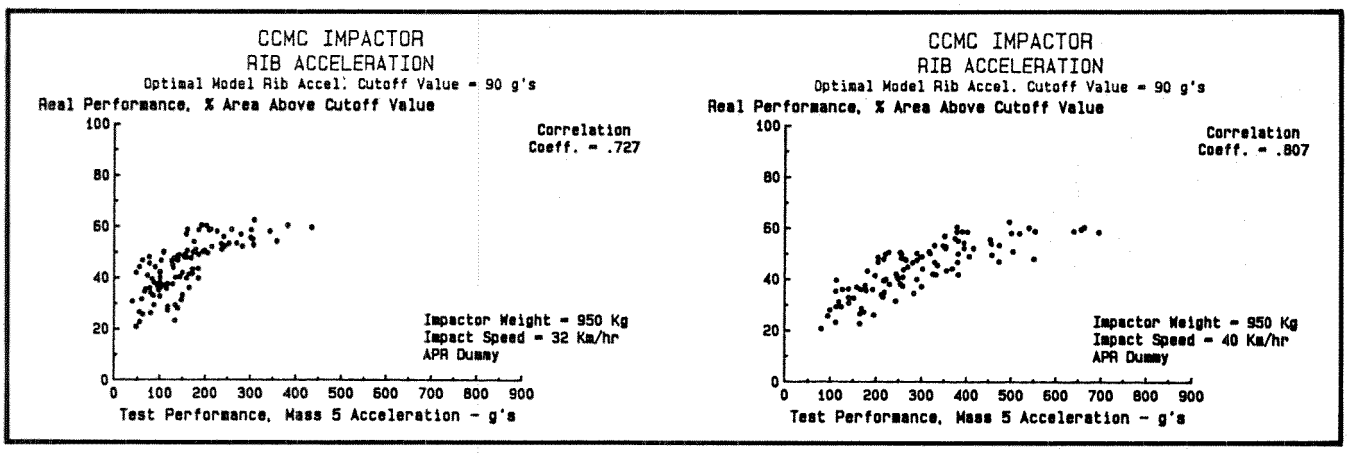

Figure 43. Validation plots—CCMC MDB impactor, speed variation—rib acceleration

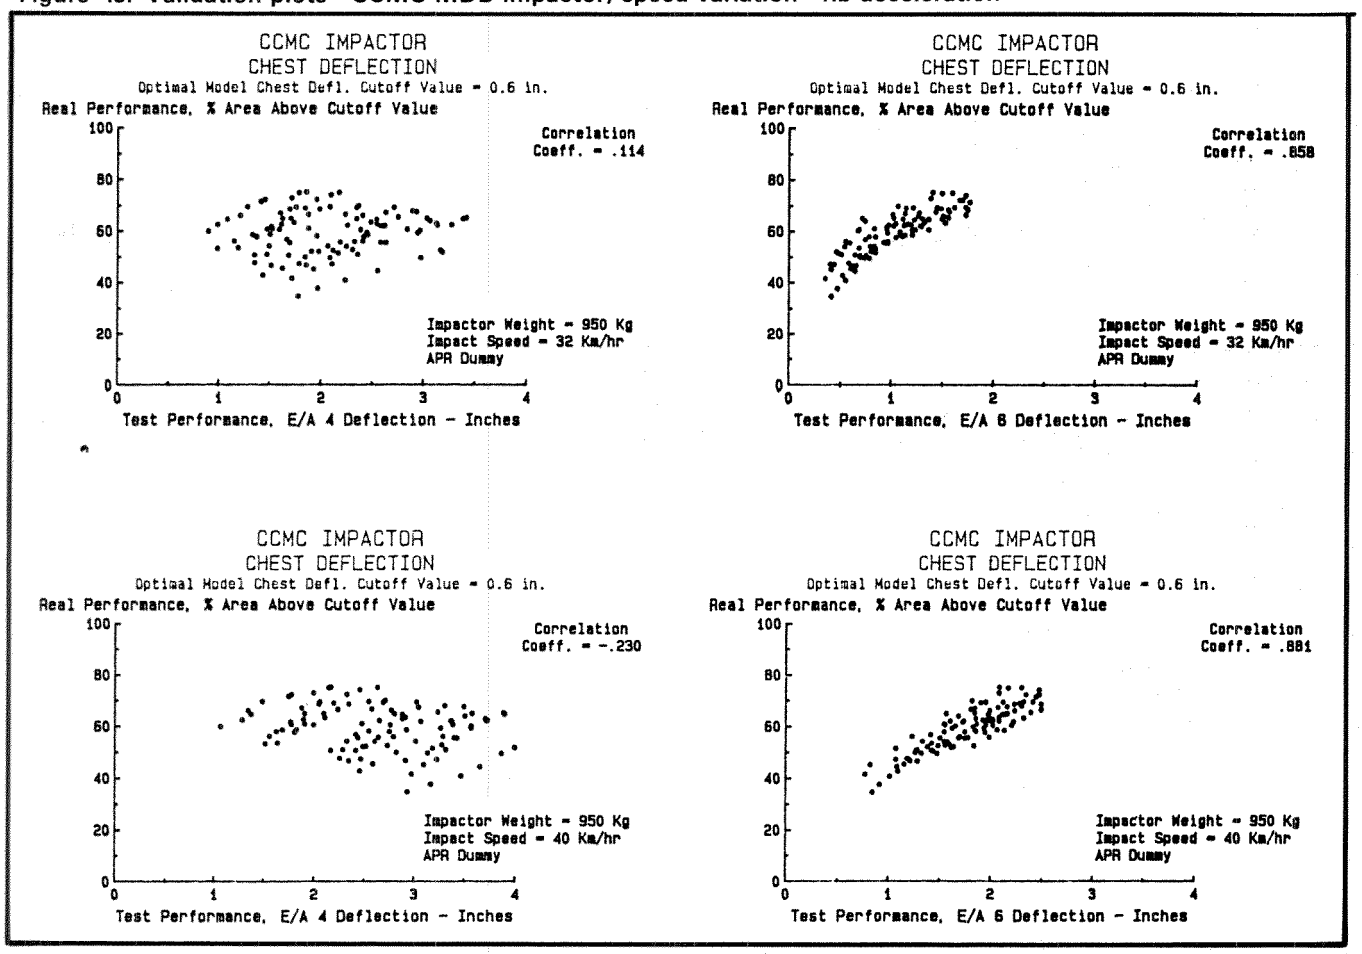

Figure 44. Validation plots—CCMC MDB impactor, speed variation—chest deflection

Figures 45 through 48 show the validation plots and correlation coefficients for the seven responses using test procedures 5 and 6.

NHTSA Impactor at 1,100kg

Test procedure 7 uses the NHTSA MDB impactor weighing 1,100kg at 32km/h with a SID dummy in the struck vehicle. This procedure, for practical purposes, produces the same correlation coefficients as test procedure 1, in which the NHTSA impactor weighs 1,361kg at the same speed. It is concluded that the weight of the NHTSA impactor is not statistically significant as far as predicting the real performance from the test performance.

Figures 49 through 52 show the validation plot and correlations of the seven performance responses for test procedure 7.

Discussion

Although these simulations are in a relatively preliminary and somewhat undeveloped condition, they suggest certain kinds of conclusions. There are factors to which the results seem insensitive and others to which they seem sensitive.

One of the questions that this kind of research is oriented toward answering is whether it really makes much difference if some of the test details are biofidelic

and realistic or not. Particularly, there has been a continuing discussion and controversy as to the minute details of the crash test dummies and of the full-vehicle moving barriers. To the extent that the kind of simulation done in this study has tapped the principal phenomena, the results indicate that some things don't matter very much because the correlation of test results to population experience seems pretty much the same. It really did not much matter whether it was the NHTSA or CCMC barrier or what their weights were. Nor did it much matter if it was the SID or APR dummy used. Furthermore, the impactor used in the component test simulations produced a similar correlation to accident simulations, whether the impactor was biofidelic or if it was just a rigid mass. These kinds of results suggest that much of the discussion about the particulars of these kinds of tests may be far less important than other considerations. For example, the running of simulations at different test speeds shows there may be an optimum speed for such tests, and it is not very high. That is, if the purpose of the test is to predict what is going to happen in the field, then it may be self-defeating to run these tests at too high a speed, because such tests may not predict what goes on in the field.

There are certain sensitivities in the findings. Particularly, it was found the weight of the test car (and/or its stiffness, which in these simulations was set proportional to the weight) had a very noticeable effect on the correlation between component test and field simulations. The correlation plots for the component tests show a very distinct patterning of the data points. This came about because each point represents a particular vehicle design, and the vehicle designs were systematically configured according to their weight and other parameters. One must not jump too quickly to conclusions about the relative quality of the correlations found with the component test as opposed to the full-vehicle test by superficial comparison of the plots. For example, see Figures 53 and 54. These are repeats of the upper left plots in Figures 27 and 38, respectively, shown earlier in the report. The first one relates to the component tester, and the second relates to the full-vehicle test, both of them for chest g. The tested vehicles have been segregated according to their weight (and corresponding stiffness) in these plots. It is seen that once the data are segregated by weight of the test vehicle, the correlations were similarly high with either type of test. But it also shows the component test must be further developed. There had already been considerable discussion about the necessity of taking into account the twin factors of structural energy absorption and occupant nearness to the door to standardize side impact component tests. The results in this report verify the need to do that. In further phases of this investigation, we will be developing an adaptive component test procedure, i.e., the speed of impact in the component test will be set after appropriate consideration of the test vehicle's properties.

This study has not, to this point, attempted to get at injury, per se, and makes no attempt at establishing any kind of pass-fail criteria. An implied criterion may evolve by working backwards from the population results to the test results by picking a criterion population performance level and then finding the test result corresponding to it. For example, one might examine any of the graphs in this report and draw a horizontal line across the graph, say, at the 50 percent level, and then drop a vertical to the abscissa to identify what might be an appropriate test criterion. This may be more easily said than done, because the attempt to do that will immediately disclose that the horizontal criterion line intersects a large scatter of test results. That is true even for the largest correlations observed in this study. Although this study is trafficking in correlations, it must be understood that in a regulatory or in an NCAP environment, it is individual models that will be branded by the test results, and fairness then becomes much more of an issue than does correlation. Individual makes having the same population experience (they are all the points intersected by any horizontal iso-level) can really have quite a range of different test results.

There are other factors to be considered such as repeatability, reproducibility, and text complexity and cost, but, in the end, a test's ability to rank cars in order of safety performance is very important. The results of this study must be considered as mainly suggestive. It is our wish that those who have ideas about improving the simulations or trying other conditions would communicate with us so we might incorporate them into our continuing work.

Future Plans

We plan to continue the development and use of the model described here and report our findings in future papers. Future work will be initially concentrated in the following areas:

- The test parameters explored for the full-vehicle and component tests will be expanded to include all combinations of the parameters. This will allow an analysis of the effects of the individual test design parameters such as impact speed, barrier weight, etc., and possible interaction of those parameters.
- We will explore various proposals for improving the predictive power of the component test. It may be possible to improve the performance of the component test by adjusting the speed of the test to account for variations in door gap and side structure stiffness.
- The effect of test-to-test variability will be introduced into the model. Test variability will

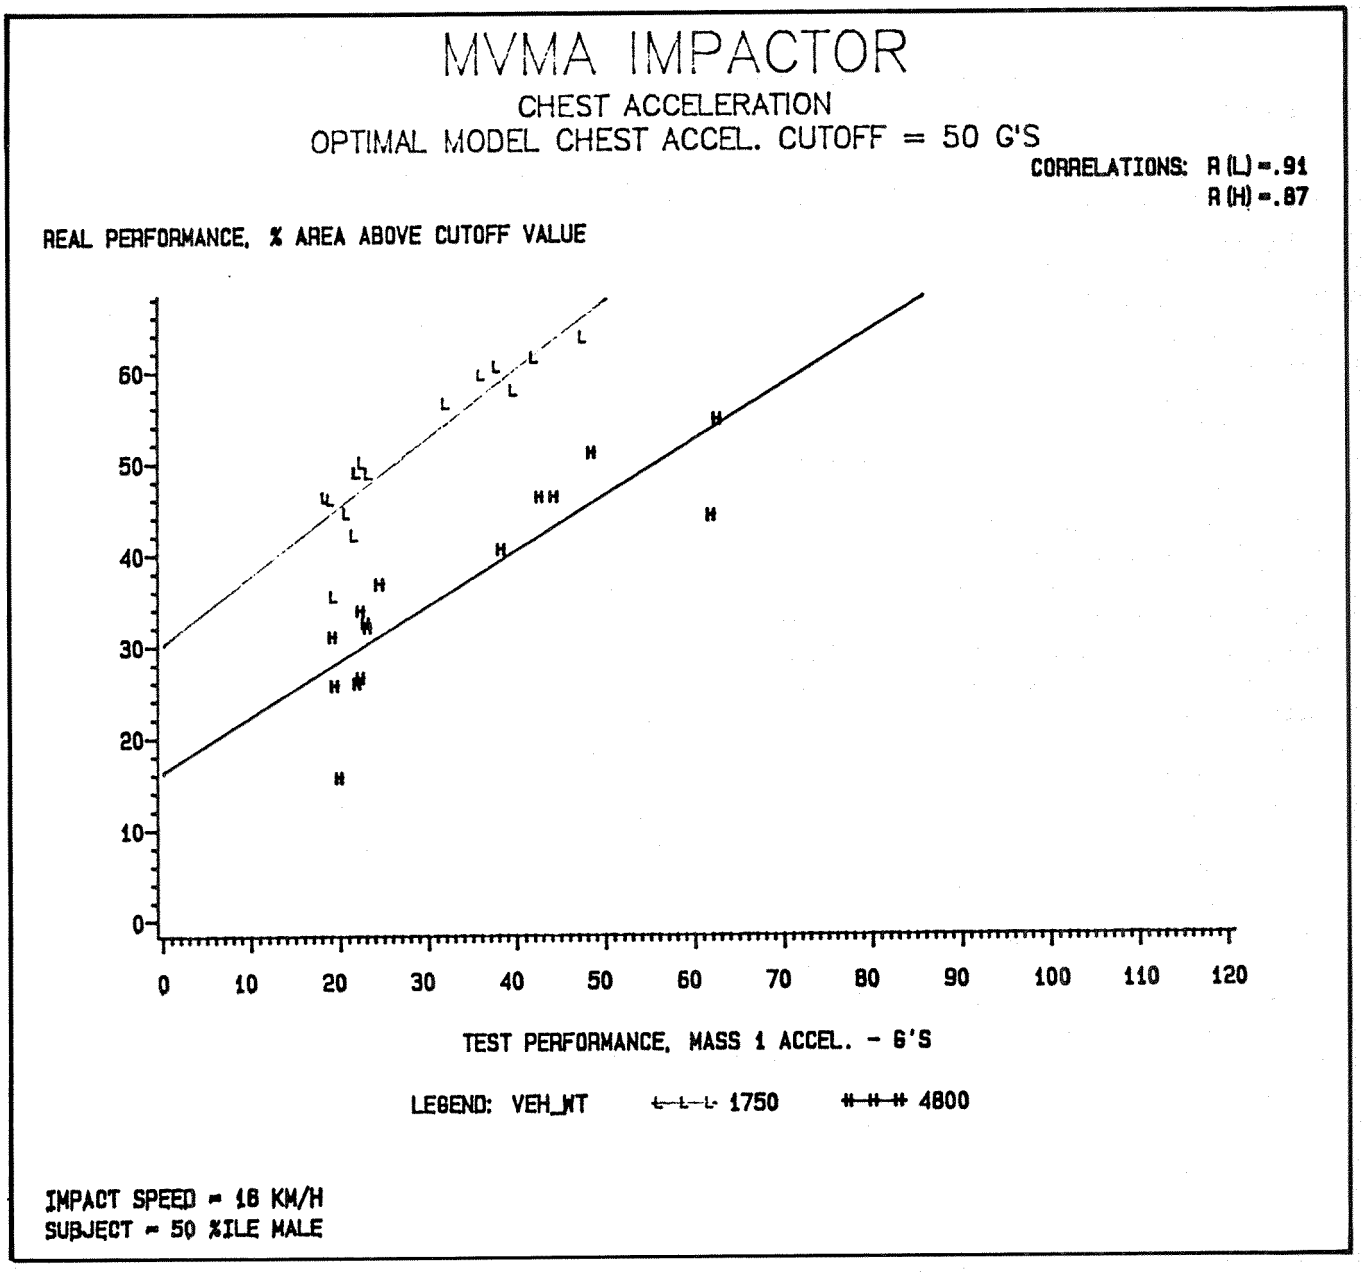

Figure 53. Vehicle weight effect on correlations—component tests

degrade the correlation between test results and real-world performance. The effect will be to either reduce or to accentuate the differences in predictability between the component and full-vehicle test.

- We will attempt injury prediction in the model rather than the current performance measure. The inclusion of injury prediction may or may not change the overall findings of the study.

Experiment Design

A three-dimensional star-cube design is used to establish the design matrix of the three side-struck controlled variables. A star-cube design is a rotatable design in which it has equal predictability in all directions from the center, and the points are at a constant distance from the center.

A pictorial representation of a three-dimensional star-cube design is shown in Table A-1. The number of design experiments in the star-cube design is fifteen. They are (1)

X = Pad thickness
Y = Elasticity of pad, Young's modulus
Z = Non-precrushed door stiffness, kip/in

one at the center of the sphere (center point 1), (2) six at the intersections of the three mutually perpendicular coordinate axes and the spherical surface (star points 10-15), and (3) eight points on the corners of the cubes (corner points 2-9) that are inscribed in the sphere. Note that the eight corner points are also on the spherical surface.

Hardware Variables

The three side-struck variables are defined as follows:

X: padding thickness, in
Y: modulus of elasticity of padding (E), psi
Z: nonprecrushed door stiffness, kip/in

Using the axial loading relationship in the strength of material, one has:

$$\delta = \frac{PL}{AE}$$

where:
δ: axial deflection of a material
P: applied axial load
L: length (or depth) of a material
A: constant cross-sectional area
E: modulus of elasticity

Rearranging Equation (1), it becomes:

$$K = \frac{A}{L} E$$

where K: material stiffness $= \frac{P}{\delta}$

Equation (2) computes the equivalent stiffness of a padding provided that the padding thickness, the contact area between the side of the occupant and the pad, and the modulus of elasticity of the padding are given. It is assumed in the side impact model that the height of the padding on the interior of the door is 6in and the padding is wide enough that the impact load of the occupant on the pad is evenly distributed. The contact area is then computed as follows:

A = effective chest depth $\times$ padding height
= (.5 $\times$ chest depth) $\times$ (6) in^2

Note that due to the protrusion of the upper arm and shoulder, the effective chest depth that is in contact with the padding is assumed to be 50 percent of the chest depth

National Accident Sampling System

The National Accident Sampling System (NASS) is a continuous nationwide accident data collection program sponsored by the U.S. Department of Transportation. It is operated by the National Center for Statistics and Analysis (NCSA) of the National Highway Traffic Safety Administration (NHTSA).

NASS was developed to provide an automated, comprehensive national accident data base for use by regulatory agencies and accident researchers. The accidents investigated in NASS are a probability sample of all police-reported accidents in the United States. A NASS accident must fulfill the following requirements: must be police-reported, must involve a harmful event (property damage and/or personal injury) resulting from an accident, and must involve a motor vehicle in transport on a trafficway. Every accident that meets these conditions has a chance of being selected. This type of sample design makes it possible to compute not only national estimates but also probable errors associated with these estimates.

Sample Selection

The selection of sample accidents for NASS is accomplished in three stages: selection of primary sampling units (PSU's), selection of police jurisdictions, and selection of accidents. The three stages of sample selection are briefly discussed below. Greater detail can be obtained from the technical report on NASS sample design(2).

The first stage is selection of geographic areas called PSU's. Each PSU is composed of a large city, a county, or

a group of continuous counties. The Nation was divided into 1,279 PSU's. The PSU's were then grouped into 75 strata, and one PSU was then selected from each strata. It is not practical to investigate every accident in each sample PSU, so a second stage of sampling is performed on a list of police jurisdictions within each PSU. The final stage of sampling is the selection of accidents from all accidents recorded in the sample police jurisdiction. A probability of selection is assigned to each accident category so that high severity and rare vehicle type accidents are oversampled.

PSU and National Inflation Factor

The sample accidents from a PSU have a unique selection probability associated with them as a result of selecting a particular jurisdiction and accident. The reverse of this probability is called the PSU inflation factor. If sample accidents in a given PSU are multiplied by this factor, an unbiased estimate of the number of NASS accidents in the PSU is obtained. The inverse of the probability of selecting PSU (Stage I of sampling procedure) multiplied by the PSU inflation factor provides the National Inflation Factor. Using the National Inflation Factor, an unbiased estimate of the national frequency of the specific type of accident is obtained.

Appendix F

Outline of Sampling Procedure

Matrix of Random Numbers

A matrix of random numbers can be constructed from a bivariate frequency distribution (Table F-1). The

matrix then can be conveniently used to locate the pairs of subgroups of two variables by selection of numbers. A method of constructing such a matrix is outlined below:

Let (R+1)*(C+1) be the matrix of bivariate frequency counts, where R represents the numbers of subgroups of one variable and C represents the other correlated variable. The (R+1)th row and (C+1)th column represent the marginal totals. The frequency counts of (R+1)*(C+1) can be expressed as row percents or column percents of their respective marginal totals. Similarly, the marginal totals can be expressed as percents of the grand total. Such a matrix is produced by the SAS Frequency Procedure. A matrix of random numbers then can be constructed by assigning each cell within each row a number from 1 to 100 based on row percents as weight (Table F-2). Similarly, a matrix from column percents can be constructed (Table F-3). An example of a matrix of random numbers is given below.

Sampling Method

A sample selection of pairs of two correlated variables can be made from the matrix of random numbers by following the three-step procedure described below:

(a) Select one of the two variables at random (variable 1) (e.g., driver's age). Then, select its subgroup by choosing a random number from 1 through 100 (e.g., 75) and locating it from the matrix of random numbers associated with the frequency distribution of its marginal totals (e.g., Table F-2).

(b) Select a subgroup of the second variable (variable 2) by choosing a random number (e.g., 49) and locating it from the matrix of random numbers associated with the frequency distribution (Table F-2) of the selected subgroup of variable 2.

(c) Select a subgroup of variable 1 by choosing a random number (e.g., 98) and locating it from the matrix of random numbers associated with the frequency distribution (Table F-3) of selected subgroup of variable 2.

The subgroups selected in (b) and (c) form a random pair of two variables. From the example given, the weight category would be 160 to 179 lb and the age category would be 55 to 70yr.

It should be noted that the selection of subgroup of variable in (a) is made independent of variable 2. Steps (b) and (c) make their selection dependent on each other.

Table F-2. A sample matrix of random numbers within each row

Example:

Matrix of Random Numbers
Driver's Weight (lb)
Sex: Male

Driver's Age	90-119	120-139	140-159	160-179	180-199	200-215	Total
15-24	1-2	3-11	12-40	41-80	81-92	93-100	1-42

Results of the Motor Vehicle Manufacturers Association Component and Full-Vehicle Side Impact Test Procedure Evaluation Program

Ronald J. Wasko
Motor Vehicle Manufacturers Association of the United States

Richard A. Wilson
General Motors Corporation (Chairman, MVMA Engineering Research Subcommittee)

Abstract

This paper presents an extensive research program undertaken to develop improved side impact test methods. The development of a component side impact test device along with an associated test procedure are reviewed. The results of accident data analysis techniques to define anatomical areas most likely to be injured during side impact and definition of test device response corridors based on human surrogate testing conducted by the Association Peugeot/Renault and the University of Heidelberg are discussed. The relationship of response corridors and accident data analyses in earlier phases of the project resulted in definition and development of a component side impact test device to represent the human thorax.

A test program to evaluate and compare component and full-vehicle test results is presented.

History

In 1982, the MVMA undertook a comprehensive, long-term research program to evaluate both full-vehicle and component side impact test procedures. This program was initially structured with seven tasks as shown in Figure 1.

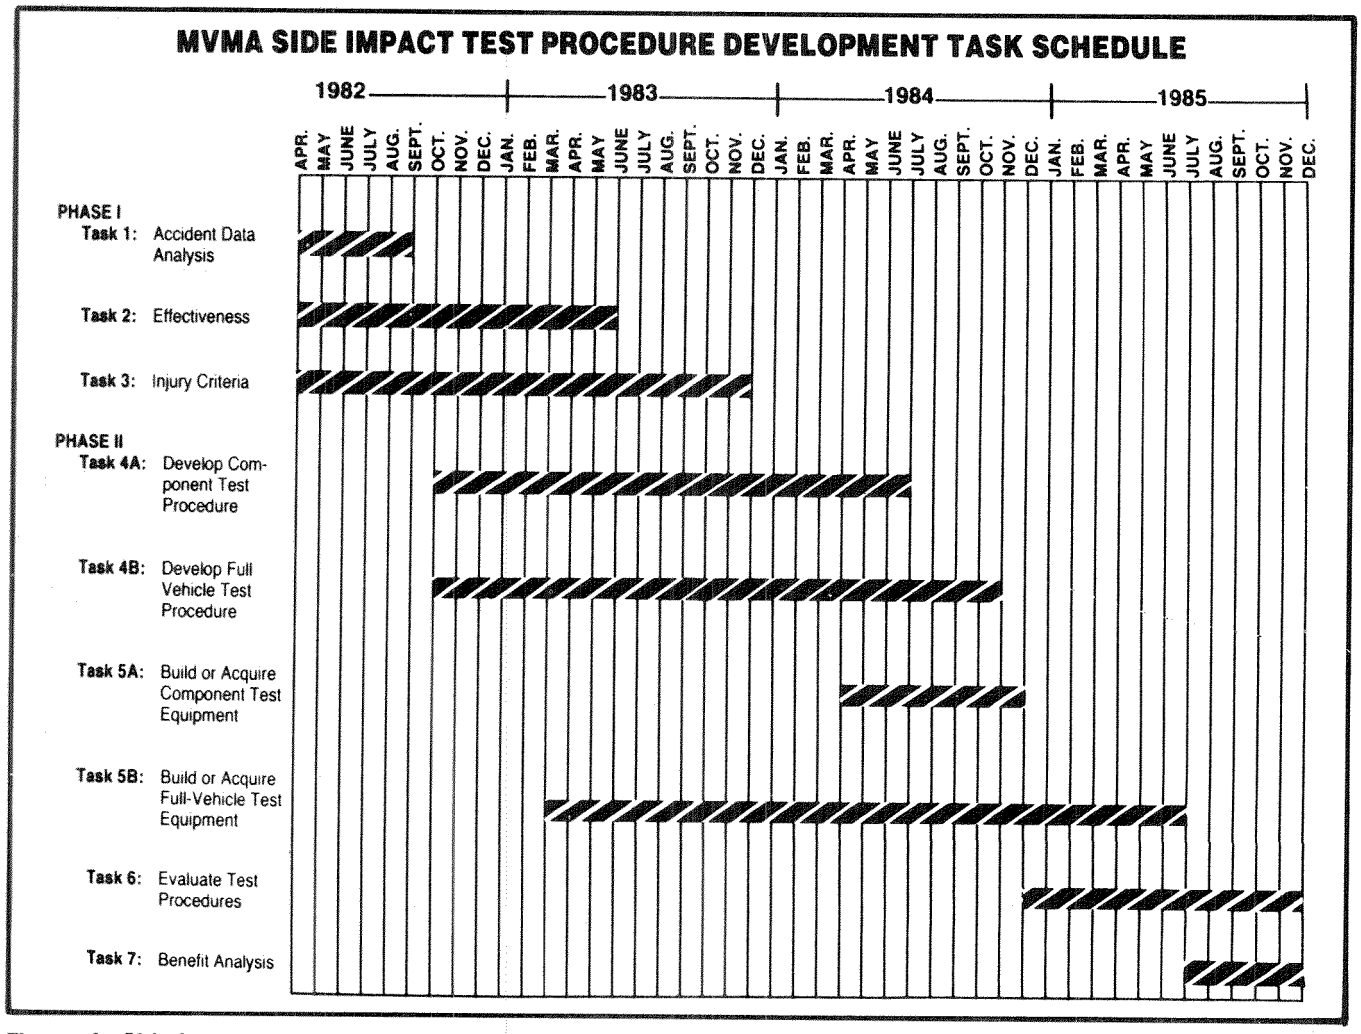

Figure 1. Side impact project task schedule

Side Impact Accident Data Analysis—Task 1

The primary objective of Task 1 was to analyze existing accident data to investigate the following aspects of injuries to occupants of side damaged passenger cars(1):

- Define and rank the predominant side impact injury categories, i.e., the body areas injured and the relation of these injuries to components of the vehicle that were contacted
- Quantify the relationship of injury to the mode and severity of the collision
- Determine the role of structural integrity with regard to occupant injury

Two accident data bases were used concurrently to develop the results of the task. The National Crash Severity Study (NCSS) was a major accident data collection program of the National Center for Statistics and Analysis of the U.S. Department of Transportation, National Highway Traffic Safety Administration (NHTSA). The NCSS file is a representative sample of passenger car towaway accidents, and it contains information on over 3,000 side impact accidents. The second is the Motors Insurance Company (MIC) Injury-Accident File, an accident data base maintained by General Motors Corporation. The MIC file contains information on accidents involving GM vehicles that were current models in the year the data were collected and in which there was an injury to at least one case-vehicle occupant. The MIC file has information on more than 5,000 side impact passenger car accidents. Whenever possible, the results from comparable analyses of both the NCSS and the MIC accident data files were presented, and the concurrence between the conclusions drawn from these separate accident data sources is discussed.

The serious-to-fatal injuries (AIS[1] 3 or greater) to nonejected occupants of side-damaged passenger cars in nonrollover accidents were grouped by body region injured and component of the vehicle contacted, each such pairing being considered as an injury category. Using both the NCSS and the MIC data files, the 10 leading injury categories were ranked for all side impact AIS 3+ injuries, and the results are presented in Figure 2. The rank orderings of the injury categories using both data files are in general agreement, but the percent of AIS 3 injuries in many of the injury categories varies considerably between the two data bases. The differences between the results from these files have two sources:

- The accident populations sampled by each file are different—NCSS represents towaway accidents to vehicles of all ages and makes on the road in the 1977 to 1979 period of data collection, while the accidents in the MIC file involve GM cars that were current models in the year the data were collected and in which there was an injury to at least one case-vehicle occupant.
- The methods used to determine and define body region injured and object contacted differ between the two files—for example, NCSS uses a restrictive procedure to obtain injury information, which may bias its large category of unknown contact data, while MIC data were completed with an expert's "best estimate" when the contact code was unknown.

A Ranking of Injury Categories for All Non-Ejected Occupants Of Side Damaged Passenger Cars in Non-Rollover Accidents

– Serious-to-Fatal Injuries –

	Accident Data File			
	NCSS		MIC	
Injury Category	Rank	Percent (%)	Rank	Percent (%)
Upper Torso/Side Surface	1	30.9	1	23.0
Abdomen/Side Surface	2	12.5	3	5.7

Total Injury Count				
Sampled		826		823
Weighted		923		923

Figure 2. Ranking of side impact injury causes

The effects of several variables commonly used to characterize the mode and severity of side impact collisions on the ranking of the side impact injury categories were investigated using only the NCSS accident data file. The results indicate the injury category rankings differ by accident type (single-vehicle impacts versus all other side impacts) and struck vehicle Delta V (Delta V $\geq$ 20mph versus Delta V $\leq$ 20mph). The four distinct injury category rankings defined by the combinations of these two side impact categorization variables are presented in Figure 3.

The order of the injury categories changes only slightly across the four injury category rankings presented in Figure 3, but the percent of serious-to-fatal (AIS 3+) injuries to nonejected occupants of side-damaged passenger cars in nonrollover accidents contained within each injury category is distinctly different for each of the four injury category rankings. Because of their close correspondence in injury category ranking, AIS 3+ injuries in side impacts with unknown Delta V were

[1] Abbreviated Injury Scale—1980 Revision, American Association for Automotive Medicine.

Injury Category Rankings for Selected Groups of Non-Ejected Occupants of Side Damaged Passenger Cars in Non-Rollover Accidents

– Serious-to-Fatal Injuries –

Group A: Vehicle-to-Vehicle Side Impacts
Side Struck Vehicle Delta V $\leq$ 20 mph*
(Based on 456 NCSS AIS 3+ Injuries)

Rank	Injury Category	NCSS Percent
1	Upper Torso - Side Surface	40.8
2	Abdomen - Side Surface	12.5
3	Upper Torso - Steering Column	7.5
4	Pelvis - Side Surface	6.1
5	Upper Torso - Instrument Panel	5.5
-	Other	27.6

Group B: Vehicle-to-Vehicle Side Impacts
Side Struck Vehicle Delta V $>$ 20 mph
(Based on 203 NCSS AIS 3+ Injuries)

Rank	Injury Category	NCSS Percent
1	Upper Torso - Side Surface	20.7
2	Abdomen - Side Surface	14.8
3	Upper Torso - Steering Column	8.9
4	Upper Torso - Instrument Panel	7.4
5	Head - Upper Side Surfaces	6.4
-	Other	41.8

Group C: Single Vehicle Side Impacts
Vehicle Delta V $<$ 20 mph*
(Based on 76 NCSS AIS 3+ Injuries)

Rank	Injury Category	NCSS Percent
1	Upper Torso - Side Surface	22.4
2	Abdomen - Side Surface	13.2
3	Upper Torso - Steering Column	11.8
4	Head - Upper Side Structures	7.9
-	Other	44.7

Group D: Single Vehicle Side Impacts
Vehicle Delta V $\geq$ 20 mph
(Based on 81 NCSS AIS 3+ Injuries)

Rank	Injury Category	NCSS Percent
1	Upper Torso - Side Surface	12.3
2	Upper Torso - Steering Column	12.3
3	Upper Torso - Instrument Panel	12.3
4	Head - Upper Side Structure	7.4
5	Abdomen - Side Surface	7.4
-	Other	48.3

* NOTE: The AIS 3+ injuries which occurred in NCSS side impacts grouped with unknown Delta V were grouped with those from NCSS side impacts with Delta V $\leq$ 20 mph.

Figure 3. Injury category rankings for side impacts

grouped with the Delta V $\leq$ 20mph serious-to-fatal injuries.

The number of injury categories ranked for each side impact subset was limited to those with more than 5 percent of their respective totals so the rankings presented for each category of side impact would be based on enough serious/fatal injuries to be reasonably reliable. As seen in Figures 2 and 3, the injury categories with less than 5 percent of their respective totals cumulate to a substantial percent of the total NCSS serious/fatal injuries. However, due to the small number of cases within each injury category, a meaningful ranking of these categories with less than 5 percent of the NCSS side impact injuries could not be constructed.

The major injury mechanisms associated with each of the five most frequent injury categories were investigated using both the MIC and the NCSS data files, and the results of this investigation are presented in Figure 4.

The data analysis of Task 1 concludes that the upper torso to side surface is the predominant injury category. The major injury mechanisms result in fractured bones and internal organ damage. A comprehensive analysis of

the data is provided in the referenced report developed by Task 1.

Injury Mechanisms for Predominant Side Impact Injury Categories

– Serious-to-Fatal Injuries –

Upper Torso - Side Surface	% NCSS	% MIC
Fractured Bones	50	62
Lung Damage	35	18
Other	15	20
Abdomen - Side Surface	**% NCSS**	**% MIC**
Kidney Damage (contusion)	25	27
Spleen Damage (rupture)	22	29
Liver Damage (laceration)	17	16
Other	36	28
Upper Torso - Instrument Panel/Glovebox	**% NCSS**	**% MIC**
Fractured Bones	53	58
Lung Damage	35	27
Other	13	15
Upper Torso - Steering Assembly	**% NCSS**	**% MIC**
Fractured Bones	53	75
Lung Damage	31	16
Other	16	9
Head - Upper Side Structure	**% NCSS**	**% MIC**
Brain Concussion	36	49
Brain Contusion	24	9
Skull Fracture	22	26
Other	18	16

Figure 4. Injury mechanisms for side impacts

Side Impact Test Effectiveness—Task 2

After accident data were analyzed in Task 1, a second task on Test Effectiveness(2) was undertaken utilizing the output of Task 1. Factors to evaluate side impact candidate tests were developed and ranked according to relative importance. The purpose of this task was to identify specific tests that would be able to discriminate among vehicle designs that should have a significant effect on side impact injuries.

In an Advanced Notice of Proposed Rulemaking on side impact protection, NHTSA had proposed a moving barrier side impact test procedure using crash test dummies. Comments by several U.S. manufacturers urged NHTSA to take a broader approach and consider component test procedures as well, which may be simpler and a more practicable alternative than the procedure proposed in the Notice. Both component tests and the full-vehicle test using crash dummies may have unique advantages when compared with one another.

During the deliberations of Task 2, two important philosophical issues were discussed extensively. The first dealt with the Task Group's perceptions of the fundamental advantages and disadvantages of full-vehicle crash testing as compared with component testing. As a consequence of this comparison, a list of evaluation factors for different tests (both full-vehicle and component) were developed and prioritized, and the advantages and disadvantages of the tests were discussed in detail.

The second issue involved the basic approach taken toward accomplishing safety improvements to vehicles. Task 2 recognized two fundamental approaches to safety advancement. The incremental approach takes into account the spectrum of existing performance within a given safety area as observed among the various vehicle designs in current production. This range of performance can be observed by testing the various vehicles. Then, an appropriate minimum performance level can be established, relative to the group performance, to eliminate outliers. In contrast, the idealized approach uses reference values derived from field accident data and human tolerance data to set an absolute goal for minimum performance in a given safety area. This second approach may or may not affect only the outliers. It could require large changes to be made to a significant portion of the whole group, all in a single step. Historically, the incremental approach has tended to involve mainly component testing procedures, while the idealized approach has been associated mainly with full-vehicle testing. These associations, however, are not necessarily tied to any particular type of test.

A key question to be answered when choosing between the two approaches is: which approach will provide the motoring public the larger overall benefit? This, of course, will be greatly dependent on performance criteria that have yet to be established. Importantly, this evaluation must take into account both the degree of improvement and the absence of delay in getting the improvements actually on the road. Thus, simplicity of a safety test procedure can be an important factor in the election of the approach taken to move ahead in vehicle safety advancement.

The deliberations included a review of past and current side impact research. For the full-vehicle tests, the NHTSA and Committee of Common Market Automobile Constructors (CCMC) Mobile Deformable Barrier procedures were reviewed. The review of the test procedures also included a comprehensive review of the anthropomorphic test devices. Component testing included an analysis of the following devices and methods:

- Ford's Side Impact Body Block (SIBB)
- NHTSA's head and thorax impactors
- GM's head area impactor
- GM's thorax area impactor
- External crush
- Hinge and lock component tests

Advantages and disadvantages of both the component and full-vehicle tests were developed, as well as areas

requiring further scientific research to support side impact test procedure development.

Items addressed by Task 2 include—

- Definition of test conditions
- Sufficient correlation to field data cover adequate spectrum of accident conditions
- Evaluate an appropriate area of the interior
- Allow an assessment of potential ejection paths
- Allow evaluation of components under impact conditions
- Exhibit injury category in question
- Validity of test output
- Employ a valid injury criteria
- Exhibit a relationship to field injury characteristics
- Discriminate levels of performance
- Detection of synergistic effects
- Allow interaction between interior energy absorption and structure
- Allow interaction between various structural components
- Allow interaction between striking object and struck vehicle
- Allow interaction among occupant body segments
- Acceptable degree of complexity
- Acceptable degree of reproducibility and repeatability
- Permit simultaneous evaluation of multiple elements in the chosen accident condition
- Evaluate a variety of loading conditions

The Task 2 need to develop side impact tests included a variety of applications such as establishing compliance with possible future rulemaking, establishing crashworthiness ratings, and improving product safety through voluntary industry efforts.

Rankings of the relative importance evaluation factors resulted in the conclusion that for any given thorax to side interior surface test procedure, three parameters are important:

- A high level of repeatability and reproducibility plus low level of test complexity
- Ability to discriminate levels of safety performance in different vehicle designs
- Ability to accurately represent the injury category and injury severity occurring in the real world under a variety of conditions that reflect real-world occurrences

The conclusion reached as a result of Task 2 was that a full-vehicle test may represent a single field accident condition because real-world crash conditions and synergism may be more accurately duplicated in a full-vehicle test than in a component test. However, the full-vehicle test involves considerable equipment, facilities, and manpower to conduct; therefore, it is extremely complicated. For an equivalent level of effort, a number of component tests can be conducted under a variety of test conditions to simulate a variety of accident conditions.

MVMA did not choose one test type (i.e., full-vehicle versus component) over the other, since both have merit.

Task 2 identified important areas for near-term research, to support both full-vehicle and component test procedure development. These areas are—

A. Full-vehicle tests:
   1. Determining the validity of extrapolating results from one test condition to other conditions
   2. Establishing repeatability and reproducibility of test results
   3. Developing dummy improvements

B. Component tests:
   1. Establishing correlation between test results and field data
   2. Determining the effects of parameters such as side stiffness and occupant seating position on test conditions
   3. Determining importance of synergistic effects between interior energy-absorbing panels and structure, or among various structural components

Component Side Impact Test Device—Task 4 and Task 5

As shown by the conclusions of Task 1, accident data analysis, the thorax to side surface was the predominant injury source. Therefore, in the development of a component test device, it was deemed essential that the thorax be the initial part of the anatomy to be evaluated by any component test device. It is anticipated that after a thorax-type test device has been developed, other parts of the body would then be investigated for side impact injury mitigations. As noted earlier, desirable characteristics for a component test device should include a high level of repeatability and reproducibility. Also, a low level of test complexity is desirable. It was also a condition of the program that any component test device have the ability to discriminate levels of safety performance for various vehicle safety designs. Also, a variety of conditions that reflect real-world occurrences should be represented in terms of the injury category and injury severity by a component test.

With knowledge of these constraints and the fact that correlation between component test results and actual field data need to be developed, the development of a component test device was undertaken.

MVMA contracted the development of a component side impact test device with MGA Research Corporation of Akron, New York, U.S.A. The project was to address the validity of developing a component side impact test procedure by designing, fabricating, testing, and delivering

a side impact component test device that would be used to simulate a human thorax impact to interior side components of a motor vehicle.

The objective of the contract with MGA was to achieve a test device capable of evaluating the energy absorption of vehicle interior side components. Initial thoughts in defining the physical profile of the impactor for the component test device was to have it physically duplicate a human thorax. Since the test device was to represent a human thorax, a decision was made to use the curvature dimensions based on an approximation of the horizontal curvature of a semicompressed human thorax. For simplicity, the vertical section of the test device was chosen, after much deliberation, to be the same curvature as the horizontal section. The component test device impact face physical parameters chosen by MVMA are—

- Diameter 190mm
- Radius of curvature 305mm

These were chosen because (1) the dimensions are representative of areas on the human thorax that are loaded in side impacts, and (2) being circular helps eliminate test device positioning error in the vehicle, permitting a variety of test conditions without increasing test complexities. By specifying a rounded face to represent the thorax, some biofidelity was sacrificed, but this loss was more than offset by reductions in test interference from armrests, door handles, etc. Also, test complexity is reduced because orientation of the test device is not as critical as in the case of a more faithful representation of the thorax.

MVMA also deemed it important that the impactor be a two-mass, constrained device. The impact face represents the ribs and outer surfaces of the human thorax, whereas the main mass represents the inertia of the spinal column and major organs. The two masses are separated by a spring and damper system to represent the biomechanic coupling within the human thorax. Figure 5 shows the two-mass impactor as finally developed by the contractor. Again, to enhance the usability and decrease the complexity of the device plus simplify the test procedure, a decision was made to constrain the movement of the two-mass impactor to a uniaxial relative motion along the impact direction.

For realistic test speeds of the device, MVMA specified that the component impactor be capable of being accelerated to an impact speed of 40km/h (24mph). Based on the accident data analysis of Task 1 and cadaver tests, this velocity is representative of impact velocities that will cause serious to fatal injuries to humans from side impacts.

Provisions were also required to prevent relative displacement errors between the two masses while the unit is accelerated to test velocity. This was accomplished by means of a mechanical locking system that holds the two masses in relative position when accelerating. At an acceleration of 30g's, a maximum relative displacement of not more than 1mm in any direction is achievable.

One of the purposes in developing a component test device is to permit a number of tests to be conducted at various velocities, impact angles, and occupant positions. Therefore, the propulsion and guidance system were specified by MVMA to be capable of delivering the impactor to an impact location within 5mm of the desired center of the test location at speeds up to 22km/h (14mph).

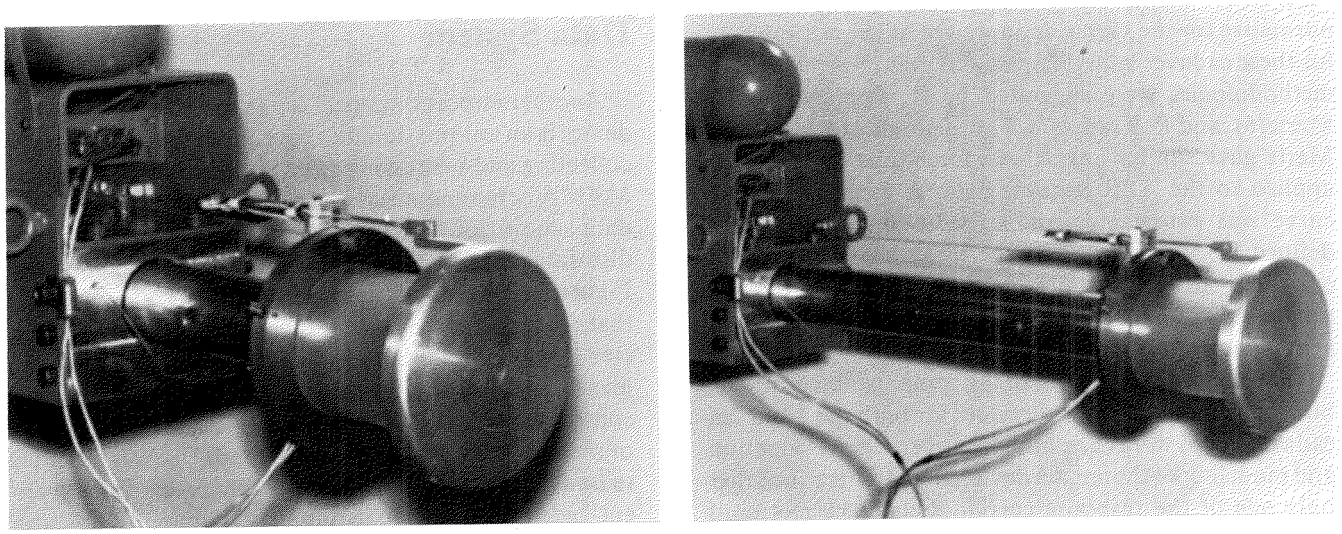

Figure 5. Two mass impactor

A prefiring interlock to prevent inadvertent actuation of the test device was deemed necessary and is incorporated in the device. Over-travel control, in case there is no test specimen in front of the test device when it is actuated, is a necessity, as well as rebound control, to absorb the energy from the test device after striking a test subject. It was also deemed appropriate that a working depth for at least 300mm of target crush would be required to provide information relatable to real-world accidents.

The mechanical design includes the ability to adapt the test device to other propulsion means to permit universal use of the device. The design of the alignment system provides capabilities for the device to withstand off-center and off-angle loads.

The following measurements can be made in each component test:

- Displacement between the outer (simulated rib) mass and main (spine and internal organs) body mass
- Force on the outer mass produced from impact with the tested structure
- Velocity of the impactor prior to impact and rebound velocity (provide energy dissipated in the test)
- Velocity of the impactor at impact

Based on the parameters that are available to measure, it should be possible to evaluate injury criteria related to the human thorax. Changes in energy dissipation from various structural modifications can be obtained easily with the component test device.

The most difficult part of the test device to define and develop was the human biomechanical response corridor. To obtain a realistic representative response corridor, the worldwide cadaver data bases for side impact were reviewed and analyzed. Two main sources of side impact cadaver tests were available—the Association Peugeot/Renault(3) and the University of Heidelberg(4) data. Considerable analysis was expended by the U.S. motor vehicle biomechanics community to develop a method to normalize for the variation in weight of the test subjects for these cadaver lateral impact test data. Normalization methodologies were suggested by R. Eppinger(5), H. Mertz(6), and P. Krause(7). The methods of Krause and Mertz gave similar normalized force-time curves when applied to the APR cadaver data. A mean force-time curve was constructed and corridor boundaries were defined as ±15 percent of the mean curve. Response corridors for both the 1 and 2m cadaver drop data as shown in Figure 6 were taken from Krause's paper(7) and are similar to those proposed by Mertz(6).

During the development of the component test device. biomechanical response corridors for both the 1 and 2m cadaver drops were to be met. However, upon evaluation and modeling of the impact device, it was determined that only one of the response corridors could be met until further comprehensive modeling and testing were undertaken. The nonlinearity of the response corridor and coupling effects of the two simulated masses for both corridors were beyond the scope of the initial effort. A decision was made by MVMA to initially have the test device meet the 2m lateral drop response corridor because it provided a more severe response and better relates to serious injuries in vehicle accidents.

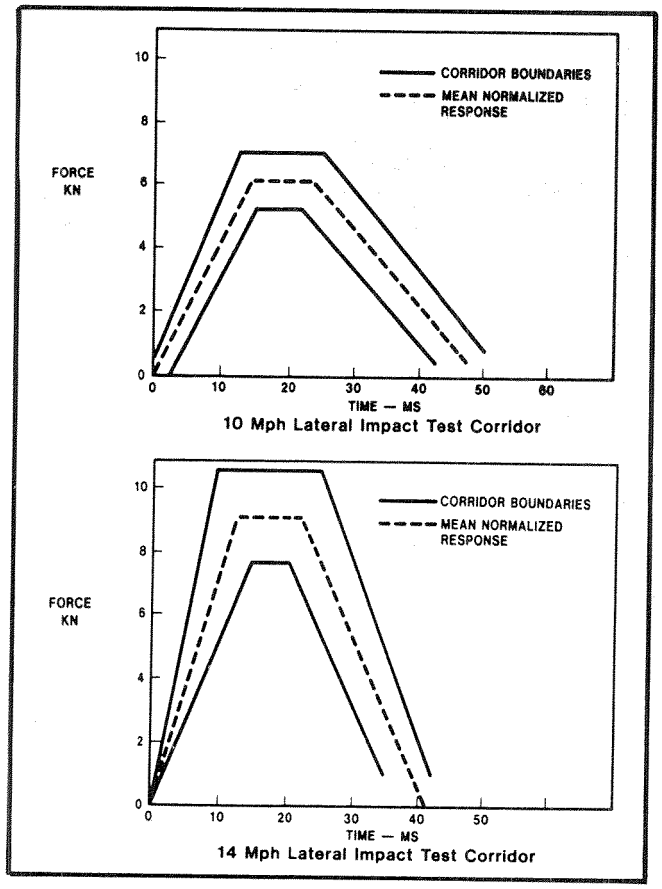

Figure 6. Normalized response corridors

Data System

Another important aspect for a usable component test device is an automatic data acquisition system capable of collecting and processing dynamic impact test data. The MVMA component test device includes a "stand-alone" data acquisition system consisting of a digital computer, disc data storage, digital plotter, and printer as shown in Figure 7. The data acquisition system has many features that make the component test device unique. All parameter changes and inputs such as test velocities and measurements of parameters can be done via computer control from the data acquisition system control console or manually. The actual firing of the device was specified to be a manual two-hand operation to preclude inadvertent activation due to equipment failure or operator inattention.

Figure 7. Component test system data acquisition

Operator selectable programmable gains and variable filter frequency responses from 60 to 1,000Hz are programmable from the computer keyboard. The frequency response can be stepped as per SAE J211, June 1980, Instrumentation of Side Impact Tests.

The computer calibrates data channels and initiates the collection of test data, then the measured test data are transferred from the data acquisition system to the digital computer. The collection portion of the data measurement sequence is performed with data acquisition software control and, after the data have been transferred into the computer, a second processing program processes and outputs the test data.

Control software was developed to provide an interactive sequence for test personnel to set up the data acquisition system and collect test data. The software program is menu-driven, and options such as determining and selecting gain, bandwidth, and the amplitude calibration of conversion of measured voltage data into physical units for each channel are provided. The data acquisition system is capable of digitizing 10,000 samples per second for each of the eight data channels provided in the test device. To insure a complete test sequence is captured on the digital data format, the system is capable of accessing and storing data for a test sequence time of at least 300ms per channel.

The processing and analysis software include menu-driven functions such as filtering, scaling, integration, addition, and subtraction. The control software allows various plotting routines such as cross-plotting and over-plotting of test results.

Data from a test can be printed immediately or plotted. As an alternative, several tests can be conducted and the data stored on computer disc. These stored data can then be over-plotted showing the results of several different tests on the plot. In this manner, changes to the test subject can be evaluated by referencing the original and subsequent test runs with various modifications made to the tested article to help in the engineering analysis.

The data system has the capability of storing at least 15 tests in archival (floppy disc) form. This storage feature permits a number of tests to be conducted, and the analysis can be done at a later date or more convenient time. Conversely, test sequence results can be compared even if a considerable real time period elapses between the tests.

Repeatability

Repeatability requirements were specified by MVMA to consist of five consecutive impact tests at 22km/h (14mph) into APR foam padding.[2] This test condition is comparable to the 2m cadaver drop onto APR foam padding. The coefficient of variation was specified to be less than 5 percent for each of these series of five consecutive tests. The test device met this requirement, and the repeatability results are shown in Figure 8. The prototype component test device also has the capability of discriminating between several energy-absorbing materials as shown by Figure 9.

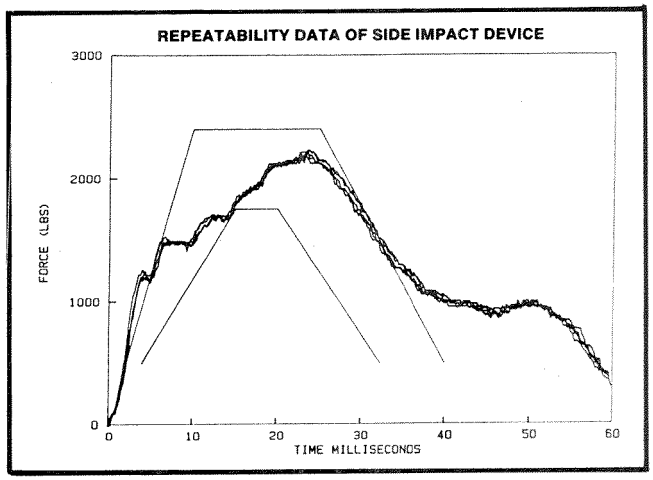

Figure 8. Force-time repeatability measures

Conclusions reached by Task 2 (Test Effectiveness) members recognized that a side impact test may be used for a variety of applications, but three major considerations are extremely important for any test device. These considerations are—

1. High level of repeatability and reproducibility plus a low level of test complexity
2. Ability to discriminate levels of safety performance in different vehicle designs
3. Accurate representation of the injury category and injury severity occurring in the real world under a variety of conditions that reflect real-world occurrences

[2]The padding was as close as could be obtained to that used for the lateral cadaver impacts in (3).

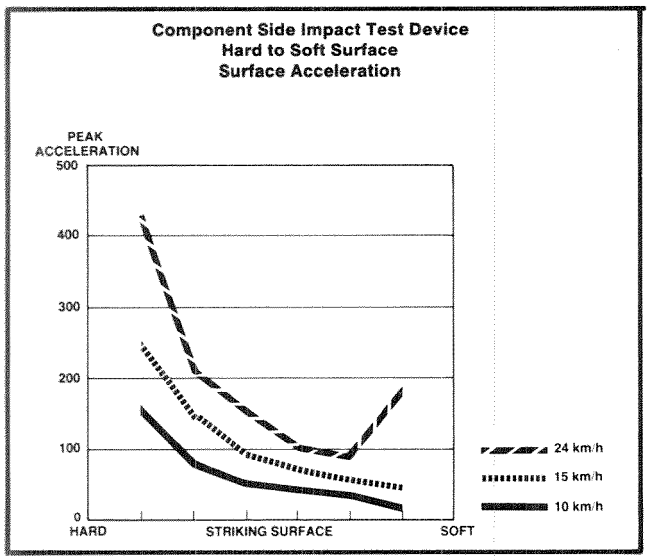

Figure 9. Discrimination characteristics of component test device

Using existing cadaver data as the reference, the component prototype test device developed under the MVMA side impact test procedure program has begun to meet the first two requirements. The third consideration will be addressed in future research.

Future Research

Enhancement to Component Test Device

To increase the biofidelity of the component test device, several enhancements will be made to the system to improve its functionality. These include—

- A specified deflection for both the 22km/h force-time corridor and the 16km/h force-time corridor
- Development of a monotonically increasing curve of peak force versus peak deflection from minimum speed to maximum test speed
- A provision to allow maximum relative deflection of 55mm between the main (spine and organs) and small (rib) mass to better represent cadaver data

A contract will be issued to incorporate these changes into the device, and these modifications are scheduled to be complete within the next few months.

Test Procedure Evaluation

MVMA is continuing the evaluation of test procedures for both the full-vehicle and component testing. Efforts to develop a full-vehicle side impact test have been underway in the United States and Europe for some time. NHTSA is in the process of developing a full-vehicle test procedure and has recently submitted a procedure to the public record.

MVMA plans to use a full-vehicle side impact procedure that is nearly identical to the procedure being considered by NHTSA. The MVMA procedure specifies a crabbed moving barrier to simulate a side intrusion obtained with a moving test vehicle. The impactor characteristics are identical to those proposed by NHTSA. The dimensions of the energy-absorbing impactor face are—

Width	1,676mm
Height	559mm
Depth	482mm
Ground Clearance	280mm
Surface Located	200mm High Bumper 330mm aboveground

The total mass of the impactor face, carriage, and ballast, as necessary, is 1,360kg ± 9kg to be consistent with the NHTSA-selected 1985 vehicle average mass of 1,224kg + 136kg to represent two occupants.

The MVMA full-vehicle test will simulate a 90° side impact with simulated speeds of 24km/h for the struck vehicle and 48km/h for the striking vehicle. Figure 10 represents the test conditions for the simulation in which the struck vehicle remains stationary and the crabbed moving barrier travels at 54km/h.

The NHTSA Side Impact Dummy (SID) will be used as the human surrogate in the full-vehicle test. The NHTSA SID was selected as the dummy to be used since it has been specified by NHTSA in their proposed full-vehicle side impact test procedure. (Selection of the NHTSA SID should not be construed as endorsement of this test device by MVMA.)

The parameters to be measured in the MVMA full-vehicle test are—

Required Measurements	Direction	Range
Accelerations		
Test Vehicle Sill	3 Axis	50G
Lower Thoracic Spine, Vertebra 1	3 Axis	200G
Lower Thoracic Spine, Vertebra 12	3 Axis	200G
Upper Rib (Near Side)	Y Axis	200G
Lower Rib (Near Side)	Y Axis	200G
Pelvis Sacrum	3 Axis	130G
Dummy Clearance to Side Interior	mm	
Velocity of Impactor	km/h	
Lateral Deflection of Impacted Ribs Relative to Spine	Y Axis	75mm

Optional Measurements	Direction	Range
Accelerations		
Sternum Acceleration	X & Y Axis	150G
Head Acceleration	X, Y & Z Axis	100G
Belt Load	Tension	10kn
Intrusion of the Interior Side Panel	mm	250mm

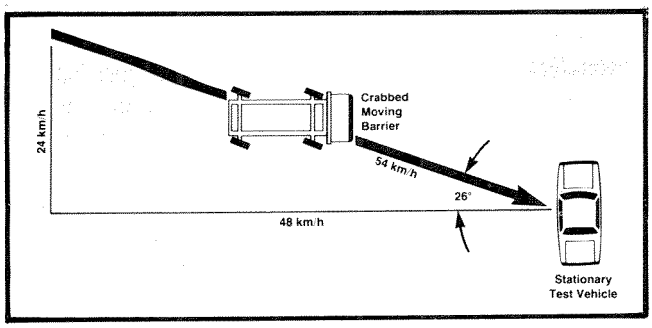

Figure 10. Full-vehicle test procedure representation

Full-Vehicle/Component Tests

Over the next several months, MVMA will undertake a comprehensive side impact test project for comparing full-vehicle and component tests. The objective of the full-vehicle portion of the project is to—

- Determine the repeatability of the full-vehicle test procedure
- Investigate the ability of the full-vehicle test to discriminate between changes in vehicle occupant protection
- Evaluate the effects of dummy position, energy-absorbing padding, and changes to vehicle structure

The objective of the component test portion of the project will be to investigate the ability of the component test procedure to evaluate changes in the vehicle and to determine if these changes are reflected by the component test in a similar manner as in a full-vehicle test.

The full-vehicle portion of the project will consist of side impact tests of 16 full-size 1985 model year vehicles under a variety of conditions including spacing of the dummy from the door, changes in the energy-absorbing characteristics of the interior of the door, and changes in the structural stiffness of the door. Two tests with each variable are scheduled.

A matrix of the tests and conditions to be investigated is shown in Figure 11.

	Baseline Door		Padded Door	
Dummy Spacing	Near	Far	Near	Far
Baseline Structure	2	2	2	2
Stiffened Side Structure	2	2	2	2

Figure 11. Full-vehicle test matrix

The test procedure to be used is the MVMA full-vehicle test. Test conditions, dummy placement, and vehicle speeds will be those specified in the MVMA procedure. The data from the tests will be placed in the NHTSA public docket for general public review.

For the component portion of the tests, the MVMA-developed component side impact test device will be used to conduct tests on doors that are identical to the doors used in the full-vehicle test portion of the project, that is, doors that are—

- Standard production
- Modified with energy-absorbing material
- Modified through increased structural stiffness

The test velocities for the component test will be determined from measurements and observations made during the full-vehicle test portion of the program. The velocity the SID dummy striking the door inner panel shall be determined and utilized as the velocity the component impactor. By using a striking velocity identical to the SID dummy, the component test can be compared to the full-vehicle test. The component test procedure specifies precrushing the door utilizing an MVMA specified ram to represent the front of the striking vehicle. The door to be tested will be precrushed and held in the crushed condition by the ram for the component test.

Three component tests are scheduled for each test condition. A matrix of the proposed component tests is shown in Figure 12.

	Speed* (MPH)	Body Buck
Baseline Door	TBD	3
	TBD	3
Padded Door	TBD	3
	TBD	3

*Test speeds to be determined based on full vehicle tests.

Figure 12. Component test matrix

After the component and full-vehicle tests are complete, an analysis is scheduled to be undertaken to compare the repeatability and reproducibility of the two types of tests.

The component test results will be compared with the full-vehicle test results for each of the conditions tested, and a comprehensive analysis shall be undertaken to determine the relationship of the two tests.

The component and full-vehicle tests are currently scheduled to be complete in the late fall of 1985. The statistical analysis of the two procedures should be complete and reported in the summer of 1986.

The complete prototype side impact test system is shown in Figure 13.

Acknowledgments

The authors would like to thank all the people who provided the time and expertise to make this project successful. Without their continuing support, it would not have been possible to perform this comprehensive analysis and development.

Task Group 1 and 2 members have been identified in the final reports issued by them and referenced herewith.

The following people have contributed to the development of the program:

F. Peters AMC
T. Hayek AMC

A Comparison of European and American Test Devices and Test Parameters for Lateral Impacts

G. Klaus,
R. Sinnhuber, and
G. Hoffmann
Volkswagenwerk AG, Wolfsburg, West Germany

Abstract

European and American side impact research efforts are directed toward the realization of further increases in existing levels of passive safety. Because side impact accident experience here and abroad exhibits many similarities, governments of the European community and the United States should cooperate and agree on a common test procedure including common test devices and test parameters.

Within this context, Volkswagen studied the deformable side impact barriers presently under discussion in the United States and Europe. The results of this comparative study are presented. In addition to this comparison, the comparative evaluations of dummies and human subjects by the German Research Association for Automobile Technology (Forschungsvereinigung Automobiltechnik—(FAT) as well as the Thoracic Trauma Index (TTI) developed by NHTSA are discussed.

With these investigations, Volkswagen demonstrates that the European CCMC deformable element mounted on the chassis of the NHTSA crabbed barrier constitutes a valuable basis for further research efforts with respect to a common European and American test device for 90° lateral impact testing that cannot be ignored.

The comparison of loads and kinematics of human subjects and dummies examined demonstrates that the biofidelity of dummies must be improved to be suitable as a test device for lateral impact testing. Because of the present lack of a suitable side impact dummy and absence of correlation between dummy loadings and occupant injury, research activities must continue so as to be able to assess the effectiveness of vehicle measures in real-world impacts.

Introduction

This paper presents and discusses results of Volkswagenwerk's extensive research effort in the field of lateral impacts to increase further the existing levels of occupant protection. It demonstrates the feasibility of developing a universally acceptable common moving deformable barrier for lateral collision testing in Europe and the United States. It discusses the suitability of side impact dummies as test devices and, in this connection, the correlation of dummy loads and occupant injuries to establish occupant protection criteria for the matching of dummy results with real-world accidents.

The behavior of human subjects and HSRI, APROD, and Hybrid II dummies is compared in 90° lateral impacts at a 50km/h impact velocity. The test subjects are seated in an Opel Kadett car body struck by the European CCMC barrier.

Volkswagen investigated and compared 90° lateral impacts with the struck Rabbit vehicles and five different striking vehicles to determine which of the most commonly discussed European and American barriers could be selected within the context of the recognized need for harmonization of future side impact performance requirements for the United States and Europe.

The striking vehicles used were the average European passenger car (VW Passat), the average American car (Chevrolet Citation), the European CCMC and EEVC barriers, and the American NHTSA barrier.

Objectives

The objectives of the Volkswagen research effort presented are to develop a meaningful scientific statement regarding the suitability of commonly discussed European and American Moving Deformable Barriers (MDB) and Side Impact Dummies (SID) for experimental simulation of 90° vehicle-to-vehicle side impacts through comparison of kinematics and loads of colliding vehicles and dummies examined. The results of this study are intended to contribute to the development of test devices and a test procedure that should be used all over the world within the context of performance standard harmonization and simulation of real-world accidents.

Test Procedure for Lateral Impact Testing

Within the scope of its investigation into suitable test procedures and test devices for simulation of lateral collisions, Volkswagen took European and American accident experience into account to establish a test configuration and meaningful test parameters.

The important parameters in this context such as—

- Impact angle
- Impact force direction
- Point of impact
- Impact velocity

- Barrier mass
- Stiffness of the deformable element
- Impactor geometry
- Ground clearance

are described in detail in a previously published SAE paper(1). In the present paper, the parameters that represent the basis for the simulation of actual side impacts are restated.

Crabbed Test Configuration

Analysis of European(2) and American(3) accident statistics demonstrates a necessity to distinguish between impact angle and the impact force direction (Figure 1).

This analysis demonstrates that the struck vehicle generally also has a forward velocity in lateral impacts. Therefore, during the M.I.V. side impact project(4), Volkswagen performed side impact tests with a crabbed barrier and crabbed Citations. Under this test configuration, it was possible to simulate both the impact angle (90°) and the impact force (crabbed angle 27°) along the direction of the resultant impact velocity of both vehicles (Figure 2) with a stationary struck and a moving striking vehicle. This impact configuration is intended to simulate the velocity of the struck vehicle, which is half that of the striking vehicle.

With the context of the goal of harmonization of future side impact performance requirements and considering available U.S. and European accident statistics, this crabbed test configuration should constitute an important part of a joint European and American research program designed to develop a common test device for lateral collision testing.

Point of Impact

Within the M.I.V, project, the defined point of impact of the left edge of the striking vehicles was selected by NHTSA based on American accident statistics(3). The point of impact is 37in forward the center of the wheelbase of the struck vehicle.

Impact Velocity

European committees CCMC (Committee of Common Market Automobile Constructors) and EEVC (European Experimental Vehicles Committee) selected a 50km/h impact velocity for 90° lateral impacts. According to HUK statistics(5) this test velocity covers more than 95 percent of the impact velocities of striking vehicles(1).

Simulating the velocity of the struck vehicle, which may amount to half that of the striking vehicle, by taking into account the main impact force direction (Figure 1), the velocity of the crabbed striking vehicle is increased to 34mph. This velocity was also selected by NHTSA for the M.I.V. project, Phase II. The new Phase II test conditions resulted from a review by NHTSA of the completed National Crash Severity Study (NCSS) accident file. NHTSA noted that these test parameters constitute a life-threatening environment. This view was also supported by the side impact project carried out by FAT(6).

The FAT side impact study at the Institute for Forensic Medicine, University of Heidelberg, sponsored by the Arbeitsgemeinschaft Industrieller Forschungsvereinigung e. V., "AiF", with the CCMC barrier as a striking and a car body mounted on a movable platform as a struck vehicle, demonstrates that this 90° impact with 50km/h impact velocity constitutes a very severe impact environment. Virtually independent of the test subject age, severe injuries (up to AIS 5) consistently result.

These findings constitute a further basis for the development of a common European and American test procedure for 90° lateral impact testing as presented in (1).

Test Devices for Lateral Impact Testing and Protection Criteria

During the discussion of test devices and procedures for the evaluation of the effectiveness of engineering measures for the further increase of present levels of occupant protection during side impact, the deformable barriers from CCMC, EEVC, and NHTSA will be compared. These barriers are intended to simulate the deformation characteristics of the average European and American striking vehicle, respectively, in simulated side impacts.

Presently available side impact dummies, HSRI SID in the United States and APROD SID in Europe, were extensively tested and evaluated by FAT. Kinematics and loadings of the dummies were compared with those of human subjects under comparable and reproducible test conditions(6). One of the purposes of this research project was to generally determine the suitability of dummies as test devices for lateral impact testing. In this context, the correlation of dummy loads and occupant injuries was also to be examined to establish meaningful occupant protection criteria.

Moving Deformable Barriers

Various studies on the development of deformable barriers have been carried out recently. They principally concern the CCMC, Fiat, NHTSA, TRRL (Transport and Road Research Laboratory (GB)), UTAC (Union Technique de l'Automobile du Motorcycle et du Cycle (F)), and EEVC barriers. The CCMC research effort on the deformable element served as a basis for the development of the EEVC element.

The main features of the CCMC, EEVC, and NHTSA barriers discussed here are presented in Figure 3.

Harmonization of side impact test procedures will require compromises acceptable to the regulatory bodies that will ultimately establish performance parameters and standards.

Mass

The CCMC and EEVC barriers have the same mass, 950kg, while the mass of the NHTSA barrier is 1,360kg. A compromise of 1,100kg has been proposed as discussed in the MVMA/NHTSA project, Side Impact Test Procedure Development, and the ISO document(7), Figure 3.

Stiffness

Figure 4 shows the force/deflection (F/D) characteristics of the three deformable elements examined. The characteristics were established in fixed barrier impact testing at a velocity of 35km/h, Figures 5 to 7.

Although the relatively sensitive NHTSA deformable element did not withstand shipping without damage and was thus already deformed at the time of the test (Figure 8), its F/D characteristic evidences a high level of stiffness. Because the first deformation phase is a very important determinant of intrusion velocity, it is very aggressive in lateral impacts as demonstrated in (1) (see also the section on Harmonization of Future Side Impact Performance Requirements). Although static deformation of the struck Rabbit was nearly identical with the CCMC and NHTSA barrier as well as with the Citation as striking vehicles, the dummy loads are substantially higher with the NHTSA barrier (Figures 25 to 31, 36, 38, 40, and 42).

Figure 9 shows the F/D characteristics of the average European sedan (VW Passat) and the average American passenger car (Chevrolet Citation). It also contains the characteristics of the CCMC element and those of the average 1976 European vehicle as calculated by CCMC.

The F/D characteristics specified for the CCMC MDB were determined by applying the test results obtained from dynamometric barrier impacts with 15 different European passenger cars at 30mph. The 15 different car models represented approximately 1.5 million vehicle registrations for the calender year 1976. Characteristics from individual cars were then weighted according to 1976 sales figures and subsequently averaged.

The characteristics depicted in Figures 4 and 9 provide a meaningful and acceptable basis for the joint development of a deformable element for the United States and Europe within the context of the desirable harmonization effort. The knowledge gained in the MDB/Rabbit side collisions demonstrates that the CCMC element provides a sound basis for the harmonization of future requirements with respect to vehicle performance in simulated side impacts.

Ground Clearance

The ground clearance of the barriers as depicted in Figure 3 lies in the range of 250 to 279mm. A reassessment of the ground clearance of the CCMC barrier was contemplated within the context of real-world accident experience and the comparative 90° side impacts with passenger cars and the CCMC barrier as striking vehicles.

According to the APR sample (2), bumper/sill engagement occurs in more than two-thirds of all side impacts (Figure 10). The final determination of the ground clearance of a joint barrier should follow out of a joint American and European research project.

Side Impact Dummies

The effectiveness of engineering measures is examined by means of experimental simulation using dummies. One of the purposes of the FAT research projects was to determine the suitability of available dummies as test devices for lateral impact testing.

The FAT research project was initiated with the goal of assessing the suitability of existing HSRI, APROD, Hybrid II, and the new Euro SID for experimental simulation of lateral impacts through comparison of dummy loading and kinematics with those of human subjects. The ultimate goal of determining the biofidelity of the new European dummy could not be achieved by FAT because of the availability of the dummy for testing. The first prototype will be presented at this ESV conference.

Comparison of the acceleration/time (a/t) histories for the three different dummies examined and the human subject group approximated by a 50th percentile male was based on mean values.

For example, the a/t histories of the 4th and 8th rib, impacted side, as well as the 1st and 12th thoracic vertebrae and the sacrum are compared in Figures 11 to 15.

Analyses of these five parameters, based on lateral impact results of 15 dummy and 35 human subject tests, clearly show there is a substantial and, therefore, unacceptable variance between data measured on dummies and actual data obtained with human subjects. Despite the fact that the HSRI and Hybrid II dummies have quite different chest structures, they demonstrate a nearly identical a/t history at the 4th rib. Because of these findings, it is questionable whether this parameter can be used as injury indicator as discussed in (9), measured at dummies examined.

Despite identical pelvis structures, the dummies provide different response data at the sacrum. This is probably caused by the interaction of the thorax and pelvis during lateral impact.

These results will contribute significantly to the development of a side impact dummy with improved biofidelity. This new dummy should be used throughout the world within the context of the recognized need for harmonization of future side impact performance requirements. During development, particular care should be taken to insure the resulting dummy will not only be suitable for the standardized side impact testing but also for existing frontal impact requirements.

Protection Criteria

Knowledge of load limits and injury mechanisms of occupants is mandatory for the definition and assessment of measures to further increase existing levels of vehicle occupant protection. Therefore, FAT performed a total of 35 lateral impact tests with human subjects at different velocities (40 to 60km/h) and in left and right side impact modes to establish by iteration the loading limits on human subjects. The test series further sought to examine the relationship between injury severity and the measured acceleration values. This constitutes a sound basis for the determination of future protection criteria. Suitable dummies and the relationship between protection criteria and occupant protection are, of course, a prerequisite for the application of dummy loads measured during tests to the real-world accident scene. Without such a correlation, those responsible for the establishment of meaningful standards will not have fulfilled their mandate.

The results of this FAT study are described in (6). They will be summarized here.

In accordance with our presentation(8), and as also noted during the continuation of the test series, the most serious injuries were observed at the abdomen. These generally consist of liver ruptures, which predominantly occur during 50km/h lateral collisions and where occupant impact occurs on the right side. In the three tests with a collision velocity of 60km/h, abdominal injuries occurred during left-side impacts, consisting principally of injuries to the spleen, the left kidney, and the liver. No abdominal injuries occurred at a velocity of 40km/h during right-side impacts. Even during left-side impacts at a velocity of 45km/h, no abdominal injuries were observed (Figures 16 and 17).

The high frequency of abdominal injuries indicates that side impact dummies must be developed to simulate these injuries.

Again, it should be noted that the simulated 90° lateral impact test performed in this study represents a very severe accident exposure, which overemphasizes the frequency of severe abdominal injury in relation to overall accident experience.

The evaluation of the severity of thoracic injuries was based principally on the number of fractured ribs. In a few cases, perforations of the pleura occurred. Figures 18 and 19 depict the correlation between the number of rib fractures and accelerations measured at the 4th rib and 1st thoracic vertebra by means of linear regression analysis. The correlation coefficients do not indicate the existence of a strong correlation. Injuries to the head and extremities were rarely observed.

Two-dimensional Spearman correlation results have been evaluated to examine the correlation of loads and injury severity. Comparison of these coefficients and significant levels of all parameters examined indicates there may well be a relationship between 4th rib or 1st thoracic vertebra accelerations and rib fractures as there is between 12th thoracic vertebra or sacrum acceleration and abdominal injury severity. Figure 20, however, depicts no such correlation between sacrum acceleration and abdominal injury. These findings will be analyzed within the scope of a further study by performing a multiple, nonlinear regression analysis. The two-dimensional Spearman correlations should be viewed only as an initial effort for assessment and evaluation of the extensive data collective.

The relationship between loads and injury is also discussed in (9). A relationship, called the Thoracic Trauma Index (TTI), has been developed by NHTSA that is intended to indicate the injury to the thoracic cage and the organs within it.

$$TTI = 1.4\ Age + 0.5\ (T12Y + LURY) * Mass/165$$

Subject age and mass (lb) and lateral peak acceleration of struck side 4th rib and 12th thoracic vertebra are parameters of the equation for the calculation of TTI.

Figures 21 to 24 depict the relationship between TTI and thoracic and abdominal injuries. Because of the lack of correlation and the great variance between data measured with HSRI dummy and human subjects, at present the algorithm is not suitable for calculation of the theoretical TTI from data measured with this dummy.

Harmonization of Future Side Impact Performance Requirements

To effectively realize further meaningful increases in existing levels of passive safety, the common goal of all concerned must be to promote uniform vehicle performance requirements on a worldwide basis. The governments in Europe and of the United States must demonstrate a willingness to cooperate and compromise with respect to appropriate test procedure, configuration, devices, and parameters.

To investigate the merits of this concept, Volkswagen evaluated and compared the behavior of five striking vehicles in 90° lateral impact tests with the crabbed test configuration and struck Rabbits (Figure 25):

- Chevrolet Citation (average American car)

- NHTSA barrier
- VW Passat (average European car)
- CCMC barrier
- EEVC barrier

Comparison Between the CCMC Barrier and the Average American Car

The side impact test with the Citation (Figures 26 and 27) was part of the M.I.V. research project performed by Volkswagen(4) under NHTSA sponsorship. The Citation was selected because it is said to represent the average American car in terms of dimensions, structure, and mass. In addition, it was selected by NHTSA for the M.I.V. project, Phase II, because, according to NHTSA test results, the deformable barrier, developed by NHTSA only for 60° side impacts, is too stiff in 90° impact configurations. This characteristic was also demonstrated by Volkswagen in a further test with this barrier, (Figures 25, 30, and 31).

The essential characteristics of the deformable element of the CCMC barrier have been matched as closely as possible to those of an average, current production European-type passenger car in terms of mass, F/D characteristics, geometry, etc.(1).

To evaluate the suitability of the CCMC barrier as a test device for lateral collision testing (Figures 28 and 29), HRSI dummy response data and the overall deformation of the struck vehicles, as well as that occurring at specific levels, are compared (Figures 36, 38, 40, and 42).

It can be seen that the CCMC deformable element, which is in part stiffer than the average European car, closely simulates the deformation behavior of the front structure of the average American car, the Chevrolet Citation, as defined by NHTSA.

The driver dummy loads are nearly identical in the thoracic area when side impacts with the Citation and the CCMC barrier are compared (Figures 25 and 36). Loads are higher in the head and pelvic region for the Citation/Rabbit side impact test. Because thoracic injuries dominate according to U.S. and European statistics(2,3), mainly thoracic loads should be taken into account.

The higher pelvic loads were caused by the 5mph bumper layout of the Citation. The CCMC deformable elements closely simulate the 2.5mph bumper layout. Here the negative effect of the more aggressive 5mph layout on occupant protection in lateral impacts is clearly evident.

With the exception of the bumper region, deformation of the struck vehicles is similar when lateral impacts with the Citation and the CCMC barrier are compared. They are, however, equal in the thoracic area (Figures 38, 40, and 42).

Comparison Between the NHTSA Barrier and the Average American Car

Comparing dummy response data from lateral impacts with the NHTSA barrier with the NHTSA deformable element and the Citation as striking vehicles, it is obvious the barrier does not simulate the deformation behavior of the average American car as defined in any region (Figures 25 and 36). The barrier is substantially more aggressive than the Citation and will thus lead to false assumptions and unrealistic measures to reduce dummy loads. The NHTSA barrier does not accurately reflect the effects and consequences of real accidents.

The static crush of Rabbits struck by the Citation and the NHTSA barrier is similar (Figures 27, 31, 38, 40, and 42). Because the difference in dummy loads of these two tests is so immense, the deformation/time history of the side structure of the struck vehicles, caused by the two different striking vehicles, disclose substantial disparities.

Comparison Between the CCMC and EEVC Barriers and the Average European Car

The design of the EEVC barrier and its deformable element is described in (10). Design parameters are compared in Figure 3.

Comparison tests with the average European vehicle (VW Passat) and the CCMC and EEVC barriers (Figures 28, 29, and 32 to 35) clearly show that the CCMC barrier represents a significant and acceptable compromise for the harmonization of future vehicle performance requirements in defined side collisions.

The F/D characteristics of the CCMC element are in some areas stiffer than those of the average European car. The F/D characteristics of the EEVC element are softer as demonstrated by a comparison of the dummy values (Figures 25 and 37) and characteristics (Figure 9). A stiffening of the element has been discussed(10), thus the characteristics of the updated CCMC and EEVC elements will ultimately be quite similar.

The side impact test with the crabbed chassis of the NHTSA barrier and the EEVC elements (Figures 34 and 35) demonstrates this element can also be used for the crabbed test configuration that is intended to simulate real-world side impacts.

Comparison of driver dummy loads (Figures 25 and 37) demonstrates that the CCMC deformable element mounted on the crabbed chassis of the NHTSA barrier appears to represent an excellent and most realistic compromise for the harmonization of future side impact performance requirements intended to further increase existing levels of passive safety. This combination should constitute the basis for further research efforts with respect to a common European and American test device for 90° lateral impact testing.

Conclusion

This report discusses the suitability of deformable barriers and dummies as test devices for the standardized side impact. Comparative evaluation demonstrates that while the available test devices also constitute a basis for further research activities for the development of side impact test procedures, the comprehensive and necessary research activities cannot be viewed as having been completed.

So that the effectiveness of measures for the further increase of occupant protection in side impacts will not be jeopardized and can be appropriately applied to real-world accidents, biofidelity of dummies must be greatly improved and the correlation of dummy loadings and occupant injuries must be reliably established. The FAT project(6) provides a useful foundation for these efforts.

An important further goal must be the development of omnidirectional dummies capable of being used throughout the world. Such a development effort must include a computer simulation and mathematical description of the very complex spring-damper-mass system to analyze fully the complex interactions of individual body parts and other relevant parameters. The FAT project also provides a basis for the validation of the mathematical dummy model.

The extent to which the newly developed European side impact dummy correlates with respect to kinematics and loadings with human subject behavior requires evaluation within the scope of the FAT project as soon as a sufficient number of prototypes becomes available.

The comparative evaluations with the CCMC, EEVC, and NHTSA barriers as well as with average European and American passenger cars, combined with the experience gained during repeatability testing at the Dutch Research Institute TNO and tests at BASt (German "Bundesanstalt für Straßenwesen"), Ford, FAT, and CCMC, indicate that the deformable element developed by CCMC constitutes a good compromise for a model of the front structure deformation behavior of the average European and American passenger car. As noted, a joint European and American research program, as already initiated between MVMA and CCMC, is warranted and needed to develop a common test device based on the crabbed NHTSA barrier chassis and the CCMC deformable element for lateral collision testing.

Dummy response data in lateral impacts with the NHTSA barrier and NHTSA deformable element differ substantially in all regions from data obtained in tests with the average American car, the Citation, as defined by NHTSA.

The EEVC deformable element is similar in design to the CCMC element. It is manufactured by the same firm (Fritzmeier) and consists of the same PU foam material. As previously discussed(10), the F/D characteristics of the EEVC element are softer than those of the average

European passenger car and those of the CCMC barrier. Because of the common features of both elements, a joint research effort by CCMC and EEVC will result in a European element that, with respect to deformation characteristics and design, will more closely resemble the CCMC element.

This finding, together with the knowledge that the European and American lateral accident experiences are largely similar, should constitute the basis for further research efforts with respect to a common European and American test device for 90° lateral impact testing. A reasonable and acceptable compromise appears to be represented by the 27° crabbed chassis of the NHTSA barrier with a total mass of 1,100kg in combination with the CCMC deformable element, with a ground clearance of 250mm. This element will cost less than DM1,000 in mass production. In contrast to the NHTSA element(4), the CCMC element is not shipping-sensitive, not sensitive to slight exterior cracks, and constitutes representation of the front structure deformation behavior of the average European and American passenger cars.

This approach should be viewed as a step toward a harmonization of future side impact performance requirements.

Occupant Response Sensitivity Analyses Using a Lumped Mass Model in Simulation of Car-to-Car Side Impacts

Thomas J. Trella
Transportation Systems Center, Research and Special Programs Administration

Joseph N. Kanianthra
U.S. Department of Transportation, National Highway Traffic Safety Administration

Abstract

Results of a sensitivity study, based on lumped spring/mass modeling approaches for the characterization of structural and occupant responses in 60° and 90° side impacts, are presented in this paper. Test data from collisions between a moving deformable barrier (MDB) and the side of a Volkswagen Rabbit in two crash configurations, simulating 60° and 90° impacts, are used to derive the force-deflection characteristics of the non-linear springs in the model.

The mathematical model is used to investigate the sensitivity of occupant responses to parametric changes in the striking and struck car characteristics. The variables included in this parametric study are striking vehicle and struck vehicle stiffnesses, crash configuration, impact velocity, occupant-to-door clearances, and padding characteristics. The striking car and struck car side stiffnesses are varied in the range of ±40 percent and ±30 percent, respectively, from the nominals. The effects of padding material characteristics and padding thicknesses up to 6in are evaluated. The effects of the above parametric changes on predicted thoracic probability of injury using the National Highway Traffic Safety Administration (NHTSA) Thoracic Trauma Index (TTI)(1) are also presented.

The results showed that the rib, spine, and pelvis peak accelerations generally increased with increases in striking vehicle stiffness and impact velocity. Increases in struck car side stiffness and the addition of door padding reduced the peak rib, pelvis, and spine accelerations. The results indicate padding is very effective in reducing the thoracic probability of injury. It is observed that the probability of injury at Abbreviated Injury Scale (AIS) levels of 3 or greater in a 30-year-old male will be reduced from 50 to 20 percent by adding a 3in-thick padding in a 90° collision with the striking car moving at 26mph and the struck car moving at 13mph, respectively. It is also observed that the relative effectiveness of the above changes in vehicle characteristics is a function of impact speed.

Introduction

Results of side impact sensitivity analyses based on lumped mass collision modeling studies that characterize parametrically the lateral acceleration response levels of a normally seated driver dummy in the struck vehicle are discussed. The crash configuration studied for the characterization of driver and structural responses was a stationary target vehicle (2-door, VW Rabbit) that was struck by a crabbed MDB simulating a two-car collision when both vehicles are moving. The impacts were on the driver's side door and surrounding structures (A- and B-pillars) at 90° and 60° as shown in Figure 1. These

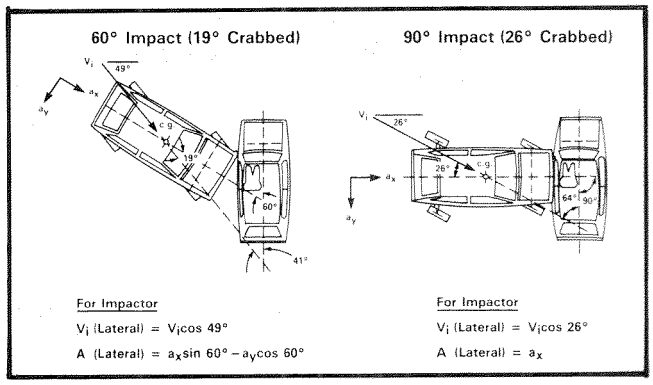

Figure 1. Crash configuration

configurations simulate side impacts where the striking and struck vehicles moved at 26 and 13mph (low-speed condition), and 35 and 17.5mph (high-speed condition). This corresponds to MDB closing speeds of approximately 29 and 39mph (26 and 35mph lateral velocity) for the 90° low- and high-speed conditions, respectively. The 60° impact MDB closing speeds were approximately 34 and 46mph (22 and 30mph lateral velocity) for the low- and high-speed conditions, respectively. In this study, the influence of striking vehicle stiffness, struck vehicle side stiffness, impact angle, impact velocity, and padding thickness and stiffness were parametrically investigated.

The characterization effort was performed in three parts. First, the dummy's pelvic and upper thorax (rib and spine) peak acceleration levels were determined from simulations in which the parameters listed above were varied. Based on these results, the sensitivities of the dummy's peak accelerations (G's) to changes in those parameters were derived. Last, thoracic probability of injuries were computed, based on the NHTSA TTI.

Validations were carried out comparing the simulation and test results. In this paper, special emphasis is given to defining driver dummy response trends.

Side Impact Model and Characteristics

The sensitivity results were derived from the one-dimensional lumped parameter nonlinear spring mass model(2) shown in Figure 2. Basically, this model is a modified version of the CRUSH model (Crash Reproduction Using Static History)(3) with a lumped mass representation of the upper thoracic as well as the pelvic regions of an unrestrained occupant. The crush of the struck vehicle's side structure is represented in this model as a nonlinear spring connecting the side door structure and compartment. The occupant simulation is based on a simple model, mainly to predict the thoracic response and probability of injury, and, therefore, does not include the head-to-interior surface contact elements. Model validations were performed by simulating three different crash conditions. These involved a baseline VW Rabbit in a 90° impact (BL-90°), a structurally modified VW Rabbit in a 90° impact (MOD-90°), and a baseline VW Rabbit in a 60° impact (BL-60°).

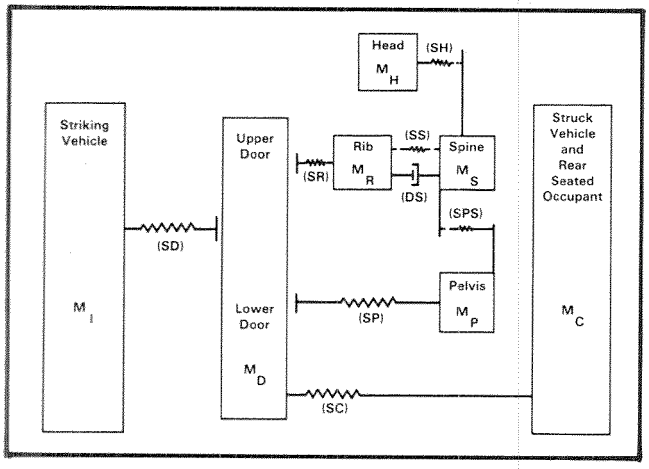

Figure 2. Side impact lumped spring/mass model

Four masses (rib, pelvis, spine, and head) with three nonlinear interconnecting springs and a damping element were used to model the occupant. The rib- and pelvis-to-door contacts were represented by two nonlinear springs. Padding was introduced as a spring between the dummy and the door. A ¾in bottomed-out thickness was assumed for all pad thicknesses considered in this study. In this investigation, the connection between the spine and pelvis was neglected. The pelvis was positioned 4in from the inner surface of the door for the sensitivity calculations. The rib-to-door clearance was composed of the pelvis-to-door clearance and the rib-to-pelvis spacing derived from accelerometer data in side impact tests using Side Impact Dummies (SID's). Rib-to-spine damping was provided by means of a viscous damper. In this model, head motions were assumed coupled directly to the spine by means of a nonlinear spring. Head contact with the side structure was not modeled.

The force-deflection properties for the modified CRUSH model were derived from acceleration traces obtained from the side impact tests in (4). Experimental accelerometer time histories of the inner surface of the door were used for this purpose. The MDB's longitudinal and lateral responses were resolved in the direction perpendicular to the side of the struck vehicle, since only the lateral motions were of concern in this collision-modeling effort. The force-deflection characteristics were based on the low impact speed (26/13mph[1]) crash test results since the force versus deflection traces derived from other speed conditions indicated that the dynamic rate effects were small. For the simulations, the force-deflection diagrams were approximated by segmented straight line elements to (a) eliminate higher order oscillations, (b) eliminate multivalued forces due to instrumentation system inaccuracies and incompleteness of the choice of the lumped mass model used in the derivation of the force-deflection characteristics, and (c) extend the range of applicability of the model to other speed conditions. Figure 3 shows the force-deflection diagrams for impactor-to-door spring (SD) and door-to-compartment spring (SC) for the three crash conditions.

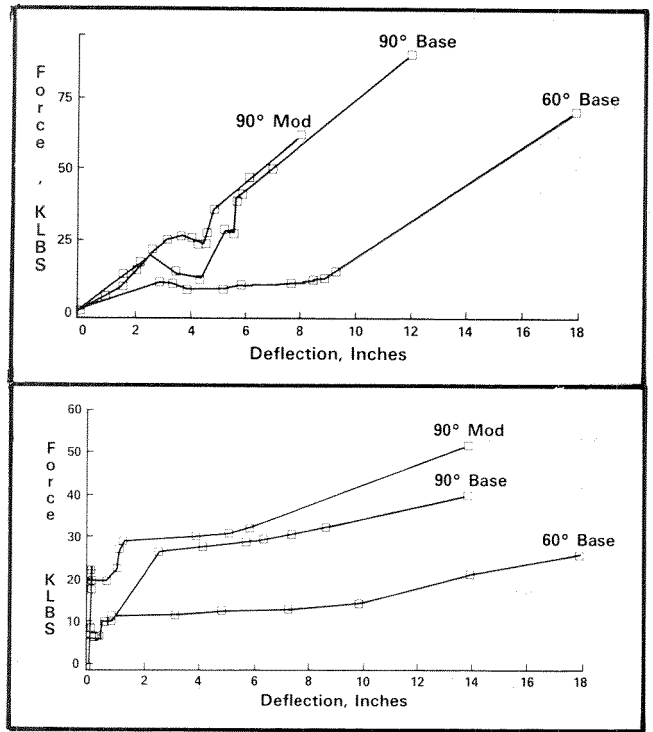

Figure 3. Assumed force versus deflection for springs SD and SC in CRUSH

The MOD-90° force versus deflection traces shown in these diagrams were obtained from the VW Rabbit MOD-90° impact padded door crash test time histories. Door padding force-deflection characteristics were based on a nonlinear expression developed from the measured

[1] Denotes the striking and struck vehicle collision speeds, respectively.

force-deflection characteristics of a General Tire and Rubber (GTR) pad used in the side impact car crash tests(4,5). This expression provided the GTR pad force level as a function of its bottomed-out thickness, a force level coefficient, a padding displacement, and a shape coefficient(2). Figure 4 shows the analytically derived GTR pad force-deflection trace for a 4.0in-thick sample.

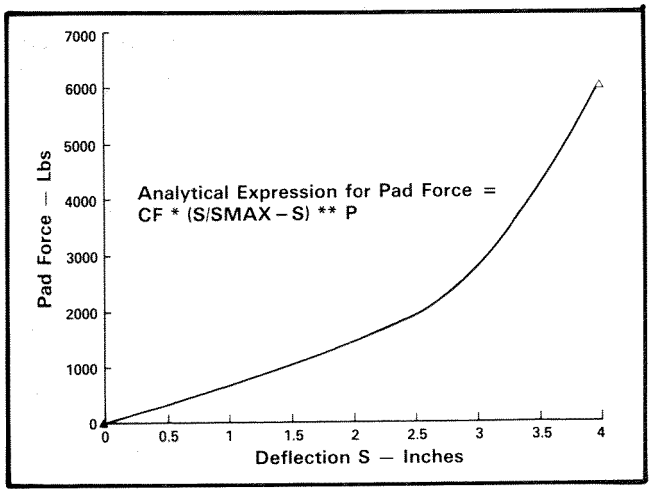

Figure 4. Analytically derived force versus deflection for the GTR pad

26/13mph and 35/17.5mph speed conditions. The calculated responses appear to show reasonable levels of agreement in terms of peak G levels for the rib, pelvis, and spine for the test conditions simulated. These simulated dummy peak G levels are based on the acceleration-derived pelvis-to-door and rib-to-door clearances derived from the dynamic crash tests. (For the 90° impact simulations, 5.20in was assumed for the pelvis-to-door clearance and 8.02in was assumed for the rib-to-door

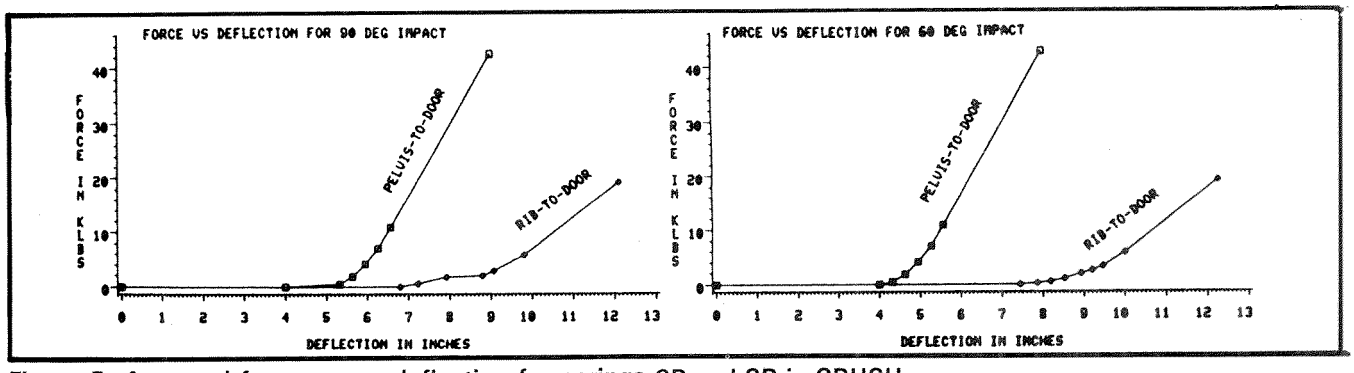

Figure 5. Assumed force versus deflection for springs SP and SR in CRUSH

Force-deflection traces are also illustrated in Figure 5 for the rib-to-door (SR) and pelvis-to-door (SP) contact. The rib-to-spine spring (SS) force-deflection characteristics, the head-to-spine spring (SH) characteristics, and all other model inputs are as shown in (2). Table 1 summarizes the component weights used for the three crash conditions that represent the best estimates for the purpose of this lumped mass modeling.

Model Validations With Characterization Test Data

Before conducting the sensitivity studies, the lumped mass model was validated with experimental data over two impact speeds. The results are shown in Figure 6, which compares the simulated peak acceleration responses of the three body components in the 90° test at the

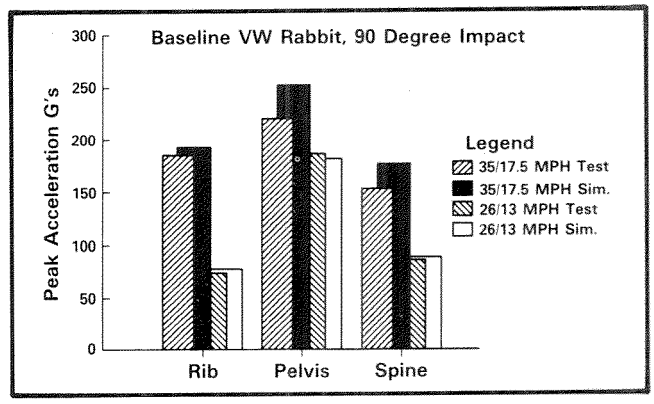

Figure 6. Comparison of simulated responses and test results at two impact speeds

clearance in the BL-90° impact.) Note, these clearances are different from the clearances used to calculate the

sensitivities discussed in the following sections where the pelvis was positioned 4in from the door.

Model Considerations

The sensitivity results discussed in this paper are influenced by the weight assumed for the door structure, the rib and pelvis-to-door clearances, the pelvis-to-rib spacings, and the bottomed-out thickness assumed for the pad. Deviations from values assigned to these parameters will yield different dummy peak G levels and trends for the parametric changes investigated. For example, a different door structure and weight will produce phase shifts and response level differences. Decreasing the clearance between dummy and door to a certain clearance value will generally increase the rib and pelvis peak G levels. Further decreases in clearance from this value will reduce the occupant peak G levels since the side structure velocities increase and then decrease in time during the collision phase in response to the colliding striking vehicle. For rib response, this occupant-to-door clearance value was estimated to be about 2in(2).

Sensitivity Investigations

Parametric investigations were conducted at two impact speeds of 26/13mph and 35/17.5mph, respectively. The parameters considered included—

- Door padding (thickness and force levels)
- Struck vehicle stiffness (VW Rabbit door-to-compartment stiffness)
- Striking MDB stiffness (MDB-to-struck VW Rabbit door stiffness)

The striking MDB and struck VW Rabbit door stiffnesses were varied in the range of ±40 percent and ±30 percent, respectively, from the nominal. Three- and six-inch door padding thicknesses were investigated with the same thickness at the rib and pelvis striking points. The range of stiffness values used for the door padding varied from -20 percent to +20 percent from the nominal in increments of 10 percent. These stiffness changes were reflected in the forces obtained by multiplying the nominal force levels in the spring force-deflection diagram by factors corresponding to the percent changes described above. Note that the striking and struck car side stiffness changes obtained in this manner do not necessarily imply that the baseline (BL) VW Rabbit door structure force-deflection characteristics, when changed by a stiffness factor, should exactly reproduce the force-deflection characteristics of the structurally modified (MOD) VW Rabbit. Typical force-deflection characteristics for the striking and struck vehicles and door interior padding to occupant body component interactions are given in (2).

Finally, as a special case, some occupant peak G level trends are discussed as a result of changes to the GTR-pad shape factor (P). These trends are based on preliminary investigations of a pad analytically tailored to dissipate the impact energy more linearly as a function of its thickness. This padding characteristic is shown in Figure 7, which compares the baseline (P = 0.8) with the analytical pad (P = 0.2).

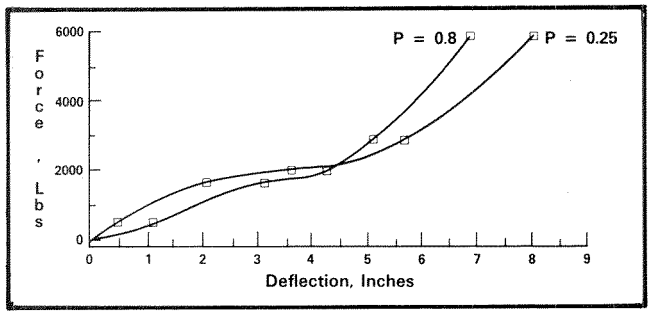

Figure 7. Combined padding and rib contact element characteristics for two different shape factors for the GTR pad

Dummy's Acceleration Response Trends

Tables 2 through 4 summarize the dummy's (rib, pelvis, spine, and head) peak G levels as a function of: (1) door padding thickness changes, (2) door-to-compartment stiffness changes, (3) MDB-to-struck-door stiffness changes, (4) padding thickness changes plus VW Rabbit door-to-compartment stiffness changes, and (5) padding thickness changes plus MDB-to-struck-door stiffness changes. These simulated responses correspond to the BL-90° and MOD-90° crash conditions for impact speeds of 26/13mph and 35/17.5mph, respectively, and the BL-60° crash conditions for an impact speed of 26/13mph.

In general, for the range of variables considered, the simulated results indicate that—

Dummy (rib, pelvis, and spine) peak G levels decreased when—

(1) The thickness of the GTR door padding was increased; and

(2) The VW Rabbit door-to-compartment stiffness levels were increased.

Dummy (rib, pelvis, and spine) peak G levels increased when—

(1) The collision speed was increased; and

(2) The MDB stiffness levels were increased.

Dummy (pelvis) peak G levels increased when—

(1) The stiffness of the GTR door padding was increased.

Dummy (rib and spine) peak G levels increased when—

(1) The stiffness of the GTR door padding was decreased.

Furthermore the results presented in Tables 2 through 4 indicate that door padding thickness changes were

especially beneficial as a countermeasure in reducing the thorax and pelvis peak G levels. The thorax G level reductions through increased door-to-compartment stiffnesses (up to 1.3 nominal), generally, were small. The model indicated that the reductions obtained as a result of stiffened door-to-compartment structure could also be achieved through increase in padding thickness. For example, in the case of the 26/13mph, BL-90° impact, a 3in GTR pad reduced the rib peak G levels from 112.6G to 61.9G, a 3in GTR pad plus a 20 percent increase in struck vehicle side stiffness yielded a rib peak G level of 55.1G, whereas a 6in-thick GTR pad alone reduced the rib peak G level to 55.2G. It must be pointed out, however, that space limitations and other considerations

limit the thickness of the padding that can be used as a countermeasure. Struck VW Rabbit side stiffness changes affected all three dummy body components' peak G levels, while changes to the striking MDB stiffness principally affected the pelvis response.

Door Padding Thickness Effects

Driver Dummy Peak G Response Trends

GTR padding was very effective in reducing the dummy peak G levels, particularly for the rib. For example, at an impact speed of 26/13mph and an impact angle of 90°, a 3in-thick door padding in the baseline and structurally modified VW Rabbit reduced the rib peak G level from 112.6G to within 61.9G for the baseline and 112.6G to 56.3G for the modified vehicle. Much smaller reductions were achieved with an additional 3in-thick pad where rib peak G levels were further lowered to 44.3G for the modified and 55.2G for the baseline vehicle. At an impact angle of 60°, a 3in-thick pad lowered the rib peak G level from 146.1G to 76.7G for the baseline vehicle and a 6in-thick pad lowered the rib peak acceleration levels to 55.2G. The GTR padding was also quite effective in reducing the rib peak G levels at the higher speed even for padding thicknesses less than 3in. For example, at the 26/13mph speed, a 3in GTR pad reduced the BL-90° rib peak G levels by 45 percent and the MOD-90° by 50 percent. At the higher speed of 35/17.5mph, rib peak G level reductions of 49 and 59 percent were calculated for the BL-90° and MOD-90° configurations, respectively. The baseline VW Rabbit's rib peak G level percentage reductions for a 3in GTR pad did not appear to be largely affected by the collision angle. Rib peak G level percentage reductions were slightly higher for the structurally modified VW Rabbit than for the baseline VW Rabbit.

For the padding thicknesses considered herein, the spine peak G levels dropped off linearly with increase in the GTR pad thickness. The spine peak G level reductions were also lower by approximately one-half the value obtained in rib responses.

The pelvis peak G level reductions, on the other hand, were somewhat similar to those calculated for the rib. Here the pelvis peak G percentage reductions were about 30 percent for the 3in GTR pad and 60 percent for the 6in GTR pad for all three impact models at the lower impact speed. Due to the higher impact force encountered at the 35/17.5mph impact speed, the BL-90° pelvis peak G level percentage reductions were lower, since the GTR pad bottomed out. For example, for the 6in-thick GTR pad, the pelvis peak G level was reduced from 205G to 82.4G (60 percent) at the lower 26/13mph impact speed, while for the same pad thickness at the 35/17.5mph impact speed, the pelvis peak G level was reduced from 266.1G to 153.4G (42 percent). Pelvis peak G level percentage reductions for the MOD-90° at the 35/17.5mph impact speed were slightly higher than the peak G level percentage reductions obtained at the lower impact speed (26/13mph).

These results showed that 3in of GTR padding added to the door significantly reduced the rib peak G levels. Moreover, the GTR padding seemed more effective in reducing the thorax peak G levels even at lower padding thicknesses than in reducing the heavier pelvis mass peak G levels, especially at the higher impact speed. To further illustrate this point, the rib, pelvis, and spine peak G levels were computed using smaller padding thickness increments up to a thickness of 8in. The results are shown in Figure 8. Here, the rib peak G levels drop off sharply at the lower GTR padding thicknesses where they are largely affected by the interaction of the pelvis with the padded door. On the other hand, at the higher GTR padding thicknesses, the thorax peak G levels seem to level off with increase in the GTR padding thickness. This

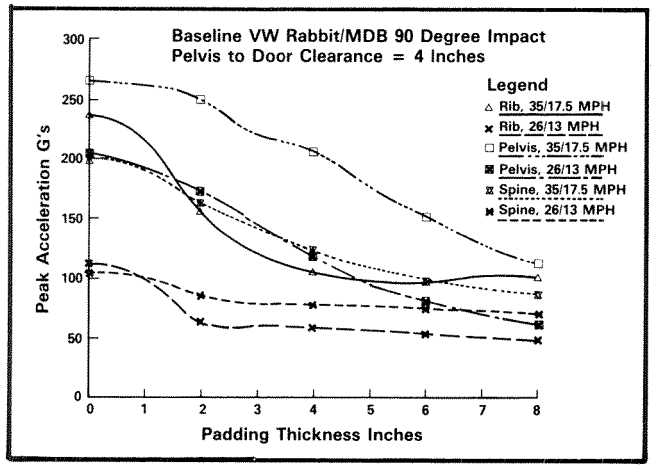

Figure 8. Effect of GTR pad thickness at rib and pelvis on dummy peak G levels

trend is due to the phasing difference between the rib and pelvis peak G levels when different padding thicknesses were applied to the door and to secondary impacts of the thorax mass. Door velocity time histories are also shown in Figure 9 for an unpadded door and a door with a 3 and 6in GTR pad, respectively, which further explains these differences. These histories show that the pelvis-to-door contact lowered the velocity of the door and, therefore, the velocity of impact of the rib in the case of the unpadded door and door with the smaller padding thicknesses (up to 3in). At the higher door padding thicknesses (beyond 3in), the influence of the pelvis on rib peak G levels diminished and the rib responded as if the pelvis never made contact with the padded door. In this case, the further reductions in rib peak G are due to the cushioning effect provided by the thicker padding in reducing the secondary impacts.

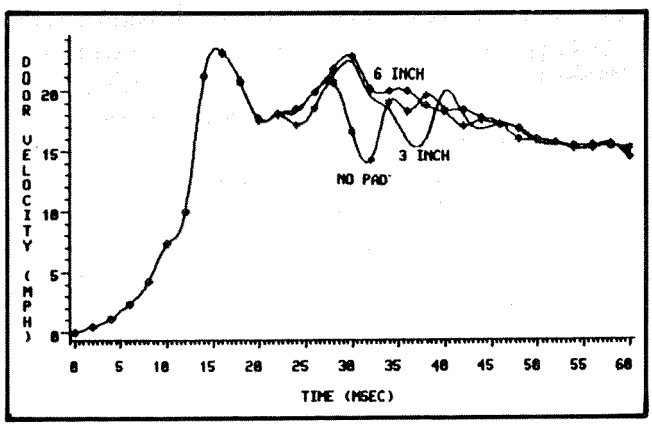

Figure 9. Door velocity time histories

Sensitivities Due to GTR Padding Thickness Changes

Sensitivities relating the change in the dummy peak G levels to the change in the GTR padding thickness (G/in of added padding) were also calculated. For sensitivity calculations, the slope between adjacent pairs of the parametrically changed padding thickness was used to denote the rate of expected peak G reduction/in of added padding.

The peak G level reductions for the rib, pelvis, and spine/in of the added GTR padding for the three mean thicknesses are given in Table 5. Additional sensitivities as a function of padding thickness for the BL-90° crash conditions are shown in Figures 10 and 11 for the 26/13 and 35/17.5mph striking speed, respectively.

In general, these results indicate that the dummy's rib, pelvis, and spine body components exhibit different sensitivity values for the different GTR padding thicknesses. Typically, these sensitivities increase, reach a maximum value, and then decrease with increasing thickness. The maximum values also occur at different GTR padding thicknesses for all three body components. In the case of the dummy normally seated 4in from the door, the maximum sensitivities related to the rib and spine occur at a lower pad thickness (the same thickness at rib and pelvis striking locations) than that for the pelvis. Generally, the pelvis peak G levels appear to be more sensitive to padding thickness changes than the rib and spine peak G levels over the range of GTR padding thicknesses investigated. At the smaller thicknesses (0 to 3in) where the pelvis-to-door interaction influenced the thorax contact velocity, the rib and spine peak G levels were highly sensitive to changes in the GTR padding thickness. The rib, pelvis, and spine exhibited roughly the same levels of sensitivity for the three simulated crash conditions, which suggests that padding effectiveness as a first approximation could be evaluated independent of the crash angle and the door strength of the struck vehicle.

As noted above, the thorax region exhibited the largest variation in the sensitivity with increase in the GTR

Table 5. GTR Padding Sensitivity Coefficients

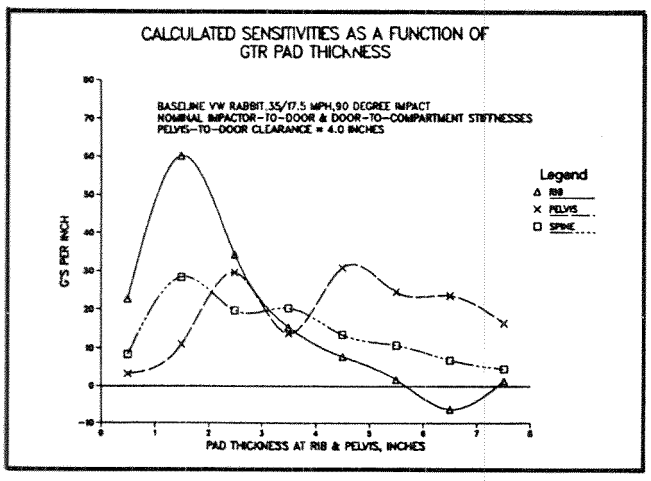

Figure 11. Sensitivities of dummy response as a function of GTR pad thickness at the high speed condition

padding thickness, whereas the variations in the pelvis sensitivity were less. The rib showed the largest variation in the thorax region. Moreover, the sensitivities related to the thoracic region showed, characteristically, different patterns where at the smaller thicknesses the thoracic accelerations are highly sensitive to the GTR padding thickness changes and the thoracic accelerations are much less sensitive at the higher thicknesses. These sensitivities also exhibited the largest changes as a function of impact speed. For example, in the case of the 26/13mph, BL-90° impact, the rib sensitivities ranged from 16.9G reduction/in of padding added to a 1.5in GTR pad to 3.4G reduction/in of padding added to a 4.5in GTR pad. In addition, in the first region, the thorax peak G levels were less sensitive at the lower 26/13mph impact speed to the GTR padding thickness changes than at the higher 35/17.5mph impact speed. Also at both speeds, the rib peak G levels were approximately twice as sensitive as were the spine peak G levels to the GTR padding thickness changes. It is of interest to note, in the first region, the pelvis peak G levels seemed as sensitive to GTR padding thickness changes at the lower impact speed as the rib and less sensitive at the higher speed. In this case, the sensitivities at the lower impact speed ranged from 17.0G to 23.0G reduction for the pelvis, compared to the 39.0G to 49.0G reduction/in of padding added to the 1.5in GTR pad for the rib, and 15.0G to 20.0G reduction for the pelvis at the higher impact speed. At the higher pad thicknesses, as the collision speed was increased from 26/13mph to 35/17.5mph, the spine peak G levels showed a higher sensitivity than the rib peak G levels to increases in the GTR padding thickness.

As a further consideration, the percentage reduction in G levels achieved by the various GTR padding thicknesses relative to the unpadded door case for the BL-90° crash condition at the low and high collision speeds (26/13mph and 37/17.5mph, respectively) indicate that—

1. Increase in the rib peak G reduction with increase in the impact speed (45.0 percent and 48.9 percent for the low and high collision speeds, respectively, for the 3in pad)
2. Decrease in the pelvis peak G reduction with increase in the impact speed (29.2 percent and 16.5 percent for the low and high collision speeds, respectively, for the 3in pad)
3. Increase in the spine peak G reduction with increase in the impact speed (23.6 percent and 28.1 percent for the low and high collision speeds, respectively, for the 3in pad)

Note here that the pelvis peak G percentage reductions appear less at the higher speed than the lower striking speed since the GTR pad bottomed out as previously noted.

Struck VW Rabbit Stiffness Effects

Dummy Peak G Response Trends

Much smaller dummy peak G reduction levels were achieved through increase in the VW Rabbit door-to-compartment stiffness ranging from the 1.0 to 1.3 nominal stiffness value than through the addition of door padding (see Tables 2 through 4). The peak G reduction levels were most sensitive to the three different crash conditions considered. In the case of the rib, the largest reduction was achieved by the MOD-90° crash condition, from 112.6G to 75.5G, followed by the BL-90° crash condition, from 112.6G to 91.2G, and finally by the BL-60° crash condition, from 146.0G to 134.7G, at the lower speed when the VW Rabbit door-to-compartment stiffness was increased to 1.3 nominal stiffness. The primary reason for the larger reduction in the modified vehicle is that the 1.3 nominal stiffness reflected a much larger change in the structurally modified VW Rabbit's door than a similar 1.3 nominal stiffness change in the baseline

compartment stiffness in either the 60° or 90° impact. Lower rib peak G reduction levels were indicated at the higher impact speed when the struck vehicle stiffness was increased from 1.0 to 1.3 nominal due to the increased force of impact. Also under this condition, no benefits were indicated for the BL-90° crash condition because of the lower strength of the VW Rabbit door-to-compartment interconnecting spring. The modified VW Rabbit design indicated marginal peak G reduction levels for the rib of 4 to 10 percent at the higher speed, where the driver dummy rib peak G levels were reduced from 246.4G to 236.8G, 231.0G, and 221.8G for VW Rabbit door-to-compartment stiffness levels of 1.1, 1.2, and 1.3 nominal, respectively.

The spine reductions through increased struck side vehicle stiffness changes were similar to those obtained for the rib. The pelvis peak G level reductions, however, were higher than those obtained for the rib. Generally, the pelvis percentage reductions were higher for the BL-90° crash condition than for the MOD-90° crash condition. These reductions were also lower when the collision speed was increased from 26/13mph to 35/17.5mph. For example, the BL-90° crash condition indicated pelvis reductions of 23 and 12 percent for the 26/13mph and 35/17.5mph impact speeds, respectively, when the compartment stiffness was increased from 1.0 to 1.3 nominal. Likewise, reductions of 13.0 and 11.6 percent were indicated for the MOD-90° crash conditions when the collision speed was increased from 26/13mph to 35/17.5mph, respectively.

Sensitivities Due to Struck VW Rabbit Stiffness Changes

The response curves describing the trends in dummy peak G levels with changes in struck vehicle stiffness were most irregular (particularly for the pelvis) exhibiting spikes due to the nonlinearities in the striking and struck vehicles' force-deflection characteristics. Because of this, the response curves were recalculated using a smaller grid to define more precisely the peak G level trends for sensitivity calculations. These response curves (peak G versus log-normalized stiffness) are shown in Figure 12 for the BL-90° and MOD-90° crash conditions at the 26/13mph impact speed, Figure 13 for the BL-90° and MOD-90° crash conditions at the 35/17.5 mph impact speed, and Figure 14 for the BL-60° crash conditions at the 26/13mph impact speed. The general rate of decrease in the dummy peak G levels with increase in the struck vehicle stiffness for log-normalized stiffnesses greater than the nominal were also calculated from straight lines connecting the extremums of the peak G levels. The results are shown in Table 6. (Note, since the sensitivities defined in this manner are mean values, they are expected to yield in some circumstances reduction trends that may

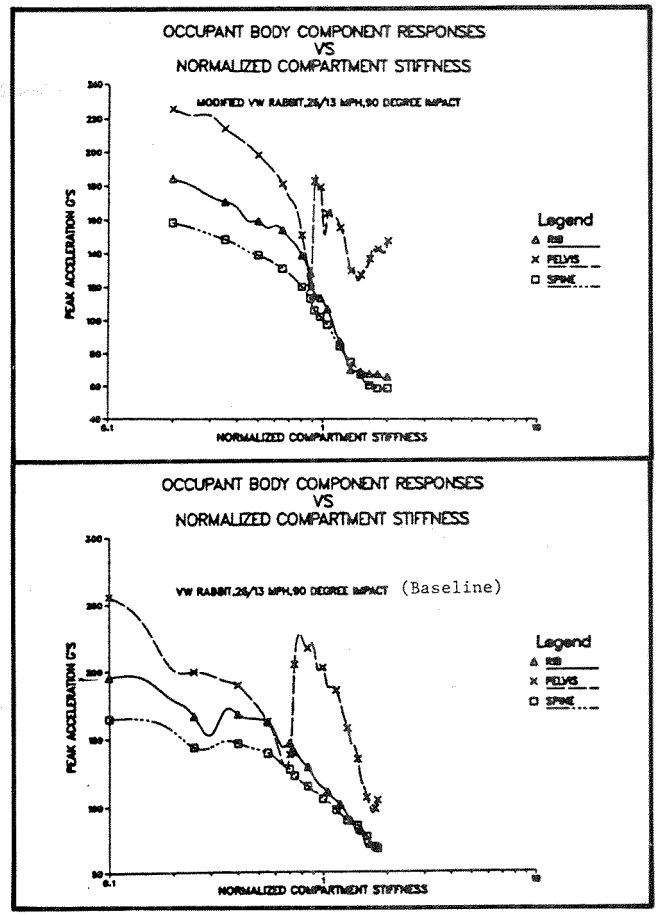

Figure 12. Dummy response as a function of normalized compartment stiffness for the baseline and modified vehicle at the low speed condition

differ from those trends discussed in the previous section.)

In general terms, these results indicate, for normalized stiffness values greater than the nominal, that the mean rate of decrease of the dummy peak G levels with stiffness depends to a large extent on the crash condition. For example, these results show that the mean rib peak G levels generally decrease with log-normalized stiffness at rates of about 80G for each doubling of stiffness for the MOD-90° crash condition, 57.0G for each doubling of stiffness for the BL-90° crash condition, and 32.0G for each doubling of stiffness for the BL-60° crash condition. Moreover, the mean peak G reductions for each doubling of stiffness are inherently higher for the pelvis than the rib and the spine. For example, in the BL-90° crash condition, the mean pelvis peak G levels are reduced by approximately 104.0G for each doubling of normalized stiffness, for the rib by approximately 57.0G, and for the spine by 42.0G, respectively. It should be further noted that when larger mean peak G level reductions were brought about through the struck vehicle stiffness changes for the pelvis, generally lower mean peak G level reduction resulted for the thorax and vice versa. This is best illustrated by the stiffness changes included in the BL-90° and MOD-90°

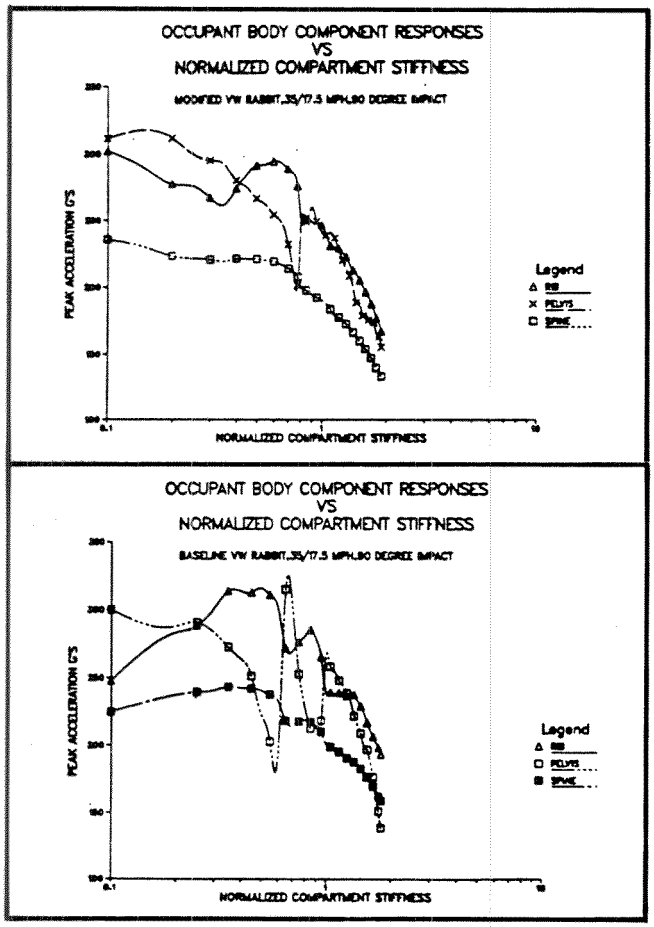

Figure 13. Dummy response as a function of normalized compartment stiffness for the baseline and modified vehicle at the high speed condition

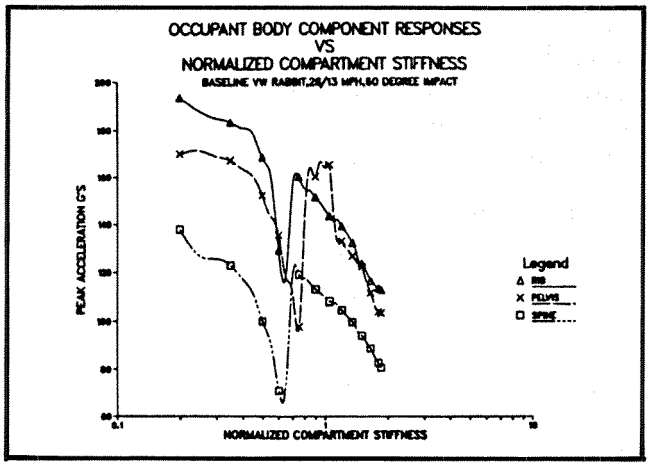

Figure 14. Dummy response as a function of normalized compartment stiffness for the baseline vehicle at a low speed 60° impact condition

crash conditions where the mean pelvis and rib peak G levels at the 26/13mph impact speed decrease with log-normalized stiffness at rates of about 104.0G and 57.0G for each doubling of stiffness for the BL-90° crash condition, respectively, and 87.0G and 80.0G for each doubling of stiffness for the MOD-90° crash condition, respectively. The thoracic mean sensitivity did not seem to change substantially with impact speed nor did the pelvis mean sensitivities.

In general, the rib and spine showed a higher rate of sensitivity with stiffness for the stiffer MOD-90° crash condition than for the softer BL-60° crash condition. The spine rates (although slightly lower) were of approximately the same order of magnitude as were the rib rates for the

Table 6. Compartment stiffness sensitivity coefficients (1.0 nominal impactor to door stiffness)

	Impact Speed MPH/MPH	GTR Padding Thickness	Estimated Mean Sensitivities* for Door to Compartment Stiffness Variations 90° Baseline	90° Modified	60° Baseline
Rib	26/13	no padding	57.0	80.0	32.0
	35/17.5	no padding	58.0	83.0	—
Pelvis	26/13	no padding	104.0	87.0	not able to define
	35/17.5	no padding	104.0	97.0	—
Spine	26/13	no padding	42.0	58.0	23.0
	35/17.5	no padding	40.0	52.0	—

* G reductions for each doubling of log-normalized stiffness.

two softer VW Rabbit door-to-passenger-compartment spring configurations (BL-90° and BL-60° crash conditions). However, this was not true for the stiffer MOD-90° crash condition where the spine rates were much lower than those simulated for the rib. Characteristically, the sensitivities increased (starting at low struck vehicle stiffness), reached a maximum value, and then decreased asymptotically to zero at the higher struck vehicle side stiffnesses where the door contacts the unrestrained driver dummy at the common velocity.

Striking Vehicle Stiffness Effects

Dummy Peak G Response Trends

Pelvis peak G levels were influenced the most through the MDB stiffness changes ranging from 0.6 nominal to 1.4 nominal stiffness (see Tables 2 through 4). Moreover, the BL-90° pelvis peak G levels were reduced more than the MOD-90° (stiffer side door) pelvis peak G levels at both impact speeds. For example, the results show that when the MDB-to-struck-door stiffness was reduced from 1.0 to 0.6 nominal, the baseline VW Rabbit's pelvis peak G level was reduced from 205.0G to 105.3G (49 percent) whereas, under identical conditions, the structurally modified VW Rabbit pelvis peak G level was reduced from 157.3G to 113.4G (28 percent). Futhermore, the pelvis peak G levels seemed as sensitive to the MDB-to-struck-door normalized stiffness changes as they were for the VW Rabbit door-to-compartment normalized stiffness changes for comparable changes in stiffness. Based on the local change in stiffness, for example, a decrease in the MDB-to-struck-door normalized stiffness from 1.0 to 0.8 nominal stiffness reduced the pelvis peak G levels by 41.1G for the BL-90° crash condition, by 3.06G for the MOD-90° crash condition, and by 24.3G for the BL-60° crash condition at the 26/13mph collision speed. An increase in the struck door-to-compartment normalized stiffness from 1.0 to 1.2 nominal reduced the pelvis G levels by 32.4G for the BL-90° crash condition, by 2.4G for the MOD-90° crash condition, and by 30.9G for the BL-60° crash condition.

Changes in the rib and spine peak G levels were small for the baseline VW Rabbit at impact angles of 60° and 90° due to pelvis interaction with a softer door-to-compartment interconnecting spring.

Sensitivities Due to Striking Vehicle Stiffness Changes

In general, for normalized striking vehicle stiffnesses less than the nominal, the mean rib and spine sensitivities (defined here as the mean rate of decrease in the dummy G level with decrease in striking vehicle stiffness) as expected are much lower in magnitude than those computed for the pelvis. The estimated rates indicate that the dummy peak G levels appear to decrease for the MOD-90° crash condition with log-normalized stiffness of about 86.0G for each halving of stiffness for the pelvis, 18.0G for each halving of stiffness for the rib, and 8.0G for each halving of stiffness for the spine at the 26/13mph impact speed. These rates also changed as the impact speed was increased from 26/13mph to 35/17.5mph. In this case, a lower mean rate of about 52.0G for each halving of stiffness was estimated for the pelvis, and higher rates were estimated for the rib and spine, 26.0G and 12.0G for each halving of stiffness, respectively.

Effect of Door Padding Thickness and Struck Vehicle Stiffness Changes

Dummy Peak G Response Trends

With the same door padding thicknesses at the rib and pelvis locations, an increase in the struck vehicle stiffness showed small benefits in reducing the rib peak G levels at the 26/13mph impact speed. Reductions were slightly higher when the struck vehicle stiffness was increased with a thicker door padding of 6in than with a thinner door padding of 3in. For example, the following rib peak G level reductions shown in Table 7 were calculated when the struck vehicle's stiffness was increased from 1.0 to 1.3 nominal. Also, at the higher impact speed, these reductions increased with increase in padding thickness.

With a padded door, the pelvis benefited most through increase in the struck vehicle stiffness. With no door padding, the pelvis peak G reductions were higher for the BL-90° than for the MOD-90°, and likewise at the higher impact speed of 35/17.5mph. For the BL-90° crash conditions with door padding, when the struck vehicle's stiffness was increased from 1.0 to 1.3 nominal, the pelvis G level reductions were approximately the same as with no padding on the door at the 26/13mph impact speed (see Table 8A). Note that at the lower impact speed of 26/13mph, the BL-90° pelvis peak G levels generally decreased with increase in the padding thickness when the struck vehicle's stiffness was increased from 1.0 to 1.3 nominal, whereas, at the higher speed of 35/17.5mph, the opposite trend was evident. For the MOD-90° crash condition, on the other hand, the pelvis peak G level reductions decreased with the increase in padding thickness at both impact speeds for padded door thicknesses greater than 3in (see Table 8B). Finally, these trends shown here indicate an increase in stiffness of a soft side structure plus the addition of door padding through thickness changes yields higher benefits in reducing the dummy peak G levels than padding thickness changes

Table 7. Occupant peak G level reductions as a function of GTR-pad thickness and crash condition due to increase in side stiffness from 1.0 to 1.3 nominal

	No Door Padding (Rib)	3in Padded Door (Rib)	6in Padded Door (Rib)
BL-90°	21.4G (reduction)[a]	6.2G (reduction)[b]	14.0G (reduction)[b]
MOD-90°	37.1G (reduction)	0.3G (reduction)	3.1G (reduction)
BL-60°	11.4G (reduction)	1.7G (reduction)	7.2G (reduction)

[a] Reduction due to increase in struck vehicle stiffness only.

[b] Reduction denotes, G(pad) - G(pad + struck vehicle stiffness)

alone. In addition, these benefits appear to increase through these two parametric changes with increase in the striking vehicle's speed.

Table 8. Pelvis peak G level reductions due to increased side stiffness from 1.0 to 1.3 nominal as a function of impact speed and GTR pad thickness

	(26/13mph) Pelvis, BL-90°	(35/17.5mph) Pelvis, BL-90°
	(A) BL-90° Crash Condition	
No Pad	48.7G (reduction)	34.3G (reduction)

3in Pad	21.0G (reduction)	39.2G (reduction)
6in Pad	7.6G (reduction)	24.4G (reduction)

Effect of Door Padding Thickness and Striking Vehicle Stiffness Changes

Dummy Peak G Response Trends

Changes reflecting reductions in the MDB stiffness affected both the thorax and pelvis peak G levels when the VW Rabbit door included the GTR pad. In general, the added GTR door padding through thickness changes and a softer MDB frontal structure combined together resulted in lowering the pelvis and upper thorax peak G levels. With a padded door, the peak G reduction levels were less for the pelvis and slightly higher for the rib when the MDB frontal structure was softened in comparison to an unpadded door. These decreasing pelvis and increasing rib reduction trends continued for doors with thicker GTR padding. This is actually due to the longer duration of time that both body components are in contact with the padded door and to the impact velocities of the rib and pelvis. As the GTR pad thickness was increased, the contact time became longer, and the pelvis G levels were less affected than the thorax peak G levels when the striking vehicle stiffness was reduced. This is illustrated in Table 9 where rib and pelvis peak G level reductions are shown for the case when the BL-90°, 26/13mph, MDB normalized stiffness was reduced from 1.0 to 0.8 and 0.6 nominal for three padded doors.

The sensitivity results shown in Tables 2 and 3 also show that with door padding included, the rib peak G levels were less affected when the MDB normalized stiffness was reduced from 1.0 to 0.8 and 0.6 nominal in the stiffer MOD-90° crash condition than in the BL-90° crash condition. For example, for the 6in-thick padded door, the rib peak G levels were reduced from 55.2G to 43.6G (21 percent reduction) and 45.4G (18 percent reduction), when the BL-90°, 26/13mph, MDB normalized stiffness was reduced from 1.0 to 0.8 and 0.6 nominal, respectively, and from 44.3G to 42.2G (5 percent reduction) and 43.4 (2 percent reduction) when

Table 9. Occupant peak G level reduction as a function of GTR pad thicknessw and striking vehicle stiffness changes (BL-90°, 26/13mph)

	MDB-Normalized Stiffness Reductions	No Padding Rib G-Reduction	No Padding Pelvis G-Reduction	3in Padding Rib G-Reduction	3in Padding Pelvis G-Reduction	6in Padding Rib G-Reduction	6in Padding Pelvis G-Reduction
				(Reductions relative to padded door)			
from	1.0 to 0.8	7.0	41.1	6.4	38.6	11.6	22.0
from	1.0 to 0.6	0.1	99.7	2.5	84.3	9.8	34.0

the MOD-90°, 26/13mph, MDB normalized stiffness was reduced from 1.0 to 0.8 and 0.6 nominal, respectively.

Larger dummy peak G level changes were also observed for the BL-90° configuration as the collision speed was increased. For example, when the MDB normalized stiffness was reduced from 1.0 to 0.6 nominal with a 6in-thick pad on the VW Rabbit door, the dummy rib peak G levels were reduced from 55.2G to 45.4G (18 percent reduction) at 26/13mph and from 97.5G to 74.2G (24 percent reduction) at 35/17.5mph. On the other hand, the rib peak G level changes were insignificant for the MOD-90° configuration as the impact speed was increased (0.9G reduction at 26/13mph and 1.8G reduction at 35/17.5mph, respectively).

Effect of GTR Padding Force Level and Shape Factor Change

Dummy Peak G Response Trends

The pelvis, rib, and spine peak G levels were not significantly affected by the GTR padding force level changes (0.8 nominal to 1.2 nominal strength) for the two GTR padding thicknesses of 3.0 and 6.0in. investigated. Actually, the GTR pad strength changes considered accounted for only marginal differences in the dummy-to-door contact spring force levels. Based on the results of the BL-90° crash condition at the 26/13mph impact speed where the VW Rabbit's side and MDB stiffnesses were varied, generally, an increase in GTR pad stiffness reduced the pelvis peak G levels and increased the rib and spine peak G levels. Other trends indicated are—

- Larger changes in the dummy component peak G levels at the lower GTR padding thicknesses than at the higher padding thicknesses
- Larger changes in the dummy component peak G levels at the lower normalized VW Rabbit door-to-compartment stiffnessess
- Very little to no change in the dummy component peak G levels for the 0.6 through 1.4 nominal stiffnesses considered for the MDB-to-struck-door spring

Based on limited calculations performed for the BL-90° crash condition, a change in the GTR-pad shape factor from 0.8 to 0.2 indicated—

- Further reductions in the pelvis peak G levels of the order of 10 to 20G's (The higher G level reductions were achieved with the thicker 6in pad.)
- Further reduction in rib peak G levels for normalized side structure stiffnesses less than the nominal and normalized MDB stiffnesses ranging from 0.8 to 1.2 nominal with a 3in-thick pad
- General trend toward increase in rib peak G levels when the VW Rabbit's side and MDB stiffness were varied with the 6in-thick pad

Thoracic Probability of Injuries

The results presented below are based on NHTSA-developed relationships that indicate the thoracic probability of injury as a function of the TTI for various AIS values.

Here, the thoracic probability of injuries in a 30-year-old for an AIS greater than or equal to 3 are considered. This probability of injuries is based on the rib and spine peak G levels predicted for the BL-90°, MOD-90°, and BL-60° crash conditions as a function of GTR padding thickness changes, striking and struck vehicle stiffness changes, and impact speed. These results indicate that—

1. At the lower impact speed of 26/13mph, the 6in-thick GTR pad effectively reduced the thoracic probability of injury below 14 percent in both 60° and 90° impacts. The lowest thoracic probability of injury (6.6 percent) resulted for the MOD-90° crash condition with a 6in-thick padded door.
   6.6 percent for MOD-90° crash condition
   13.6 percent for BL-90° crash condition
   12.5 percent for BL-60° crash condition
2. Side stiffness plus door padding rendered additional benefits above those already achieved with door padding alone in lowering further the thoracic probability of injury. However, these benefits were small, particularly for the strengthened side (MOD-90°) crash condition, which showed only a marginal change in thoracic probability of injury. For example, for the 26/13mph impact condition, the thoracic probability of injuries was reduced to—
   4.9 percent compared to 6.6 percent (padding only) for MOD-90°
   5.1 percent compared to 13.6 percent (padding only) for BL-90°
   6.3 percent compared to 12.5 percent (padding only) for BL-60°
   by increasing the side stiffness by 1.3 nominal of a 6in-thick GTR padded door.
3. As expected, higher thoracic probability of injuries resulted when the collision speed was increased from 26/13mph to 35/17.5mph. As far as the side structure of the VW Rabbit vehicle was concerned, much larger increases in the thoracic probability of injuries were indicated for the BL-90° than for the MOD-90° crash conditions. As an example, the following thoracic probability of injuries resulted for the 35/17.5mph impact speed for a door with a 6in-thick GTR pad:

26.5 percent for MOD-90° crash condition
65.2 percent for BL-90° crash condition

Both side stiffness and door padding clearly showed some advantage.

4. The thoracic probability of injuries was not substantially reduced at the higher impact speed through increase in the struck VW Rabbit stiffness from 1.0 to 1.3 nominal alone or through decrease in the striking MDB stiffness from 1.0 to 0.6 nominal alone.

Conclusion

An investigation was undertaken characterizing, parametrically, the thoracic and pelvic acceleration response levels of a driver dummy during side impacts from a lumped nonlinear spring/mass model. Force-deflection characteristics were derived from three different crash conditions where the striking vehicle engaged the struck vehicle's door during the collision. Padding force-eflection characteristics were based on a GTR pad used in car crash tests. The parameters considered included striking vehicle stiffness, struck vehicle stiffness, impact angle, impact speed, and door padding thickness and stiffness. Based on these results, sensitivities and thoracic probability of injuries were computed. The following conclusions are based on the driver dummy in a normal seated position located 4in from the door.

Model Features and Capabilities

1. The response of the dummy is a dynamically coupled process related to the interactions of the dummy with the door. The time of impact of the dummy's body components with the door, the duration of the contact of these body parts with the door, and the corresponding door velocities and accelerations influence the outcome of their peak G levels.
2. The lumped mass model was validated with experimental data over a range of impact speeds and shows reasonable agreement for the rib, pelvis, and spine. No attempt was made to verify the parametric changes investigated in this study with tests. However, they show trends consistent with some of the findings from dynamic tests in (4). The model in its present form is incapable of predicting the head response, since the model did not include the appropriate head-to-neck spring compliance or the head-to-contact-surface spring resistance.

General Observations

1. The driver dummy's peak upper thorax (rib and spine) and pelvis G levels were reduced through (1) increased padding thickness, (2) increased door-to-compartment stiffness, (3) decreased MDB-to-struck-door stiffness, and (4) decreased impact speeds.
2. Much larger G level reductions appeared for the pelvis than for the thorax through all of the above parameter changes explored in this study.
3. Different degrees of sensitivities were observed among rib, pelvis, and spine peak G levels for the parametric changes in padding thickness, MDB, and struck vehicle stiffness.

Effect of Door Padding

1. Door padding of various thicknesses, in general, was found to be a very effective countermeasure explored in this study in reducing the dummy thorax and pelvis peak G levels. (This is based on the GTR door padding used in car crash tests.)
2. For upper thorax peak G level reductions, the relative effect of padding is more pronounced at the higher than at the lower impact speeds.
3. The reduction/in of added GTR padding seemed generally to be independent of the impact angle and stiffness changes to the side structure or the MDB frontal structure.
4. The rate of reduction of the peak thoracic acceleration is high up to a certain thickness of padding. The effectiveness is reduced as the padding thickness is further increased. This padding thickness varies depending on the impact speed.
5. The upper thorax (rib and spine) peak G levels seem to be less sensitive to padding thickness changes at the lower (26/13mph) impact speed than at the higher (35/17.5mph) impact speed, and the rib peak G levels seem to be more sensitive than the spine peak G levels to the GTR padding thickness changes examined. The pelvis peak G levels, on the other hand, seem to be as sensitive as the rib peak G levels were to the GTR padding thickness changes at the lower speed and less sensitive than the rib peak G levels were to padding thickness changes at the higher speed. These sensitivities ranged for the smaller size GTR pad anywhere from 17G to 23G reduction/in of added padding for the rib, 16G to 20G reduction/in of added padding for the pelvis, and 7G to 8G reduction/in of added padding for the spine at the 26/13mph impact speed and 40G to 49G reduction/in of added

padding for the rib, 15G to 20G reduction/in of added padding for the pelvis, and 19G to 21G reduction/in of added padding for the spine at the high 35/17.5mph impact speed. The thorax exhibited a wider variation in the sensitivity with increase in the GTR pad thickness.

6. Altering the force levels of the general force-deflection shape of the pad did not significantly affect the upper thorax and pelvis peak G levels. However, a general change in shape could potentially produce beneficial differences.

Effect of Side Structure and Striking Vehicle Stiffness

1. Increased side structure stiffness reduced the dummy peak G levels. The increased side structure stiffness affected the pelvis peak G levels more than the upper thorax peak G levels.
2. A softer striking vehicle frontal structure offered small benefits in reducing the upper thorax G levels. Pelvic responses, on the other hand, were found to be reduced by decreases in stiffness of the MDB.
3. The rate of decrease of the driver dummy peak G levels with increases of the side structure stiffness seems dependent on the crash condition. The mean rib peak G levels decreased with log-normalized stiffness at rates of about 80.0G for each doubling of stiffness for the MOD-90° crash condition, 57.0G for each doubling of stiffness for the BL-90° crash condition, and 32.0G for each doubling of stiffness for the BL-60° crash condition. Moreover, the G level reductions for each doubling of stiffness were higher for the pelvis, followed by the rib and spine in that order (for example, for the BL-90° crash condition, the mean pelvis peak G levels were reduced by about 104.0G for each doubling of stiffness, the mean rib peak G levels were reduced by 57.0G for each doubling of stiffness, and the mean spine peak G levels were reduced by about 42.0G for each doubling of stiffness).
4. Substantially lower sensitivities were indicated for the rib and spine for MDB-to-struck-door stiffness changes less than the nominal. For example, for the MOD-90° crash condition, the mean of the dummy G levels decreased with log-normalized stiffness at a rate of about 86.0G for each halving of stiffness for pelvis, 18.0G for each halving of stiffness for rib, and 8.0G for each halving of stiffness for spine at the 26/13mph impact speed. These sensitivities increased with impact speed for rib and spine.

Effect of Door Padding Plus Side Structure and Striking Vehicle Stiffness

1. The combination of padding and increased side structure stiffness seems to provide the best reduction for the G-level magnitudes investigated for soft side structures. However, the reductions achieved because of the increased side structure stiffness are proportionately less and generally could be achieved through further increases in the GTR padding thickness. (It is clearly obvious that padding thickness is limited by space and other considerations in cars.)
2. For a padded door, increasing the side structure stiffness or decreasing the struck vehicle stiffness seems to have more of an effect in reducing the thorax G level than in reducing the pelvis G levels. Generally, as more door padding is added, the pelvis peak G level reductions decreased and the thorax G level reductions increased through these two stiffness changes.

Acknowledgments

The authors wish to express their sincere appreciation for the many suggestions offered throughout the course of this work to Mr. James R. Hackney (DOT-NHTSA/NRD), Mr. John E. Tomassoni (DOT-NHTSA/NRM), and Mr. Herbert H. Gould (DOT-RSPA/TSC). Special thanks is also extended to Mr. John D. Guglielmi (DOT-RSPA/TSC) for his many valuable contributions.

Inclusion of Crashworthiness in Concept Design

G.D. Suthurst and

Cranfield Impact Centre, United Kingdom

Abstract

A side impact study carried out on a particular vehicle has been described and used as a case study to represent a methodology for incorporating side crashworthiness in a new vehicle concept design. In the automotive design environment, it has proved difficult to include side crashworthiness satisfactorily in the initial stages of the passenger car design. Lack of vehicle data at such a stage does not allow detailed finite element analysis. It is, however, possible to suggest the required collapse properties for individual components within the structure so that, through a coarse finite element idealization, a design for crashworthiness can be carried out. The crash properties of the structure can be arrived at by parametric studies of individual components that are absorbing the major portion of the crash energy.

This paper describes a methodology that, as a tool, can be used at the start of a vehicle program enabling the side impact performance to be monitored continuously and thus the structure to be designed in the most efficient way for a specified level of side crashworthiness. This has major advantages over current methods where a late finite element analysis or a late crash test is the first indication of how well a vehicle meets a specified standard and, if unsatisfactory, the necessary structural modifications are normally costly and result in inefficiencies in design and manufacturing processing.

Introduction

The inclusion of a good crashworthiness performance is a prime objective in any new vehicle concept development. It would be ideal if the implications of a good performance could be evaluated at the same early stage when marketing studies, alternate packages/clay models, legislative reviews, and manufacturing process decisions are taking place. Such an ideal system must be capable of assessing concept changes quickly and producing structural guidelines for an acceptable performance in return.

In the absence of any physical systems to test for performance at this stage, side crashworthiness assessments must depend on past experience or the development of a nonlinear finite element analysis that takes into account the nonlinear behaviour and large-scale deformations associated with crash conditions. The current state of the art of such nonlinear finite element codes, combined with a lack of essential detailed structural data for the analysis at the concept stage, makes a crashworthiness prediction difficult. This paper describes a test methodology for side collisions that overcomes many of these difficulties by combining known structural data with a coarse finite element model based on the new vehicle package.

It allows a continuous assessment to be made of side impact performance including structural collapse, energy absorption, impacted vehicle trajectory and occupant kinematics, and injury levels. The continuous interchange of data between the finite element model and the new vehicle design is an essential feature of the methodology providing broad guidelines initially and becoming more detailed as the structure develops. This results in minimum crash testing since the first crash test is more to confirm a performance level that has been continuously monitored than to determine a level that normally then requires modifications to achieve the desired standard.

This paper shows its application in relation to the development cycle of a new model and how it substitutes for a detailed finite element model initially and subsequently complements it in the later stages. Validation of the methodology is also discussed, and a typical case study is included that demonstrates the procedure from the initial concept stage.

The Side Impact Methodology

The basic problem with finite element analysis is well known and is demonstrated in Figure 1.

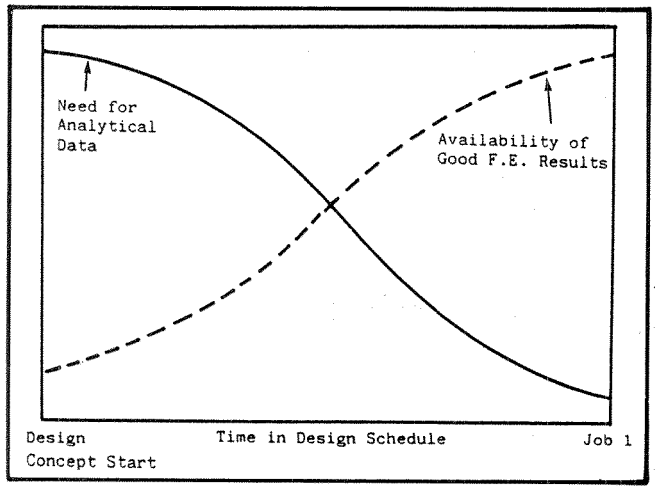

Figure 1. The problem with finite element analysis

This problem is compounded when considering nonlinear finite element codes where the state of the art is such that programs are large, complex, and costly, and meaningful results are usually only available late in the design cycle when their results are too late to influence the design. The methodology adopted for side impact crashworthiness studies is shown in graphical form in Figure 2.

The concept here is to use the previous vehicle component data—established by tests—assembled into the new vehicle package and the performance assessed initially relative to the new vehicle. Shortfalls in performance due to the new package can be established and, using parametric studies, guidelines can be produced to obtain a specific performance. As shown in the figure, as more detailed structural data become available, a detailed finite element model can be developed, eventually taking over from the initial coarse beam model, but the initial model is still available for a quick assessment of major vehicle modifications.

The methodology consists of a suite of programs:

- SimSim 1—a nonlinear large deformation beam element structural finite element method
- SimSim 2—a vehicle rigid body and dynamic deformation program
- Calspan 3D—a crash victim simulation program

The most important part of the methodology is the SimSim 1 program as the vehicle structural integrity largely determines the side impact occupant protection performance, assuming a standard crash test procedure. Due to its hybrid nature, this program can be used in the concept stage of a new vehicle. It uses test-derived data on the nonlinear behaviour of beams and joints, and analyses the overall collapse behaviour of the assembled structure. The contribution of each individual element in the structure can also be quantified.

The SimSim 1 structural result is then used in the SimSim 2 program, which is able to simulate a 90° side impact test. This program will predict the vehicle trajectory as well as the dynamic side structure deformation of the impacted vehicle in the collision.

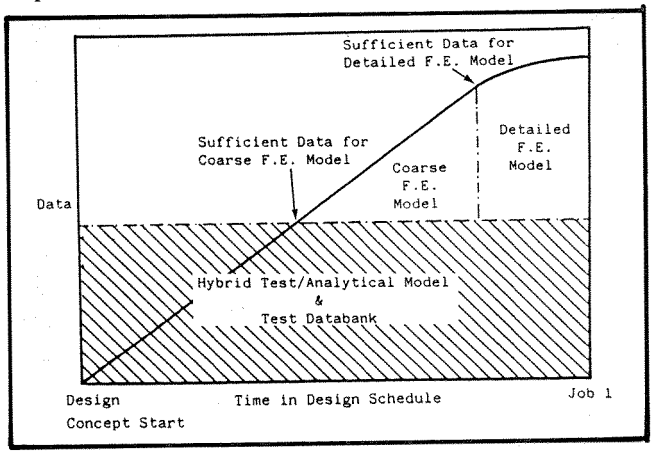

Figure 2. Crashworthiness model

Finally, the effects of such structural and vehicle dynamic behaviour on the occupant can be assessed by utilising the SimSim 2 results into an occupant simulation program, e.g., Calspan 3D CVS program.

The methodology is well suited for early crashworthiness parametric studies as a typical analysis turnaround time is an hour and the analysis costs are in the order of pounds sterling per run. A detailed description of the programs is to be found in the Appendix.

Application of the Methodology

The application of the methodology in a design environment is envisaged as follows (Figure 3):

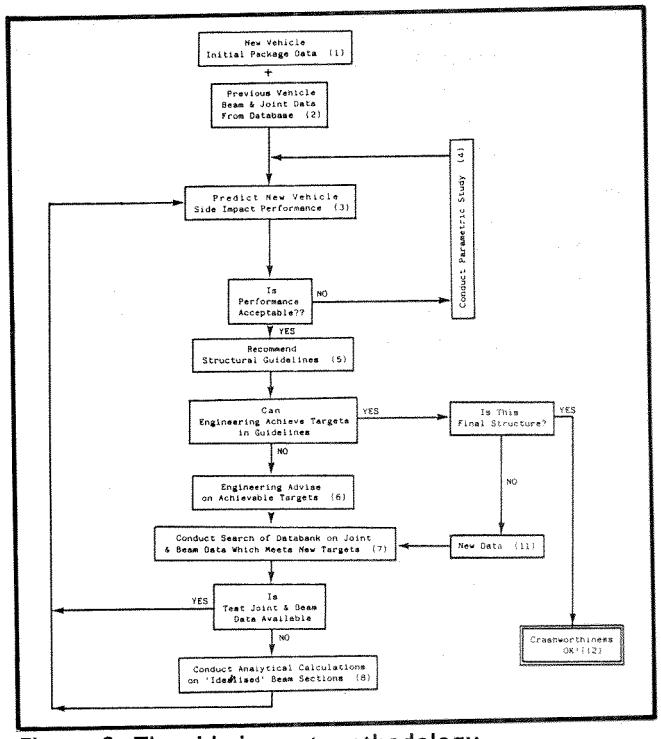

Figure 3. The side impact methodology

- Step 1—The new vehicle package data are obtained, and a beam model is assembled using the SimSim 1 program.
- Step 2—The beam and joint data required by the SimSim 1 program are initially assumed to be similar to the previous vehicle; a valid assumption as the design of new vehicles is generally evolutionary. New structural configurations (e.g., a new 5-door variant) can be analysed using existing structural element data (e.g., B-pillar) from other vehicles, which are stored in a computerised databank.
- Step 3—The initial side impact performance for the new vehicle is established by the SimSim 1, SimSim 2, and Calspan programs. Redundant or overstressed structural elements can be highlighted.

- Step 4—If the performance is not acceptable in relation to legislative or corporate standards, a parametric study can be conducted to optimise the side impact performance.
- Step 5—When the performance is acceptable, design guidelines on the side structure can be recommended, e.g., cross-section area.
- Step 6—Engineering/manufacturing advice on the achievable structural targets.
- Step 7—A search of the databank for suitable beam and joint data to meet the new structural targets.
- Step 8—If the data are unavailable, analytical calculations can be made to derive the required beam and joint nonlinear data using idealised cross-section shapes for the particular element(1).
- Step 9—Repeat Steps 3-8 updated with achievable engineering targets until a satisfactory and workable set of design guidelines can be established.
- Step 10—Initiate detailed finite element techniques for identified problem areas, e.g., weak joints if appropriate.
- Step 11—Return to methodology as more data are available due to hard points approval or design changes.
- Step 12—Achieve specified crashworthiness targets.

Validation of the Methodology

The validation of the methodology was conducted using crash test results in which a European hatchback was subjected to a 90° side impact with a CCMC (Committee of Common Market Automobile Constructors) mobile deformable barrier as the impactor. The impact velocity of the barrier was 50km/h, as currently under discussion in Europe for side impact test procedures.

Figure 4 shows a good comparison of the impacted vehicle centre-of-gravity velocity of simulation (SimSim 2) versus the test result.

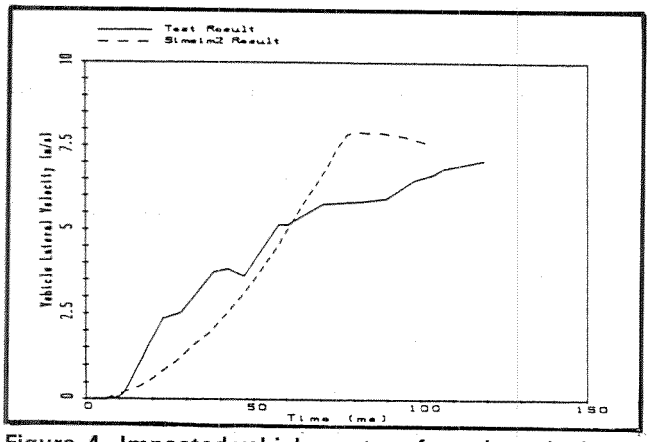

Figure 4. Impacted vehicle centre-of-gravity velocity of SimSim 2 simulation and test result

Figure 5 shows a better comparison of the B-pillar velocity of the impacted vehicle. This result is more important as it determines the injury levels inflicted on the occupants.

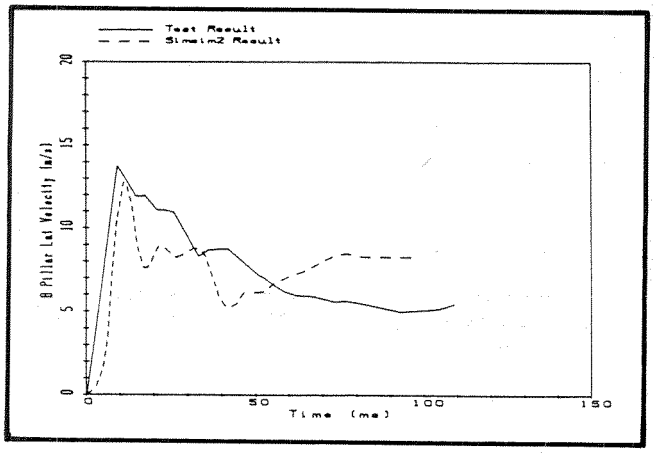

Figure 5. Impacted vehicle B-pillar velocity of SimSim 2 simulation and test result

Figures 6 and 7 are comparisons of velocities of the chest and pelvis of the impact dummy for the simulation and test results. In view of the simple structural models analysed and the low computer resource usage, the comparison of the simulation with the test result is very good.

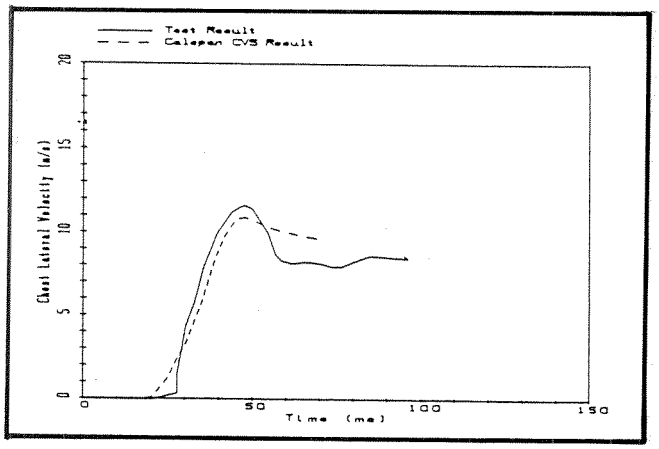

Figure 6. Driver chest velocity of Calspan CVS simulation and test result

Case Study of the Methodology

A case study was conducted to test the capabilities of the methodology. The vehicles selected were concept studies for a new European 3/5-door hatchback for which only package information was available. Suitable beam and joint data from the previous vehicle were used except for the 5-door vehicle whose B-pillar data were assumed from a similar vehicle.

Structural models for the 3- and 5-door vehicles were assembled using the geometric data from the new vehicle package information but using the previous vehicle beam

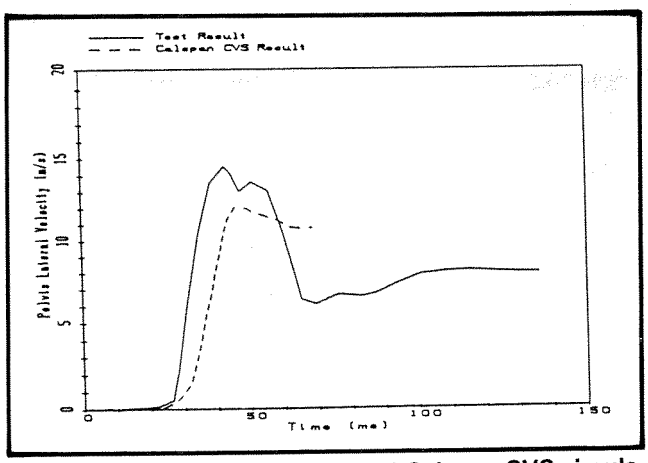

Figure 7. Driver pelvis velocity of Calspan CVS simulation and test result

or joint data. The SimSim 1 program was able to simulate the collapse mechanism of the structure when impacted in the side by the CCMC mobile deformable barrier (Figures 8a and 8b). It was also able to quantify the

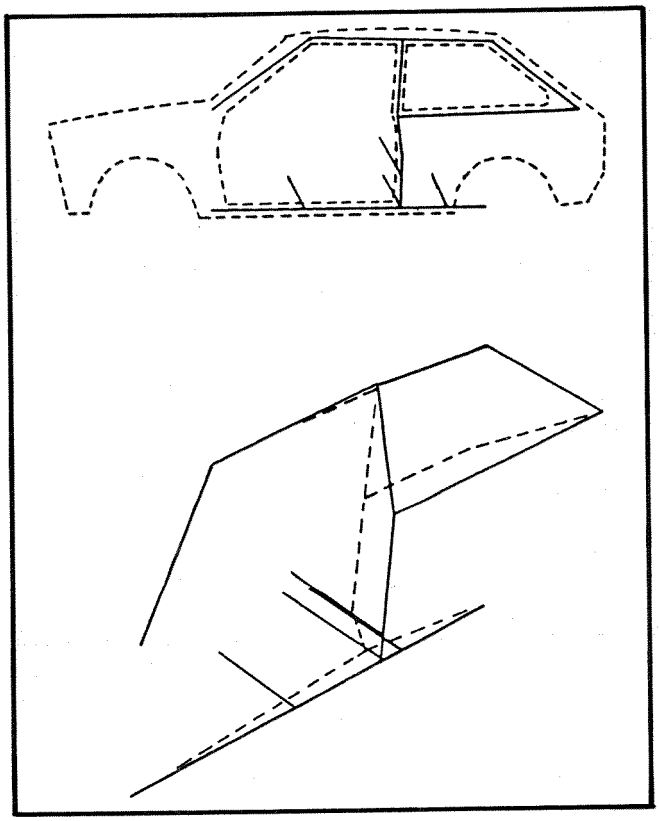

Figure 8a. Initial 3-door vehicle and structural model

structural contribution of each failed beam element by calculating the crash energy absorbed (Figure 9). The results showed the bottom of the B-pillar (A) in the 3- and 5-door initial vehicle designs absorbed up to 25 percent of the crash energy. This will result in excessive deformation in the B-pillar assembly. The structural integrity of the B-pillar is important in preserving the occupant survival

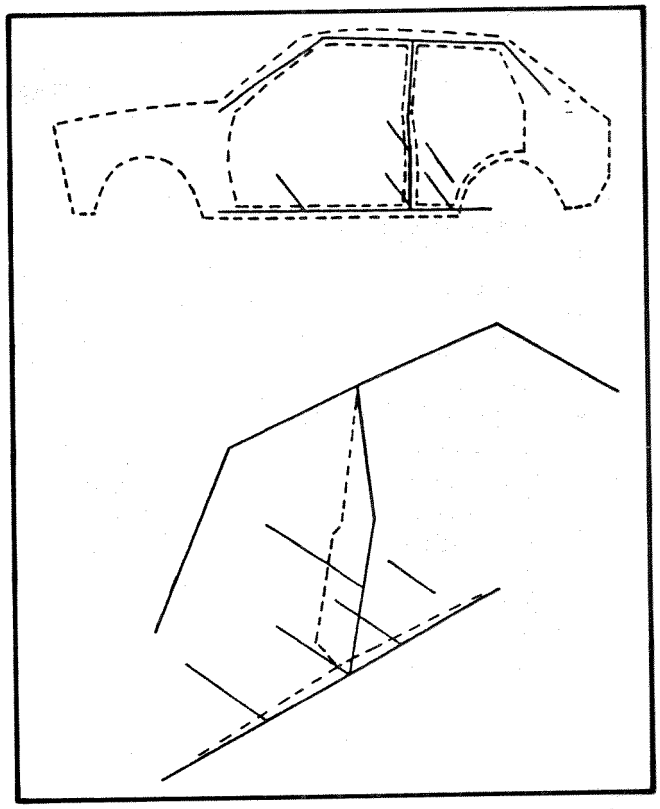

Figure 8b. Initial 5-door vehicle and structural model

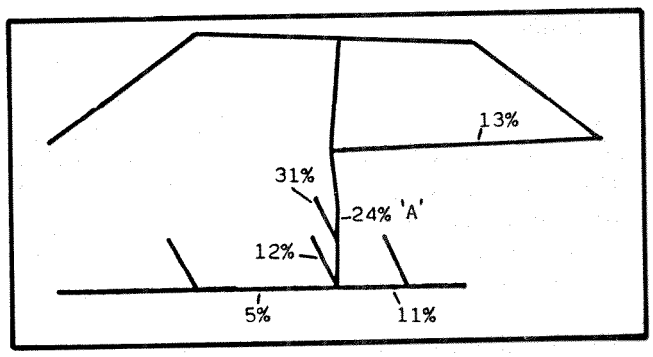

Figure 9a. Initial 3-door vehicle

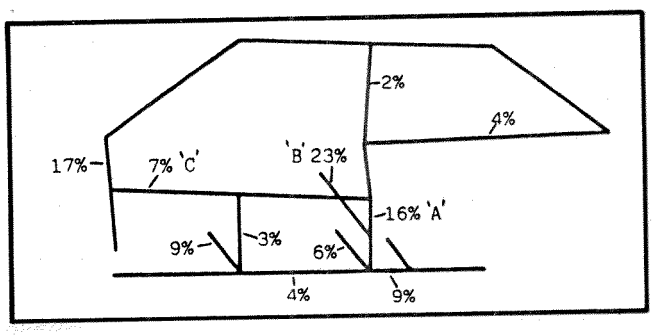

Figure 9b. Optimised 3-door vehicle

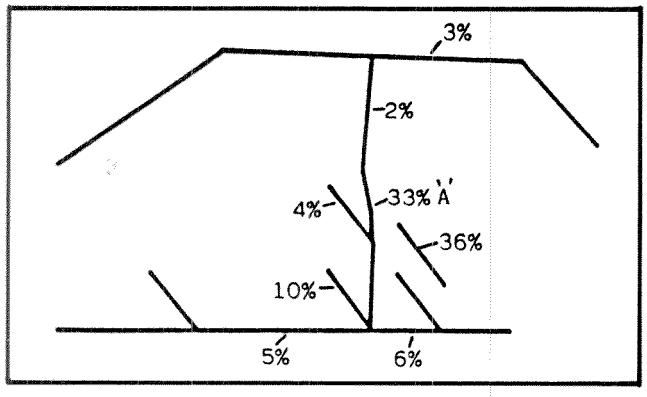

Figure 9c. Initial 5-door vehicle

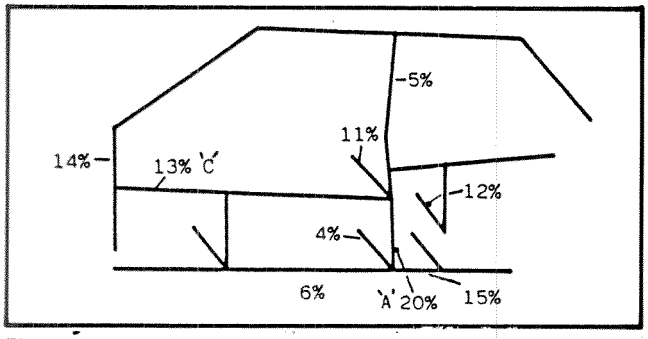

Figure 9d. Optimised 5-door vehicle

space. A weak B-pillar assembly will tend to pull the door toward the seated occupants. SimSim 2 and Calspan occupant simulations were also conducted to establish the initial side impact protection for both vehicles. These results will be presented later for comparisons.

Having established the initial performance, a parametric study was conducted to achieve the required performance. The structural criterion used was to limit the side structural collapse by distributing more evenly the loading by the impacting vehicle into as many beam elements as possible, preventing large local structural deformations.

Various structural configurations were investigated by including additional structural elements in the initial vehicle designs and modifying the beam or joint properties in these configurations. Only the results of the initial and optimised vehicles are presented here, for clarity.

The methodology showed the best results were achieved by structural compatibility through additional structural elements (e.g., door intrusion beams) and increasing the beam or joint properties of the structure. The optimised structural configurations studied were as follows: (Figures 9b and 9d)

- An increase in the B-pillar properties (A), significant increase in the rear-seat pan property (B), and the addition of a door intrusion beam (C) for the 3-door vehicle
- Increases in the B-pillar and rocker panel properties (A) and the addition of a door intrusion beam (C) for the 5-door vehicle

Note: The increases in the B-pillar and rocker panel properties are increases in the joint linear and nonlinear properties in these areas and not the beams themselves. This is because joints are normally the weak areas in the side structure and will fail before the beams.

Figure 9 shows the distribution of the crash energy absorbed throughout the structures in both the initial and optimised vehicles. The consequence of this optimisation is that there will be a reduction in the deformation of the B-pillar assembly in the optimised vehicles. Figure 10 shows a significant increase in the B-pillar strength over the initial vehicles. Using a standard 3kJ crash energy input, the deformation predicted by SimSim 1 showed a significant reduction in the B-pillar deformation in the optimised initial vehicles (e.g., 147 to 70mm for a 3-door and 175 to 67mm for the 5-door variant).

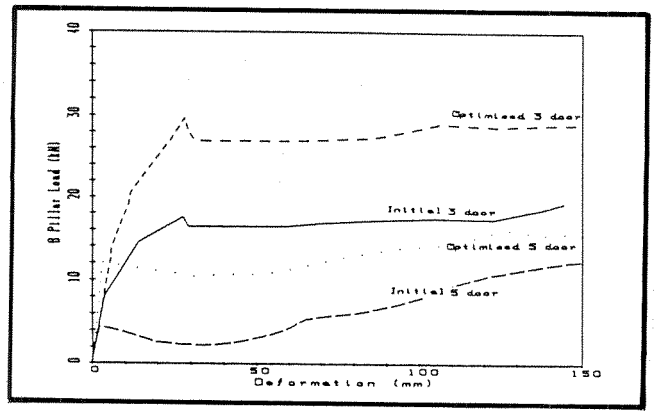

Figure 10. B-pillar stiffness characteristic for 3- and 5-door SimSim 1 structural models

These trends were also seen in the SimSim 2 results in Figure 11 where there is a significant reduction in the B-pillar deformation in the optimised vehicles.

Finally, the effects of the improvements were seen in the Calspan results (Table 1). The effect of reducing the side structure velocities resulted in the reduction of injuries sustained by the occupants (e.g., lower HSI and CSI induces) and dummy accelerations.

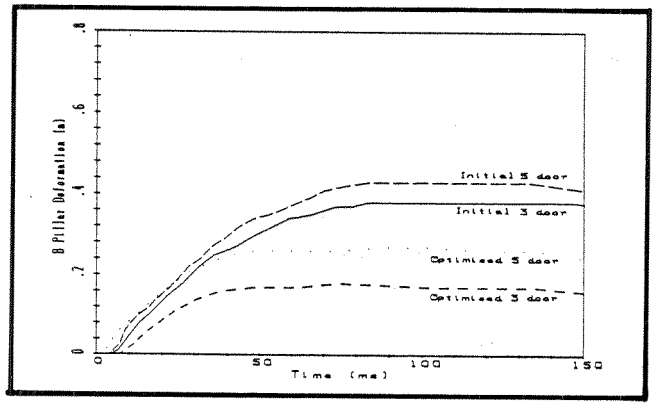

Figure 11. SimSim 2 results of B-pillar deformation at waist height for 3- and 5-door structural models

Table 1. Calspan CVS results

CVS Analysis	Initial 3 door Vehicle	Optimized 3 door Vehicle	Initial 5 door Vehicle	Optimized 5 door Vehicle
Max Velocity of Side Structure (m/s)	12.5	10.7	15.2	12.7
Velocity of Side Structure on Contact with Dummy (m/s)	12.5	10.2	15.1	12.2
Velocity of Side Structure at Chest Velocity of 0.1 m/s (m/s)	7.9	4.7	9.9	7.2
Head Injury Criteria (HIC)	138.0	67.0	224.0	94.0
Max Lateral Head Acceleration (g)	29.5	21.2	31.8	22.7
Chest Severity Index (CSI)	375.0	154.0	497.0	229.0
Max Lateral Chest Acceleration (g)	67.3	49.5	76.2	51.8
Max Lateral Chest Velocity (m/s)	10.5	7.8	12.5	8.9
Max Lateral Pelvis Acceleration (g)	110.0	80.6	117.5	83.9
Max Lateral Pelvis Velocity (m/s)	12.0	8.5	14.4	9.8

An example of the Calspan results output is shown in Figure 12. When the methodology has been established in an engineering environment, it should be possible to conduct a similar parametric study in a man-month analysis time.

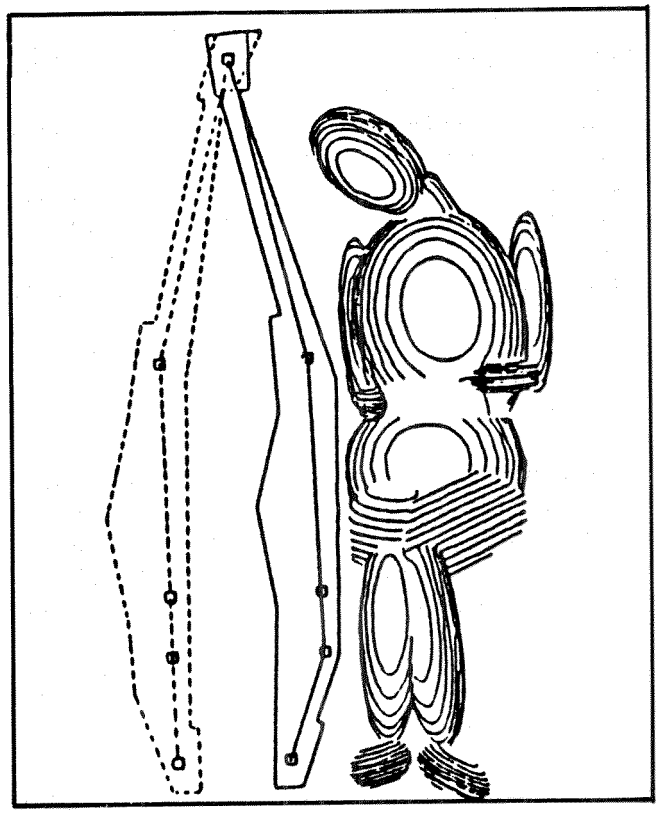

Figure 12. Calspan result showing dummy kinematics and impacted door deformation

Conclusion

- It has been shown that the described methodology can be used, at the early concept design stage of a new vehicle development, to achieve a specified side impact performance.
- Guidance at this early stage in the vehicle development will result in a more efficient design/structure and a more efficient manufacturing process. This will have benefits in the cost and weight of the vehicle and with additional development savings through the reduction in the number of crash tests that are currently necessary to achieve a specified crashworthiness performance.
- This type of hybrid prediction method has a short analysis turnaround time compared to other nonlinear finite element codes and has the additional benefit of improved accuracy through the inclusion of empirical data.

- The short analysis turnaround time and the low computer running costs enable the structural model to be up to date with the latest design update in the vehicle program, thus allowing a continuous interchange of data between the finite element model and the vehicle design.
- Finally, with its ability to predict the effects of a side collision on the structure, vehicle trajectory, and the occupants in the impacted vehicle, the methodology is ideal to use to assess and influence impending side impact legislation so that practical and achievable requirements are specified.

Further Developments

Developments are underway to reduce the reliance on test beam and joint data, i.e., to refine the methodology toward a more analytical approach. Investigations will be made to see if it is possible to develop a computer code to predict the linear and nonlinear properties of any given cross section of a beam. This will enable elastic buckling failure of the cross section of a beam to be examined as this mode of failure limits its theoretical load-carrying capability. This analytical capability will enable optimisation of the cross section of the beam elements and assess the influence of access holes, flanges, etc. The SimSim 1 structural analyses can then begin with optimised beam sections.

Acknowledgments

The authors would like to express their thanks to K. Stone of the Ford Motor Company and R. Hardy of the Cranfield Impact Centre for their valuable contributions during the development of this methodology.

Appendix

SimSim 1 Program

The SimSim 1 program is a customised coarse mesh beam element nonlinear finite element code. It is well suited to analysing vehicle structures in side collisions as these structures are essentially beams in bending. Other modes, e.g., compression and torsion, can also be simulated. It is a hybrid program that analyses elastic behaviour from traditional beam theory but requires test-derived nonlinear material behaviour to determine the nonlinear behaviour of the structure.

The program is based on a matrix method of structural analysis that is able to simulate large deformations plus the local and global collapse mechanism in a side structure of a vehicle. The stiffness matrix of the structure is assembled, and the loading increment (force or displacement) is applied. After each loading cycle, the beam element's internal loads are compared with its failure load derived from beam and joint tests in a yield criterion check. The program can simulate nonlinear behaviour such as perfectly plastic (i.e., the beam can maintain its load-bearing capability after failure) or moment drop off (i.e., the load that the beam can support before failure falls off rapidly after it has failed).

The program takes into account the deformations in the structure and any remaining beam strength before failure in the previous load cycle. The loading of the structure continues until either the structure collapses or the load limit is reached.

The program incorporates some useful features such as—

- The crash energy absorbed by each element due to plastic deformation can be analysed and quantified in relation to the input energy.
- A restart option allows any changes to be made to the structural model during the analysis due to changes in the boundary conditions, etc.
- The loading increments can be automatically scaled to insure the beam or joint yield failure behaviour determined by tests will be accurately modelled in the analysis.
- The finite stiffness of joints can be taken into account as they can significantly degrade the analysis result.

The application of this analysis method will lead to a better understanding of the behaviour of structures under side collision conditions and provide input to the SimSim 2 program to analyse the impacted vehicle motions.

SimSim 2 Program

SimSim 2 is a computer code developed to predict the rigid body motions and vehicle side deformations experienced in a 90° side collision.

The side collision dynamics are simulated by a series of unidirectional spring-mass systems representing the impacting and impacted vehicles while in contact with one another. The spring elements represent the impacting vehicle front end stiffness characteristics and impacted vehicle side structure stiffness characteristics. The mass elements represent the mass of both impacting and impacted vehicles, assuming the proportion of the mass of the impacted vehicle side structure is negligible compared with its overall mass. The impacting vehicle or mobile barrier front-end stiffness characteristics are obtained from vehicle crash tests, and the impacted vehicle side structure stiffness characteristics are derived from the SimSim 1 nonlinear analyses. The program can then predict the side structure dynamic deformations experienced in the side collision.

General equations of motions, together with the impacted vehicle tyre and suspension data, are utilised to predict the whole vehicle motions (e.g., centre-of-gravity velocity, yaw, and pitch).

The vehicle centre-of-gravity velocity and the side structure deformation data are used in an occupant simulation program to assess the effects of the collisions on the occupants. When these data are unavailable for a new vehicle due to lack of tyre and suspension data, the impacted vehicle rigid body motions can be calculated from crash test data of similar vehicles, taking into account the new vehicle mass and side structure stiffness characteristics.

The use of the SimSim 2 program, together with the occupant simulation program, will help to understand fully the effects of the collision on the occupants. The Calspan program is not described here as it is well documented in past conference papers.

Development and Testing of Optimized Deformation Structures

Florian Kramer and
Alfred Heger
Institut für Fahrzeugtechnik, Technische Universität Berlin

Abstract

To improve occupant protection in side collisions, it is not sufficient to consider only lateral structures deformation characteristics. It is also necessary to modify frontal structures, which are generally designed for rigid barrier frontal impacts.

In the following study, an analytical simulation model is used to optimize lateral as well as frontal deformation structures of passenger cars. The aim of the optimization is to minimize the risk of injuries of passenger car occupants, considering all relevant types of car-to-car and car-to-obstacle accidents.

Structures built according to the analytical results are likely to show differences in their dynamic behavior compared with the calculated characteristics. As the analytical optimization yields optimum reduction of occupant loadings, differences of actual structures do not lead to optimally low loadings. Restrictions have to be considered as to what extent nonoptimal reductions in safety can be accepted.

In full-scale tests and component tests, the performance of the structures has to be demonstrated.

The Analytical Optimization of Vehicle Structures

The aim of the research project "Occupant protection"[1] was the optimization of deformation structure characteristics of the front and lateral areas in vehicles of various weights, as seen from the economic aspect (Figure 1).

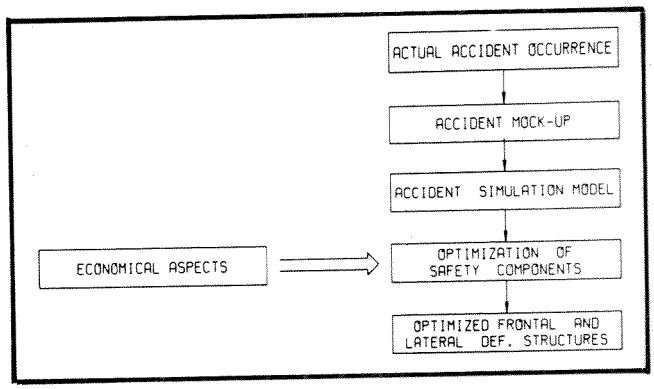

Figure 1. Aspects of development of passenger cars considering economically optimal occupant protection

[1] "Development of passenger cars with regard to optimum occupant protection from an economical aspect," promoted by the Federal Ministry of Research and Technology and carried out by the parties working in cooperation: Volkswagenwerk AG (project management), Institut für Fahrzeugtechnik der Technischen Universität Berlin, Dr. Ing.h.c. F. Porsche AG and HUK-Verband.

Accident Occurrence

The complexity of the actual accident occurrence was taken into consideration by condensing the essential factors influencing the injuries of the vehicle occupants, such as type of collision (frontal and lateral collisions for vehicle/vehicle accidents and for single-vehicle accidents), mass distribution and impact speeds, to one accident mock-up with the aid of a relevant analysis. The accident mock-up consists of 57 different individual accidents: vehicle/vehicle accidents, 18 frontal and 27 lateral; vehicle/obstacle accidents, 6 frontal and 6 lateral; with three reference vehicles of various weights and 3- and 2-speed classes, respectively(1).

Simulation Model

A mathematical simulation model was developed on the basis of extensive accident data analysis and detailed evaluation of crash tests. Despite the necessary simplifications, this model clearly illustrates the manifold interrelationships between the deformation structures of the vehicles involved in collisions and their effect on the severity of injuries incurred by the occupants(2). The translation of mathematically determined occupant loading values into corresponding grades of injury severity and the ensuing costs of injury resulting from these is made possible by the procedure of so-called statistical biomechanics(3).

National Economic Aspect

The monetary evaluation of the occupant injuries alone is not sufficient, however, because a complete assessment of the national economic aspect and assessment of costs for all design measures involved had to be provided. The evaluation of these so-called effective field costs not only includes the sale price of the vehicles but also the fuel consumption, which is influenced by the weight and geometry of the vehicle(4).

Optimization

A process based on the principle of biological evolution was used in optimizing the deformation behavior of the vehicles in the substitute accident occurrence(5).

In the above-mentioned research project, three optimization runs were carried out, each being different in the formulation of their aims and the restrictions imposed, and each of which led to a different interpretation of the deformation structure characteristic(6). All the optimization runs had in common that the occupants were connected to the vehicles by safety belt systems. The choice of the restraint system (3-point automatic belt, with and without preloading) led to vehicle structures that were especially suited to these.

In addition, in all three optimization runs it could be determined that the desired protection, especially for the laterally struck occupant, could be achieved to a considerable extent by matching the design of the front structures of the colliding vehicles (30 to 70 percent, depending on the formulation of the object function). From this it ensues that the isolated examination of the frontal barrier crash tests as carried out and prescribed—at least by American law—at the moment may possibly lead to an improvement of self-protection in frontal collisions, but the important aspect of partner protection, in particular in frontal collisions but also in lateral collisions, is neglected.

The Deformation Structures of the Laterally Crashed Car as the Result of Optimization

In the two-dimensional modeling of the lateral car collision, the characteristic curves door/roof frame, door/floor group, door/occupant thorax, and door/occupant pelvis were made variable (Figure 2). The door

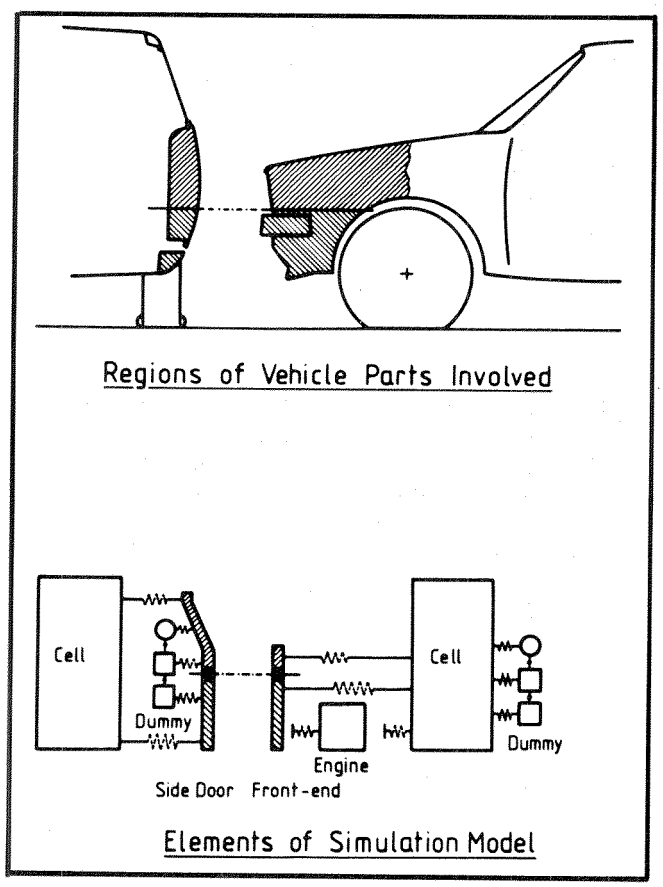

Figure 2. Structure characteristics of lateral accident simulation model

has to be subdivided due to the different loadings on the thorax and the pelvis of the laterally hit vehicle occupant; the permitted relative movement was not varied once it had been predetermined. Head impact was not considered due to the fact that Hybrid II dummies were used in the test, and the lateral impact characteristics determined here were unrealistic.

In the optimization runs, the following four characteristic curves were determined in accordance with the model:

- Upper side/cell
- Lower side/cell
- Door paneling at thorax height (inner door panel, inside padding, rigidity of thorax)
- Door paneling in pelvis area (inner door panel, inside padding, rigidity of pelvis)

As an example of characteristics of curves optimized in this way, the results of an optimization run are shown in Figure 3(6).

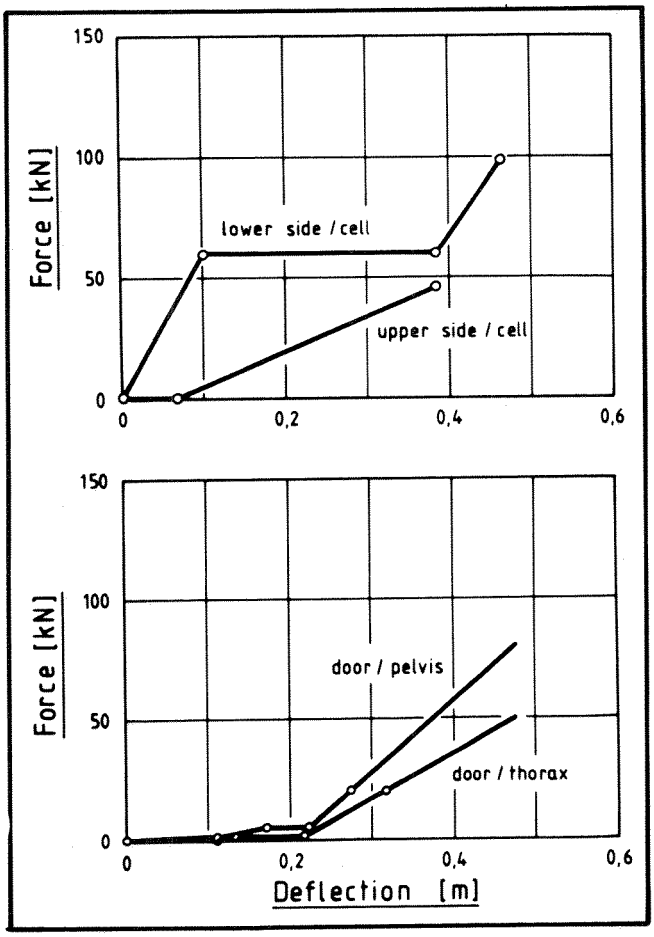

Figure 3. Optimised lateral deformation structures

Concept of the Experimental Examination of the Lateral Structures of Cars

Using the analytical determination of the structure characteristics as shown above, the following necessary requirements for deriving a test concept(7) can be formulated (Figure 4):

- Reliability of accident mock-ups
- Accuracy of reproduction of the simulation model
- Validity of the object-system limits in the formulation of the object function

Once these basic requirements have been fulfilled, the objectives of the tests are reduced to the question of—

- Extent to which the structure modifications can be checked
- Comparison between the characteristic curves as determined in the analysis and their realization in design
- Measures to be taken when there are discrepancies

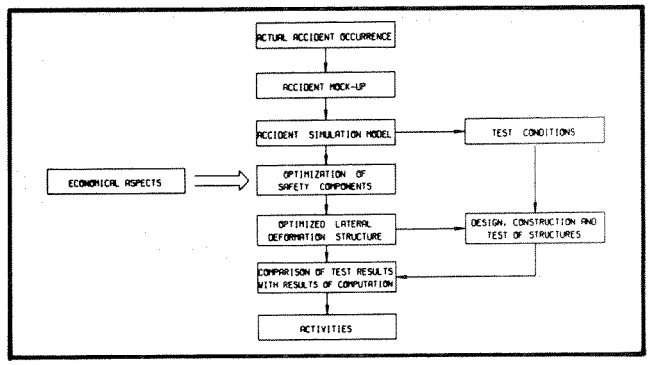

Figure 4. Conception for experimental verification of analytically designed side structures of passenger cars

Connection Between Mathematical and Experimental Simulation

The close interlinkage of simulation and experiment is prescribed by the fact the vehicle lateral structure is determined by analysis and it is necessary to examine the structure characteristic curves realized in the design experimentally. Compared with previous tests on lateral collisions, the test conditions that determine the test object, test procedures, measured variables, and the evaluation criteria are oriented less toward the accident occurrence than to the structuring of the simulation model. One must be able to check the parameters introduced in the model experimentally.

Apart from this, in the experiment, one can leave out areas for examination that have already been taken into consideration in the course of optimization, e.g., the accident constellation, the characteristics of the collision opponents, the loading of the occupants and their biomechanical effects, as well as the effects of the structure modifications from an economic aspect. The experiment thus merely serves to examine the structures for their deformation characteristics and to provide measured results for comparison to the mathematically obtained results; for this, component tests, which are

noted for providing considerably better reproducibility in the test results, are adequate. Integral vehicle tests, in which dummies serve only to check and validate the simulation model, can be made outside of the strict time limits involved in preparing an automobile for series production.

Extent to Which the Deformation Characteristic Curves Can Be Checked

In the optimization model, the front and lateral structures of colliding vehicles were matched to one another, but, as opposed to this, the mutual interaction of the front and lateral structures of one and the same vehicle was ignored. This corresponds to the accident mock-ups and, to a large extent, to the actual accident occurrence; also to a large extent because the structure elements set out for the lateral impact only take effect in frontal collisions when there is considerable deformation of the cell. Such serious deformation only takes place, however, at a speed range that, from a statistical point of view, occurs far less often than the range at which the frontal structure can absorb the whole of the deformation energy.

In lateral collisions, no effects of the front structure, which acts in a longitudinal direction, on the deformation behavior of the vehicle hit side-on could be established. Therefore, tests can be used for lateral structures separately.

The structure characteristic curves introduced into the optimization as initial values are derived from characteristic curves determined by means of static and dynamic test procedures. As opposed to these, the optimized characteristic curves are the result of the optimization calculation in which they act dynamically as part of a complex spring-mass system.

The dynamic definition, however, is the result of the vehicle model-structuring and the distribution of mass in the simulation model. In the experiment, therefore, both the static and dynamic deformation behavior had to be examined. If one assumes a suitable vehicle modeling as a precondition, however, the dynamic behavior is characterized merely by velocity- (damping) and acceleration-dependent (mass moment of inertia) influences(8). These characteristic quantities of the material are introduced into the optimization as constants and are not subject to any changes. Therefore, if these conditions are retained in the realization of the design, the dynamic checking can be omitted in the test. As already mentioned, dynamic tests are merely necessary for validating the simulation model.

Another range of problems arises from the fact the optimization calculation determines individual structure characteristic curves that can be realized in the design but cannot be examined separately, e.g., the characteristic curves upper side/cell and lower side/cell since it cannot be excluded that these support and, therefore, influence each other. Examination of the lateral structure, which consists of several individual characteristic curves, has to be carried out while, at the same time, insuring that several characteristic curves correspond with the respective predetermined results obtained from calculation. The experimental proof is, therefore, necessary since the injury mechanics depend to a large extent on the definition of the characteristic curves.

In view of the demand for reduction of the development costs in automobile construction and, at the same time, for improvement of occupant protection, one can conclude that an examination of the lateral structure with quasi-static component tests is possible and can be carried out with a relatively small amount of effort regarding time and costs. This procedure requires, however, that the simulation model must be continuously checked with the aid of integral vehicle crash tests and, if necessary, be adapted accordingly.

Agreement Between Calculations and Tests, and Considerations To Be Taken in the Case of Deviations

In the optimization calculation, a total of four characteristic curves are prescribed for the lateral structure of cars. These are:—

- Upper side/cell
- Lower side/cell
- Upper door padding
- Lower door padding

It is not probable that the mechanical structures were to achieve an exact reproduction of the calculated characteristic curves, so deviations must be allowed for from the start and must be tolerated within firmly established limits. Since these deviations lead to the vehicle showing a different behavior in an accident situation compared to the precisely calculated occurrence, they have to be estimated.

The accident simulation model was subjected to great simplifications in favor of the shortest possible calculating times. For this reason, a more detailed simulation model in which a subsequent calculation of the individual accident is carried out on the basis of the characteristic curves determined by measurement is used for the estimation (Figure 5). In this, the evaluation algorithms used for the optimization are utilized for assessing the injury-dependent costs and the effective field costs. Of course, only the calculated results and test results can be compared for agreement; this only leads, however, to a yes/no statement. The effects on the ensuing costs situation cannot be predicted in this way.

An agreement between the structural characteristics as set out in the design and the mathematically predetermined characteristic curves leads to the structure being accepted.

If an acceptance agreement between these two cannot be obtained, the design must be adapted to suit the appropriate requirements, either in part or as a whole. In an iterative process "design-construction-testing-comparison," the design realization of the mathematically established deformation structure within a tolerable permitted range is retained.

At the same time, when these test results are made available, the simulation models used can be examined and validated and can thus be subjected to a continuous process of adaptation (Figure 5).

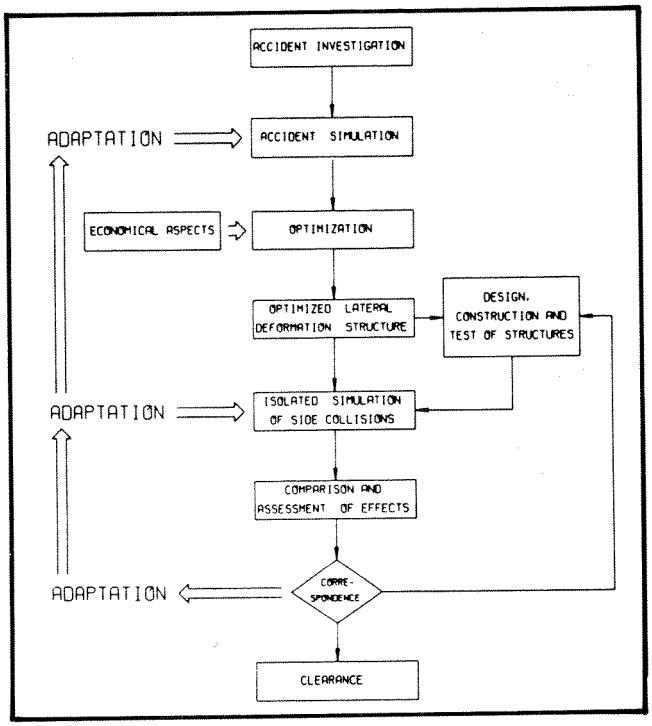

Figure 5. Conception for verification of constructed side structures of passenger cars and following consequences

Test Conditions for Checking Analytically Determined Lateral Structure Characteristic Curves

If one follows the concept of closely linking the simulation calculation and the test technology as explained above, this simplifies experimental examination of the design realization of the mathematically determined lateral structure characteristic curves in the following areas:

- Test objects
- Test procedures
- Measured variables
- Evaluation criteria

Test Objects

In accordance with the structuring carried out in the simulation model, the test objects to be examined are the door paddings and the door connection to the passenger cell.

From the characteristic curves of the door paneling at the thorax and pelvis levels, the rigidity of the dummy can be eliminated so the combined characteristic curve comprising the padding and the inside door panel rigidity can be examined in a single test setup. Here, the form of the test body corresponds to the respective part of the occupant's body. In the examination of the characteristic curves upper side/cell and lower side/cell in the two-dimensional simulation model, the complete occupant cell serves as a test object, and a front-contoured ram serves as a test body.

Test Procedures

The experimental examination of the structure characteristic curves is static. In this, the door paneling or the occupant cell has to be fixed in such a way that it cannot evade the quasi-static penetration process. On the other hand, the mounting must not influence the rigidity characteristics of the test object.

Measured Variables

In the examination of the padding characteristic curves, it is no problem to measure the deformation force and the deflection. More effort is involved, however, in determining the characteristic curves for the door/cell structure by measurement. On the one hand, it is necessary to establish the force-deflection curve of the examined body, which is suitably subdivided. On the other hand, the three-dimensional penetration movement of the inner door panel must be determined using displacement transducers to obtain a correlation for the distribution for the upper and lower structure characteristic curves. A distribution statement can be deduced from the relative position of the displacement transducers and, in this way, the upper and lower force-deflection curve for the door/cell system can be determined.

Evaluation Criteria

First of all, relative deviation is the decisive quality criterion for an agreement between the mathematically predetermined and the measured characteristic curve.

The relative deviation, however, provides no assistance in deciding whether to retain an existing structure or whether a modification and reexamination of the structure is necessary. To do this, it is necessary to enter the measured results as a set of data for the single-case simulation models and to calculate the effects on the ensuing costs of injury and effective field costs.

Summary

In the close connections between mathematical and experimental simulation, which are desirable objectives, a wide range of aims such as the determination of the dummy loading, as well as the selection of relevant accident constellations, can be set for the mathematical calculation. This method may not necessarily reduce the total effort involved in vehicle and component tests, but the tests during the strictly time-limited phase of preparing for series production can be carried out more simply and quickly, so that necessary adaptations of the structure characteristic curves are easier to introduce and check. A higher degree of reproducibility of the test results can be achieved by the more simple construction of the test setup. Deviations in the objective/actual-state comparison can be clearly allocated. Integral vehicle crash experiments for adaptation and validation of the simulation models or as acceptance tests to prove that legal requirements are being met can be carried out in accompaniment to the model and thus lie outside of the critical path of an automobile development project.

Status of the MADYMO Crash Victim Simulation Package 1985

J. Wismans
T. Hoen, and
L. Wittebrood
Research Institute for Road Vehicles TNO, Delft, The Netherlands

Abstract

MADYMO is a compact, general purpose, computer program package for two- or three-dimensional crash victim simulations. The program predicts the kinematics and dynamical behavior of the victim during the crash, based on data of the victim, environment, safety devices, and crash conditions. The package differs from most of the existing CVS programs by its flexibility in choice of number of linkages and number of elements in each linkage. Great flexibility in the modeling of force interactions between elements and environment is assured by the fact that user-defined submodels can be incorporated readily.

This paper summarizes the most important features of the current MADYMO 2D and 3D versions and reviews a number of applications. Topics covered include side impacts, pedestrian safety, human body segment models, and computer-aided design. An attempt to identify areas of future developments and general trends in the field of crash victim simulations concludes this paper.

Introduction

In the field of automotive research, simulation of crashes is of vital importance to evaluate and improve safety devices and occupant environment. Most of this

work is done by experiments, using instrumented dummies, cadavers, and occasionally animals or volunteers. During the past years, a strong increase could be observed in the use of computer simulations in this area due to the fast developments both in computer hardware and simulation software. Similar trends could be observed in other engineering disciplines where mathematical modeling has been an accepted tool for many years.

The behavior of dynamical systems in a crash environment appears to be of a very complex nature where, in general, a large number of system parameters will influence the system's dynamic response. Due to this, a strong emphasis should be placed on experimental verification. As soon as an adequate level of reliability is obtained for a specific application, an effective economic tool will be available for further analyses or optimization of that system.

This paper describes the most important features and reviews of various applications of the MADYMO Crash Victim Simulation program. The program is of the type gross-motion simulators, which describe the human body (or other structures) by means of a number of connected rigid bodies. A review of several programs of this type, including the CALSPAN CVS model and the MVMA model, is given by (1,2,3).

Theoretical background of the MADYMO package will not be discussed here. Readers interested in this subject are referred to (4) for a general treatment of rigid body dynamics theories and to (5) for a brief summary of the specific MADYMO equations of motion.

Current MADYMO Features

General

MADYMO is a compact, general purpose, computer program package for two- or three-dimensional simulations of human body gross-motions. The program, which is based on rigid body dynamics using Lagrange equations, can be used to simulate one or more linkage systems without closed loops. Such systems are also known as tree-structures(3). However, MADYMO allows the behavior of a closed loop system to be approximated by connecting the end segment of a tree to any other segment by means of a massless element. The number of elements (rigid bodies) in each linkage system can be selected freely. The connections (joints) between the elements in a linkage system are of the hinge type for the two-dimensional and of the ball and socket type for the three-dimensional simulations.

Motion of the tree-structure of joint-connected elements is caused by external forces. MADYMO offers the user a set of standard force-interaction models, e.g., for belts, joints, and contacts of segments with each other or with the environment. The program is organized in such a way that the user can modify these routines in a relatively simple way while, in addition, user-defined submodels can be incorporated readily.

The standard solution technique to solve the equations of motion is a fourth order Runge-Kutta-Merson method with a fixed time step. In MADYMO 3D optional, a fifth order Runge-Kutta-Merson method with variable time step is available. A restart option in MADYMO 3D allows restart of a simulation at any point of time on the basis of calculation results in a preceding simulation.

The description of MADYMO to be presented here relates to MADYMO 2D version 3.0, which has been available for several years for external users, and MADYMO 3D, which will become available later this year. A number of features described for MADYMO 3D and not yet incorporated in the current MADYMO 2D version will be included in the next MADYMO 2D release. Both the 2D and 3D versions have been applied extensively in various research programs in the past years as described later. Based on the experience in these research applications, the MADYMO 3D version has gone through considerable debugging and optimizations with particular emphasis on the user convenience of the package.

In the next section, some of the current features of MADYMO 2D and 3D will be discussed in more detail. Among other things, attention will be given to joint, contact, and belt models.

Joint Loads

In MADYMO 2D, elements are connected by pin joints with 1° of freedom (Figure 1a). A nonlinear joint torque can be specified, consisting of elastic, viscous damping, and coulomb friction components. The standard features of MADYMO 2D allow in addition the simulation of a 3° of freedom planar joint, i.e., with 1 rotational and 2 translational degrees of freedom by specification of the joint segments as elements of different systems. Interaction between the two elements can be represented, for instance, by spring-damper models and contact models. A hypothetical example simulating the human knee joint is illustrated in Figure 1b.

The standard joint connecting two segments in the MADYMO 3D version is of the ball and socket type with 3° of freedom. Three methods are currently available to apply joint loads (Figure 2):

- Option I—The cardan joint model
- Option II—The flexion-torsion joint model
- Option III—Spring-damper and/or contact models

In the cardan joint model (option I), the relative position between the joint segments is considered to be the result of three successive rotations. The first rotation is around an axis fixed to segment i, the second rotation around a floating axis, and the third rotation around an axis fixed to segment j (Figure 2a). The centers of

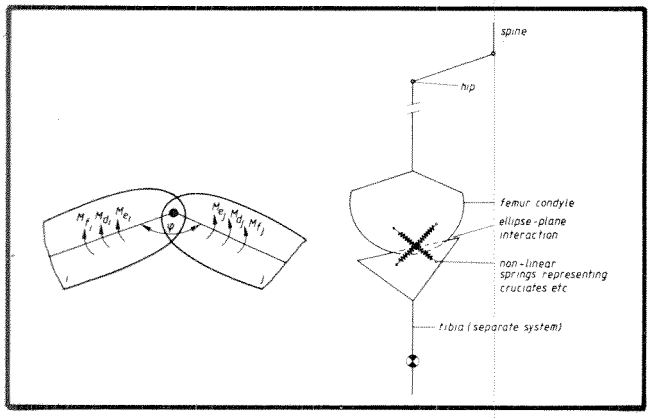

Figure 1. Methods to apply joint loads in MADYMO 2D (a. pin joint; b. hypothetical example of a joint with 3 degrees of freedom)

rotation for the three hinge joints are assumed to coincide in one point. Joint torques can be specified for each rotation separately by means of nonlinar elastic, viscous damping, and friction torque components similar to the MADYMO 2D version. One or more rotations can be locked by defining relatively stiff elastic torque characteristics. This joint model is suitable to describe, for instance, some of the joints in the Part 572 dummy such as the shoulder, elbow, and knee joints.

In the flexion-torsion model (option II), the relative rotation is thought to be the result of a flexion α and a torsion β (Figure 2b). Similar to the cardan joint model, nonlinear elastic joint torques can be specified as a function of these angles. In addition, a damping and friction torque can be applied as a function of the relative rotational velocity between both segments. This joint model can be used, for instance, to approximate the behavior of the rubber cylinders representing the spine and neck in the Part 572 dummy.

For each joint in a MADYMO 3D linkage system, it is possible to define the cardan joint model or flexion-torsion joint model. Both joint models can also be defined in combination for the same joint, which allows the user additional flexibility in modeling a more complicated joint type. In some situations, the application of spring-damper systems or contact models (option III) might also offer realistic additional possibilities for joint modeling (Figure 2c).

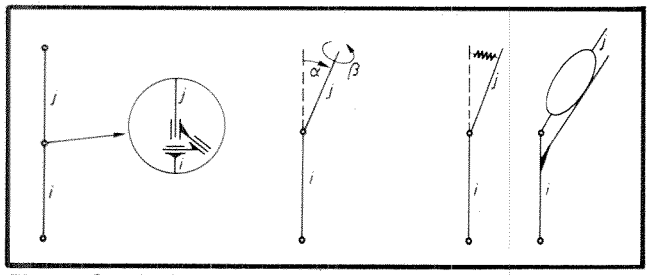

Figure 2. Methods to apply joint loads in MADYMO 3D (a. cardan joint model; b. flexion-torsion joint model; c. spring-damper and/or contact models)

Joints with 6° of freedom can be represented in MADYMO 3D by assigning the two joint segments to separate linkage systems similar to the 3° of freedom joint in MADYMO 2D (Figure 1b).

Contact Loads

In MADYMO 2D, contact lines and hyperellipses can be attached to any element of any system or to the laboratory reference frame. A hyperellipse is defined as follows:

$$\left(\frac{|x|}{a}\right)^n + \left(\frac{|y|}{b}\right)^n = 1$$

where a and b are the semi-axes of the hyperellipse and n is the degree (Figure 3). If n = 2, this equation describes a standard ellipse; if n increases, the hyperellipse approximates more and more a rectangle as illustrated in Figure 3. In this way, edge contacts can be described quite realistically. In a similar way in MADYMO 3D, contact planes and hyperellipsoids can be specified.

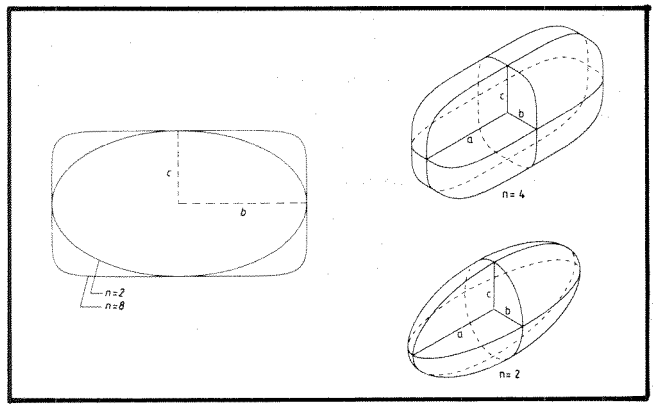

Figure 3. Hyperellipses (left) and hyperellipsoids (right)

The contact lines (planes) and hyperellipses (hyperellipsoids) describe the occupant interaction with vehicle interior surfaces. Two contact models are available, namely for contact lines (planes) interacting with ellipses (ellipsoids) and for hyperellipses (hyperellipsoids) interacting with each other. The reaction forces on the system segments are generated as a function of the penetration between these contact contours. More details on the penetration algorithms are provided in (6). Nonlinear elastic damping, as well as friction forces, can be applied.

Additional features of these contact models are—

- Simulation of Intrusion, etc.—A user-defined subroutine (standard in MADYMO 3D) allows specification of the position of contact contours as a function of time. In this way, for instance, intrusion of the car-side structure into the compartment can be simulated.

- Initial Penetration Correction—The penetration used to calculate contact forces can be taken relative to the initial penetration. In a relatively simple way, a state of equilibrium can be obtained at the start of the simulation, provided the effect of gravity can be neglected.
- Hysteresis—The effect of energy absorption in material can be simulated by defining the unloading slope of the force-deflection characteristic.

Belt Loads

Two force-interaction routines are available to represent belt restraint systems:

1. A simple massless spring-damper element, which can be used to simulate a lapbelt or the upper or lower part of a torso strap.
2. An advanced belt system model. This model is basically the same in MADYMO 2D and 3D and describes the real spatial belt geometry (Figure 4). The model consists of five segments and can account for slip between the belt segments and initial belt slack (or penetration). For the belt material, energy dissipation and permanent elongation can be specified. An option called "film spool effect" is available for belt systems with a retractor.

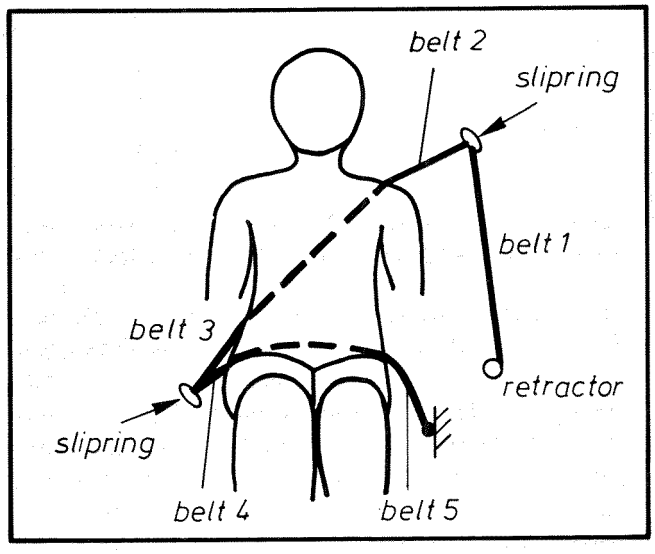

Figure 4. Advanced belt model

Point-Constraint Model

This routine constrains the position of one point of a segment relative to an arbitrary point fixed to another segment (or the environment). Both elastic and damping constraint loads can be specified in three mutually perpendicular directions (MADYMO 3D). Application of this model is useful to constrain the motion of a separate rib cage segment(7) or to simulate a deformable steering column.

Deformable Steering Column

MADYMO does not have a separate force-interaction routine for a deformable steering column since the standard features of MADYMO specify such a system directly in a simple way. Figure 6 illustrates a realization of such a model as it was successfully implemented by several MADYMO users. A two-segment linkage system is used here where one segment represents the steering column and one segment the steering wheel. The column is connected to the vehicle by means of two point constraints describing the column deformation characteristics.

Airbag

The current MADYMO versions do not include a standard force-interaction model for an airbag. A user-defined subroutine has been developed recently for the driver-airbag interaction where the airbag can be connected to a deformable steering column. This routine is expected to be available as an option in the next MADYMO 2D release.

Software Characteristics

MADYMO is a compact modular program package written in FORTRAN 77. Due to the limited size of the program, the MADYMO package can be implemented even on small computer systems, which is illustrated by the following figures.

A simulation of an occupant in a frontal collision with MADYMO 2D requires 100k byte memory and 3.5min CPU time, whereas a complicated simulation of a cyclist impacted by a car with MADYMO 3D needs only 200k byte memory and 12min CPU time (above data relate to a VAX 11/750).

Pre- and Postprocessing

The input for the current MADYMO versions is contained in a single formatted input file, which can be changed simply by the user's editor. A special user-convenient subroutine has been developed in MADYMO 3D for specifying the initial position of the occupant and the various local coordinate systems that define inertia axes, joint rotation axes, hyperellipsoids orientations, and point-constraint directions.

Special attention has been paid to user-convenient postprocessing in MADYMO 3D. In the input dataset,

the user has to define which parameters must be calculated for output purposes, such as—

- Kinematics
- Linear displacements, velocities, and accelerations of specified points
- Angular velocities and accelerations of specified elements
- Forces of specified force models
- Torques of specified joints

For additional output, a user-defined subroutine can be incorporated in the program to generate the model data in a format similar to experimental test data to apply user's standard experimental analysis software for further data processing.

For postprocessing of the kinematics, a three-dimensional graphics package is available that can be used in conjunction with both MADYMO 2D and MADYMO 3D. Features of this package include—

- Isometric projections of ellipsoids and planes
- User-defined viewpoint
- Intersecting ellipsoids
- Countour lines on the surface of the ellipsoids
- Hidden lines elimination
- Self-contained; only simple plot routines are used

Some of the features of this graphics package are illustrated in Figures 5, 6, 7, 9, and 12.

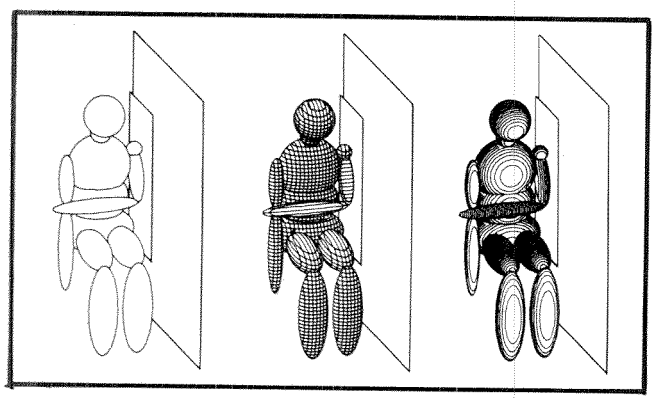

Figure 5. Examples of output from the MADYMO 3D graphics package

Applications

The versatility of the MADYMO program package will be demonstrated here by means of a number of simulations conducted in the past years. For most of these examples, a detailed experimental verification was performed. The applications will be divided into six categories:

- Frontal collisions
- Side collisions
- Pedestrian and cyclist impacts
- Child in a child restraint system

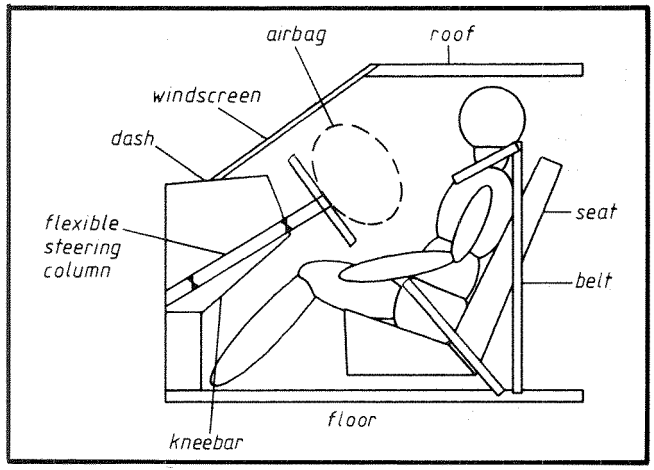

Figure 6. General model setup for an occupant in a frontal collision

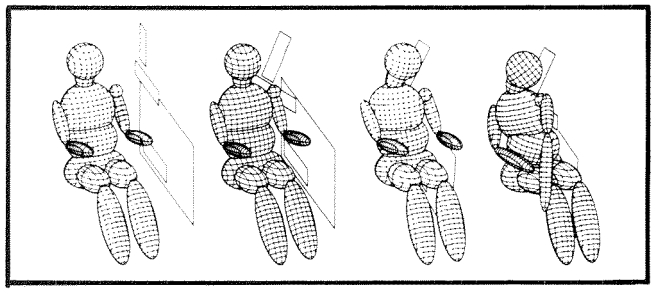

Figure 7. Mathematical simulation of a Part 572 dummy in a Peugeot 504 during a lateral collision (75km/h)

- Human body segment models
- Computer-aided design studies

Frontal Collisions

The general model setup of an occupant in a frontal collision most often used today is illustrated in Figure 6. The first experimental verification of the MADYMO 2D model was for a sled test with the simple five-segment TNO adult test dummy. This verification was followed by several studies with the (much more complicated) Part 572 dummy under various test conditions.

In a research program started in 1979 in cooperation with the Organisme National de Securité Routiere (ONSER), an attempt was made to simulate a real accident(8,9). This accident had been experimentally reconstructed before with dummies and human cadavers, which allowed a detailed validation of the MADYMO model for this specific accident situation. For both the dummy and cadaver tests, quite realistic results were obtained from the mathematical simulations. Based on these results, a mathematical reconstruction could be made for the real accident by simulating the real occupant anthropometry.

Side Collisions

The first side impact simulations conducted in our laboratory were rigid wall sled tests and drop tests with the Part 572 and APROD 80 dummies(10). The 3D option of MADYMO was used. Model predictions such as contact loads and dummy accelerations were found to agree quite well with experimental results.

Side Impact Accident Reconstruction

The model of the Part 572 dummy was also used in a simulation of a more complicated impact: a real collision between a Peugeot 504 (stationary) impacted on the side (impact angle 70°) by another Peugeot 504 having a velocity of approximately 75km/h(11). For this accident, several experimental reconstructions were conducted by the Lab. of Phys. and Biom. Peugeot S.A./Renault. The mathematical simulation was limited to the interaction between the occupant in the struck vehicle (a Part 572 dummy) and the inside structure of the vehicle. The displacement of the struck door was used as model input. The stiffness characteristics of door padding and of the armrest were determined with a hydraulic tester. The predicted dummy kinematics in this accident are illustrated in Figure 7.

Dummy Thorax Models

Another side impact application of MADYMO presented here is the analysis of the dynamical behavior of the thorax section in four different side impact dummies: the DOT/SID, MIRA, APROD 82, and ONSER. The basic design characteristics of the four thorax sections are completely different. Several models with varying complexity were formulated during this project. In these models, the complete dummy was simulated in a rigid pendulum impact as illustrated in Figure 8. Dependent on the complexity of the thorax design, the rib cage was simulated by zero, one or two segments in case of two-dimensional simulations, and seven segments in the three-dimensional model setup. The mathematical simulations offered a very good insight into the dynamical behavior of the four thorax designs. In the ONSER as well as the MIRA dummies, the thorax behavior appeared to be determined mainly by the elasticity of the rib cage structure. In the DOT dummy, elasticity as well as damping (due to the viscous damper in this design) and inertia effects were found to play a significant role. These effects were of such a complex nature that a detailed three-dimensional representation had to be used for adequate simulation. A decisive judgment of the reliability of the APROD mathematical simulation could not be given due to inadequate functioning (jamming) of this thorax design. More details of this study are presented in (7) and (12).

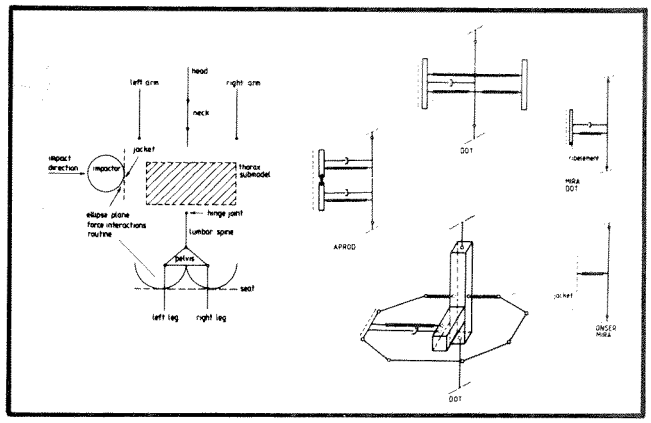

Figure 8. Simulation of thorax pendulum impact tests with four different side impact dummies

Pedestrian and Cyclist Impacts

In the past, the Research Institute for Road Vehicles TNO has been involved intensively in research in the field of pedestrian and cyclist safety. As part of this research program, four pedestrian models with varying complexity were formulated with MADYMO: three two-dimensional models with two, five, and seven segments, respectively, and one three-dimensional model with fifteen segments (Figure 9). Model results were compared with experimental results of a Part 572 dummy impacted laterally by an Audi 100 vehicle at two velocities (30 and 40km/h). In general, all models appeared to provide values for the body segment accelerations within or close to the experimental range of responses. A slight improvement of the model results could be observed in the more complex models. For instance, due to the lower head impact velocity in the three-dimensional model, a lower and much more realistic peak head acceleration during the hood impact could be observed. More details of this study are presented in (6) and (13).

More recently, research in this area in our laboratory has focused primarily on the integration of pedestrian and cyclist safety(14). As part of this study, a model of a cyclist has been formulated where the bicycle is represented by a separate one-segment system (Figure 9). The cyclist

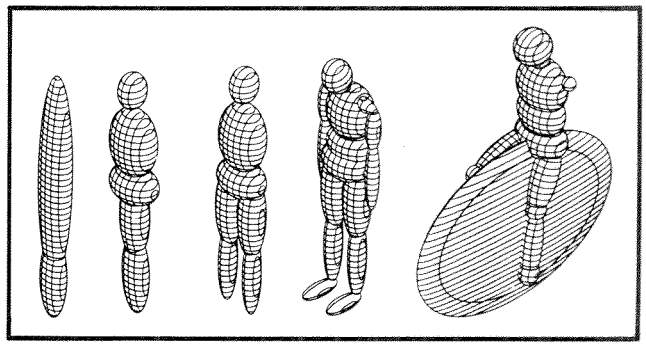

Figure 9. Geometry and contact ellipses of 2-, 5-, and 7-segment 2D pedestrian, a 15-segment 3D pedestrian, and a 9-segment 3D cyclist model

is simulated by a nine-segment system without arms to avoid the complex interaction of the arms with the hood in this type of impact. Experimental verification for several test conditions with a simulated vehicle front is incorporated in a separate contribution to this Conference(15).

Child in a Child Restraint System

The next example is the simulation of an impact sled test with a child in a harness-type child restraint system (Figure 10). Details of this study were presented at the 23rd Stapp Conference(16). The child restraint system is represented by a separate one-segment system connected to the sled by a lapbelt and back strap. Because of the 2D nature of the motions, the 2D option of MADYMO was used for this analysis. Model results were compared with two sled tests conducted at the Highway Safety Research Institute in Michigan: one sled test with a 3-year-old Part 572 dummy and the other with a child cadaver. In general, a satisfactory agreement could be obtained between model and experimental results. Model predictions of the dummy behavior were, however, found to be more realistic than for the cadaver, which may be due mainly to the great number of estimations that had to be made for the mass distribution and joint properties of the child cadaver.

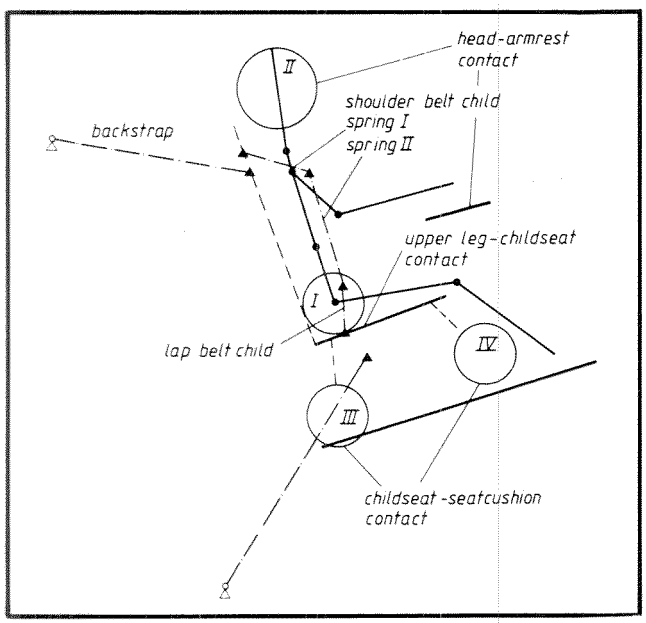

Figure 10. Mathematical representation of a child in a child restraint system

Human Body Segment Models

Applications in the preceding sections all relate to the simulation of the whole body response. MADYMO has also been applied to study the behavior of specific body structures. Two examples will be presented here: a model for the head-neck kinematics of human volunteers and a model for the thorax behavior in human cadavers.

Head-Neck Model

The model describing the head-neck kinematics was formulated with MADYMO 3D and consists of three segments: a torso link, a neck link, and a head link, which are connected by means of a pivot in the head near the occipital condyles and a pivot close to the T1 vertebral body in the torso (Figure 11). A detailed description of

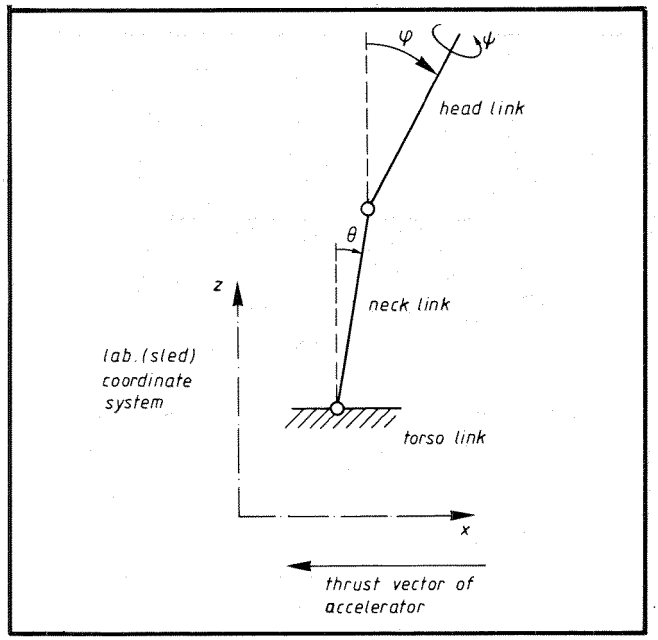

Figure 11. Mathematical model for head-neck motion of human volunteers in frontal, lateral, and oblique impacts

this model and the experimental verification by means of lateral, oblique, and frontal human volunteer tests is given in (17-20). Figure 12 illustrates model predictions in a lateral human volunteer test.

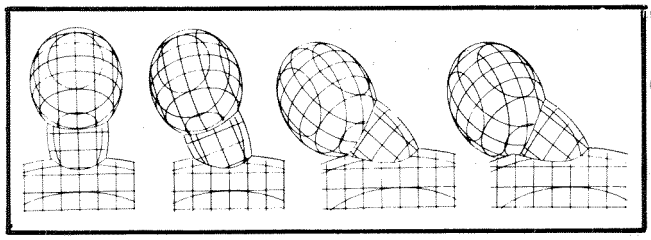

Figure 12. Prediction of the head-neck kinematics of a volunteer in lateral flexion

Thorax Model.

The thorax model was developed at the Ohio State University using the MADYMO 2D program(21). The model, which represents the rib cage, including sternum,

consists of a series of 17 elements (Figure 13). A special user-defined subroutine was developed that accounts for pressure changes within the chest cavity during simulation. The model was used to study some of the thorax impact tests with human cadavers conducted during the mid-1970's at the Highway Safety Research Institute. Thoracic accelerations in these tests were collected using a 12-accelerometer array(22). The general shape of the acceleration time histories and force-deflection characteristics predicted by the model showed good agreement with the tests. Predictions for the thorax pressure, however, showed significant deviations.

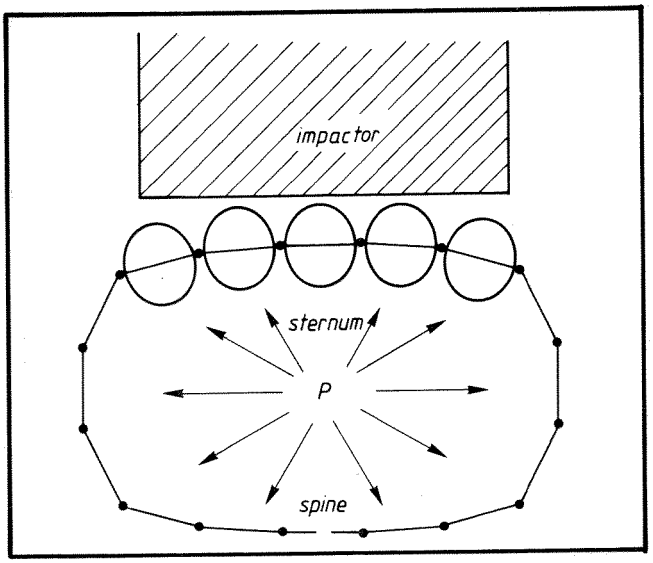

Figure 13. Thorax mathematical model

Computer-Aided Design Studies

In the preceding sections, a number of examples have been presented illustrating the use of MADYMO as a basic biomechanical crash research tool. Another interesting application of this type of program is the development and optimization of crash safety devices such as seatbelts, child seats, and vehicle paddings. One example presented here illustrates this, namely, the design of a dynamic-acting child restraint system. Two other examples relate to the computer-aided design of dummy components, namely, a dummy abdomen section and a dummy neck.

A Dynamic-Acting Child Restraint System

This new child restraint system features a moving impact shield, which is horizontal during normal use. The shield rotates upward during a frontal collision to restrict the forward motion of the child's head and thorax. The 2D option of MADYMO was first used to design and optimize the actuating mechanism for the shield and, second, to optimize the performance of the whole system in a standard ECE 44 50km/h sled test with a 3-year-old child dummy (Figure 14). The shield-actuating mechanism consists of a lever arm on the pivoting shield to which a rod with a mass is connected. During the car crash, the shield moves into an upright position due to deceleration forces acting on the mass. The downward motion of the shield caused by loadings from head and chest is prevented by a locking device. Several calculations, together with only a limited number of sled tests, finally led to an optimized child restraint system, which is commercially available today. Details of this study are provided in (23).

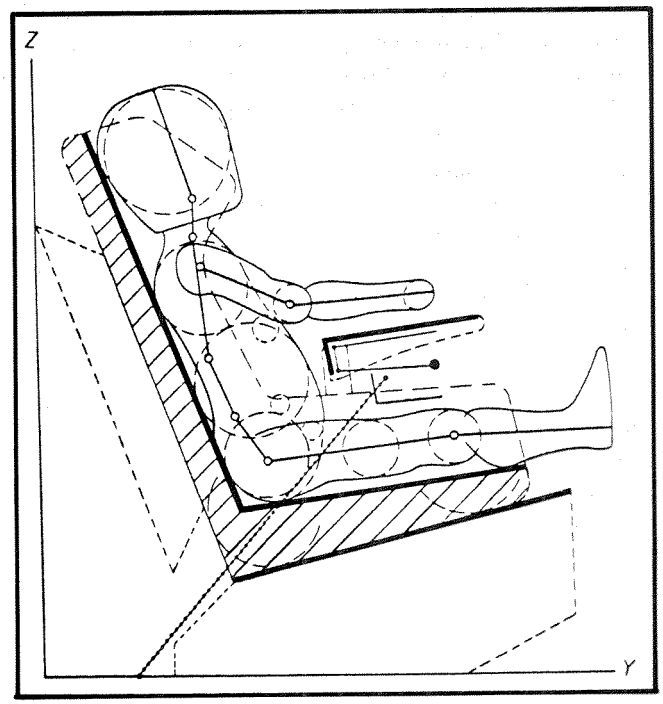

Figure 14. Mathematical model of child restraint system with dynamic-acting impact shield

A Dummy Abdomen Section for Side Impacts

The principle of this design is a rigid drum placed at the critical penetration tolerance level around the lumbar spine, with pressure-threshold contact switches on its surface. This drum is covered by a composite material that should have a dynamic stiffness identical to the human abdomen. The outside layer of the abdomen is made of a relatively heavy but flexible material. To avoid preparing and testing a large number of specimens necessary to obtain the correct response empirically, it was decided to use computer simulations to find the design parameters. MADYMO was utilized to formulate a dynamical nonlinear finite segment model of the cross section through a half abdomen (Figure 15). This model was exercised with a wide variety of mass distributions and for different impact velocities. A few specimens of the most promising combinations were made and tested

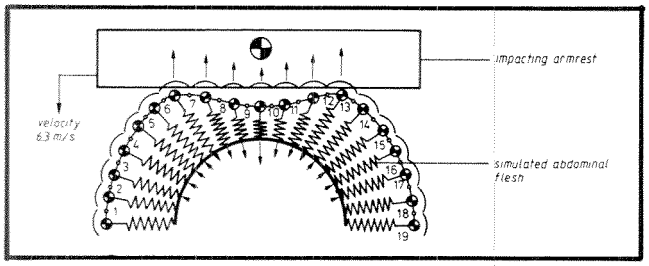

Figure 15. Mathematical model of dummy abdomen section

and were used for validation of the model. A prototype abdomen section has been built, based on the optimal parameters found with the simulation model, and will be incorporated in the future Eurosid side impact dummy. More details of this study are provided in (24).

A Dummy Neck With Improved Biofidelity

Experimental evaluation of the Part 572 neck system with respect to the volunteer behavior showed that this neck is much too stiff(20). Mathematical simulations have been conducted to optimize the design of this neck(18). A model of the Part 572 head-neck assembly was used for this purpose where the neck is represented by a seven-segment linkage system. Experimental verification of this model was conducted for a calibration pendulum test and a more severe sled test. The first results of the computer-aided design efforts that include simulation of longer and softer necks were quite promising. The best results were obtained by a design that consists of a soft neck reinforced by a relatively stiff structure in the front and back sections (Figure 16). A possible realization of such a design principle is a soft rubber cylinder imbedded in strong fibers or provided with one or more separate stiff rubber segments. Based on these findings, several prototypes have been built that are currently tested at the Vehicle Research and Test Center under test conditions representative for the human volunteer tests.

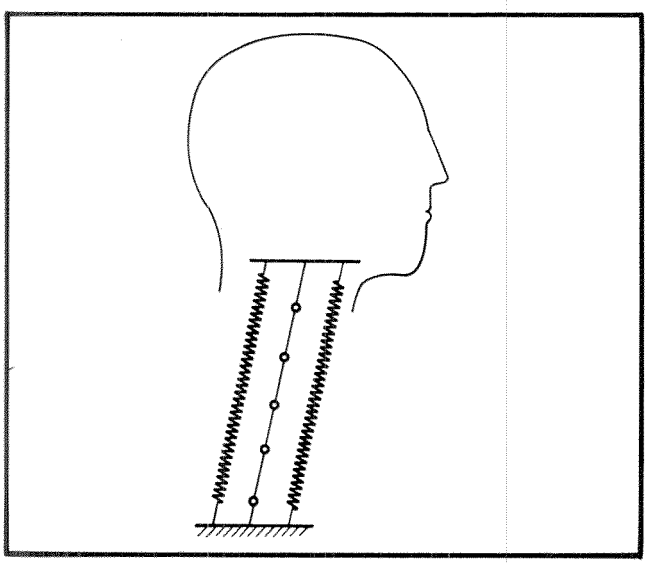

Figure 16. Mathematical model of a dummy neck with improved frontal biofidelity

Discussion: Future Trends and Developments

In the past, the MADYMO package has gone through a continuous process of optimizations, refinements, and extensions. It is expected that such developments will proceed. In fact, the rapid growth and progress in computer technology will open new directions and perspectives, particularly in the field of data base management and postprocessing. Another trend will be that further progress in vehicle structural crash models can lead to an integrated computer analysis approach for the vehicle-occupant interaction in a crash situation.

One of the most critical areas in current crash victim simulation programs is the description of contact between occupant and environment. Present algorithms applied for contact interaction of occupant with vehicle interior or between pedestrian and vehicle cannot account in a realistic way for the effect of strain rate and shape of the contact geometries. As a consequence, a large number of impactor tests is often required with varying impactor velocities and impactor shapes to obtain realistic model input data. The need for such elaborate input data experiments can be reduced considerably if more realistic contact models become available. Beside improvements in contact-interaction models, further developments can also be expected in the area of restraint system modeling, for instance with respect to the description of the belt-occupant interaction or the development of advanced three-dimensional airbag models capable of simulating the complex occupant interaction with passenger and driver airbag systems.

Human body data bases used today in crash victim simulation programs relate mostly to a representation of crash test dummies. A comparison of the data bases for the description of the standard Part 572 test dummy by various researchers showed differences, particularly with respect to the joint characteristics. Therefore, a strong emphasis should be placed on future standardization of this type of data base.

Experimental validation of the whole body response predicted by mathematical models is related mostly to dummy experiments. Studies reporting model verification for human volunteer or human cadaver tests appear to be limited. In most cases they are related to the behavior of certain body segments such as the thorax or neck, as was illustrated in the application section in this paper. Development of well-validated human body data bases describing different size real vehicle occupants and pedestrians is considered to be a challenge in the near

future for the biomechanical community. If the status of mathematical models becomes such that they offer a more realistic representation for the human body than current crash test dummies, a major step forward in the field of automotive safety modeling will have been made. Further program extensions with respect to flexible elements might be necessary to achieve an adequate level of validation.

Further acceptance of this type of model can also improve by an increasing user convenience. A MADYMO 2D version is expected to become available in 1986 as a special-purpose program for the simulation of frontal collisions. This program will be installed on a microcomputer system and could be used as a local computer-aided design work station in design departments. Although detailed specifications are not available at the present time, features expected to be included are menu-driven modules to generate data bases, interactive graphical-supported positioning of the occupant, and extensive output display capabilities with animation facilities.

A final trend, which will be mentioned briefly here, is found in the area of computer graphics. The MADYMO 3D graphics package used to visualize the complex occupant kinematics appears to be of invaluable importance for the analysis of three-dimensional motions. An even more realistic representation, however, can be obtained with a color graphics package developed in the field of solid modeling. Figure 17 illustrates the use of such a program for the visualization of the MADYMO Part 572 dummy model. This graphics program was developed at the Department of Industrial Design Engineering of the University of Technology in Delft and is still in an experimental stage. A relatively large CPU time is required for this type of visualization, which at the moment prevents applications on a large scale.

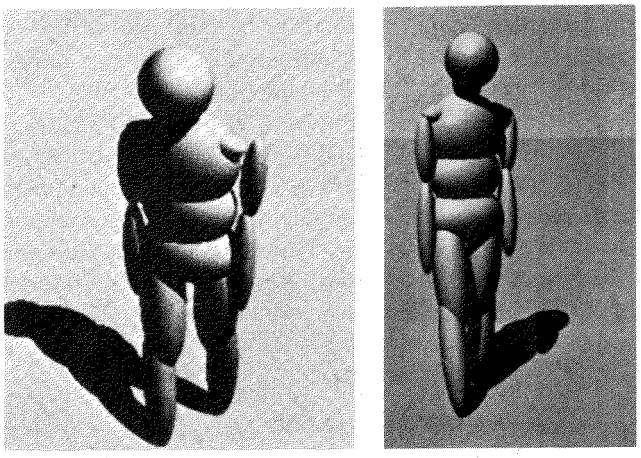

Figure 17. Part 572 dummy represented by the new generation 3D graphics package

Acknowledgments

MADYMO has been developed at the Research Institute for Road Vehicles TNO in cooperation with The Netherlands Institute for Road Safety Research SWOV. Development has been supported by the Dutch Government and the European Communities.

Abstract

Following the European Experimental Vehicles Committee's definitions(1), the mobile barrier frame was built by several partners and rigid polyurethane foam selected as the material for the front deformable face. A validation process consisted of different tests distributed among ONSER, BASt, and TRRL. ONSER, UTAC, and TRRL conducted impact tests on individual blocks, total tests against a dynamometric wall, and lateral impact tests against the Renault 14 as struck cars.

The validation was completed by performing barrier-to-car tests at the BASt facility according to the proposed EEVC impact test procedure. The basis for comparison was given by car/car tests under the same conditions and with cars of the same type. These cars were the Golf and Daimler Benz (W 123 series). Results from this test series show the barrier face has a very useful crash simulation fidelity and repeatability.

Introduction and Aim

In 1982, Working Group 6 of the European Experimental Vehicle Committee proposed a side impact standard test procedure(1). To perform this test, it is necessary to use a mobile deformable barrier, the characteristics of which were determined by the group and based on characteristics of European cars.

To validate the test procedure proposed by EEVC and especially the force-deflection characteristics of the barrier, four European research groups—BASt in the Federal Republic of Germany, ONSER and UTAC in France, and TRRL in the United Kingdom—decided to work together in a coordinated research program.

This work is done under an EEC contract, for which ONSER is the project leader. Its aim is to validate the proposed solution, which is rigid polyurethane foam for the front deformable face. Different validation tests were conducted such as individual block tests, barrier against a dynamometric wall tests, and barrier-to-car tests.

Proposed Solution for the Front Deformable Face

The front deformable face studied and built by Fritzmeier GmbH is described in Figure 1. Each block is constituted with two elements of different rigid polyurethane foam densities. Six different densities are useful:

- 28kg/m^3 for 4a, 5a, and 6a elements
- 30kg/m^3 for 5b and 6b elements
- 35kg/m^3 for 4a elements
- 42kg/m^3 for 1a and 3a elements
- 50kg/m^3 for 2a and 2b elements
- 60kg/m^3 for 1b and 3b elements

The real densities must take place in ±5 percent around the theoretical values. Figure 2 shows the design of the EEVC barrier.

Work Done by ONSER, UTAC, and TRRL

This section describes and gives results of part of the research performed in France and England. UTAC performed a frontal impact of the barrier against a dynamometric barrier and a barrier-to-car test. ONSER made the evaluation of force-deflection characteristics of each block of the barrier and also conducted two barrier-to-car side impact tests under the same conditions as the test performed by UTAC. TRRL conducted individual block tests and two impact tests of the mobile barrier against a dynamometric wall.

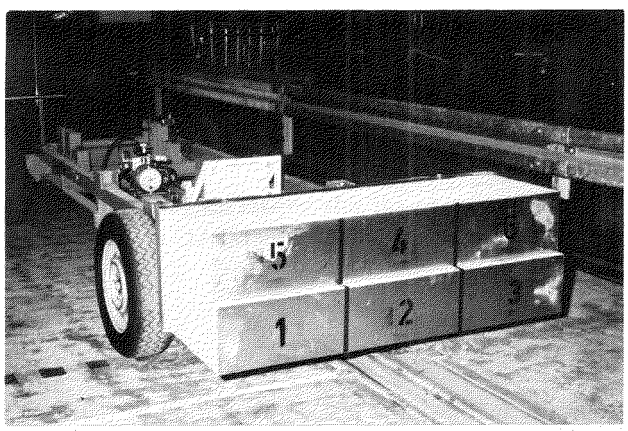

Figure 1. Front deformable face in polyurethane foam

Tests of Individual Blocks (ONSER and TRRL)

These tests were conducted first to determine the behavior of each block when tested separately.

The force-deflection characteristics of individual blocks tested separately show that the curves are closed to the corridor but partly under them. This relatively low stiffness can be explained by the absence of edge effect when one block is separated from the others. In a complete front force, the blocks cannot extend on interfaces with other blocks. The tests show a breaking down of the foam, which in some of them is associated with a high force peak at the maximum of deformation.

Test Against Dynamometric Barrier (UTAC and TRRL)

One frontal test with the mobile deformable barrier was conducted by UTAC. This test is necessary to check if the force deformation characteristics fulfill the specifications.

Test Conditions

The weight and sizes of the mobile deformable barrier used in this test were in agreement with the values decided by Working Group 6 of EEVC. The dynamometric barrier allowed the measurement of impact forces on each block of the barrier front end. The test impact speeds were 31.8km/h in the UTAC test, which is a little lower than the specification (35 ± 2km/h), and 35.1km/h in the TRRL tests. Longitudinal, transverse, and vertical accelerations were recorded in two points (one on each side) and the longitudinal acceleration at the center of gravity of the barrier. The dynamic deformation of the barrier front end was calculated by double integration of the longitudinal acceleration. High-speed movies and post-test pictures were taken.

Test Results

From data recorded during the test, we were able to draw the following curves

- Longitudinal acceleration, speed, and crush for each side of the barrier frame as a function of time

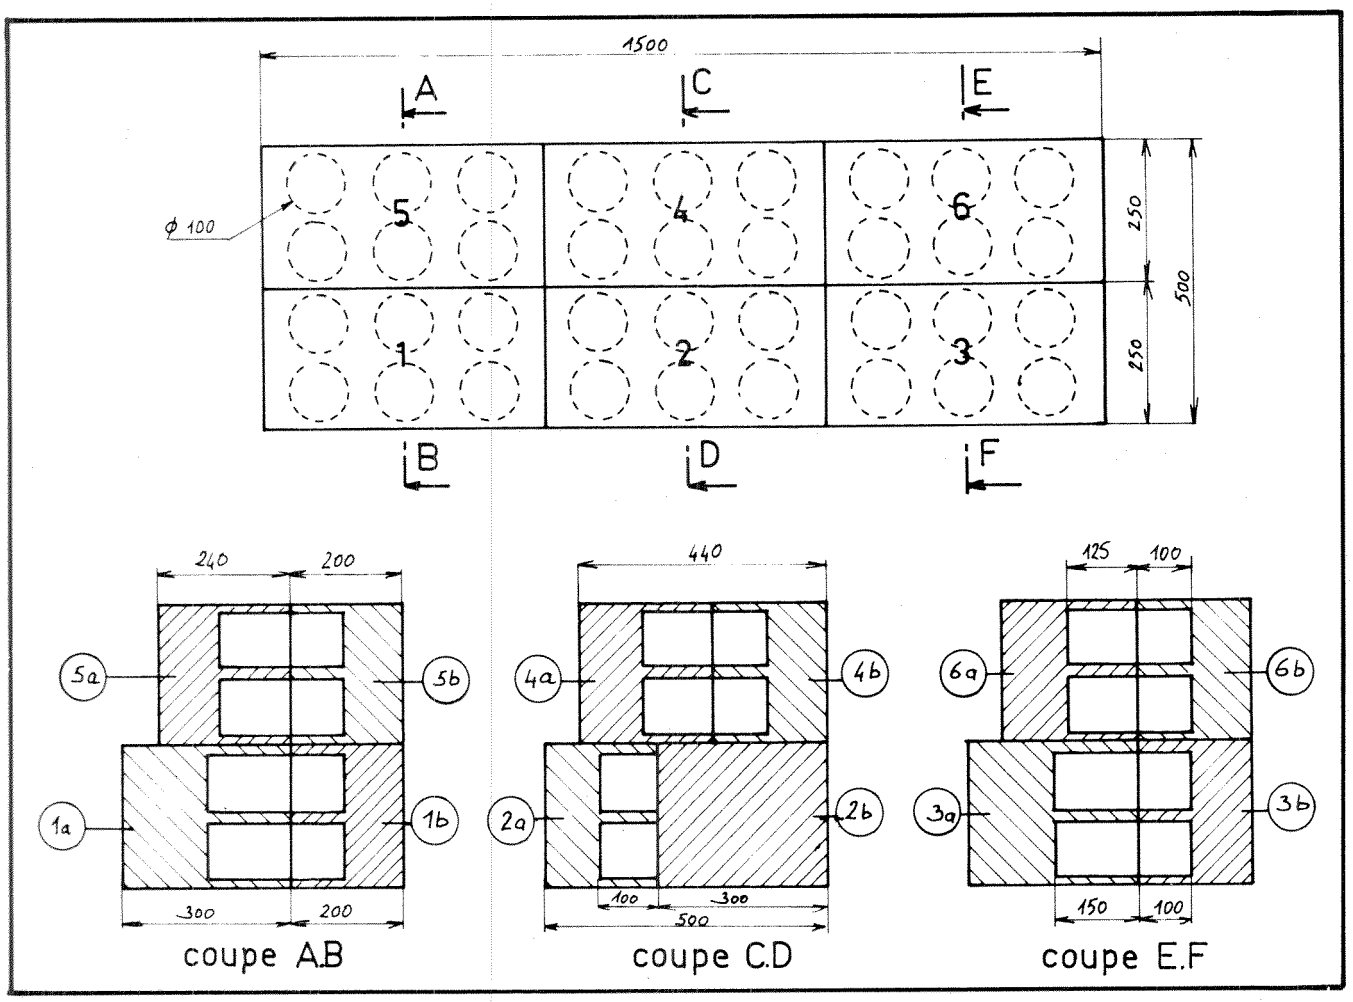

Figure 2. The EEVC mobile deformable barrier

- Transverse and vertical accelerations at the same locations versus time
- Longitudinal acceleration of the center of gravity versus time
- Impact force on each plate and total impact force as a function of time and crush
- Comparison of the total force/time curve with the mass acceleration versus time curve.

Figures 3 to 5 are the force-deflection characteristics of each block and the total force-deflection variation of the mobile deformable barrier during the UTAC test. Analysis of these figures shows that the blocks of the upper row give results almost included inside the specification corridor whereas the impact force of the lower row blocks is partly under the corridor. For blocks 1 and 3, this occurs for the second half of the deformation; on block 2, the curve was below the corridor in the second third of the deformation.

These figures show a good symmetry of barrier front elements: the force-deflection curve of block 1 can be almost superimposed on the block 3 one, and it is the same for blocks 5 and 6.

The maximum crush of each block is slightly lower than the specifications, but this can be related to the lower impact speed. According to kinetic energy difference at the correct impact speed, the dynamic crush would be 34/35cm instead of 31cm, and this corrected value is inside the specified bracket.

Barrier-to-Car Side Impact Tests (ONSER and UTAC)

Three barrier-to-car side impact tests were conducted, one in the crash test facility of UTAC and two in the facility of ONSER.

Test Procedure

Figure 6 shows the test configuration of the barrier tests, which was laid down in the report of EEVC's Working Group 6, "Structures"(1).

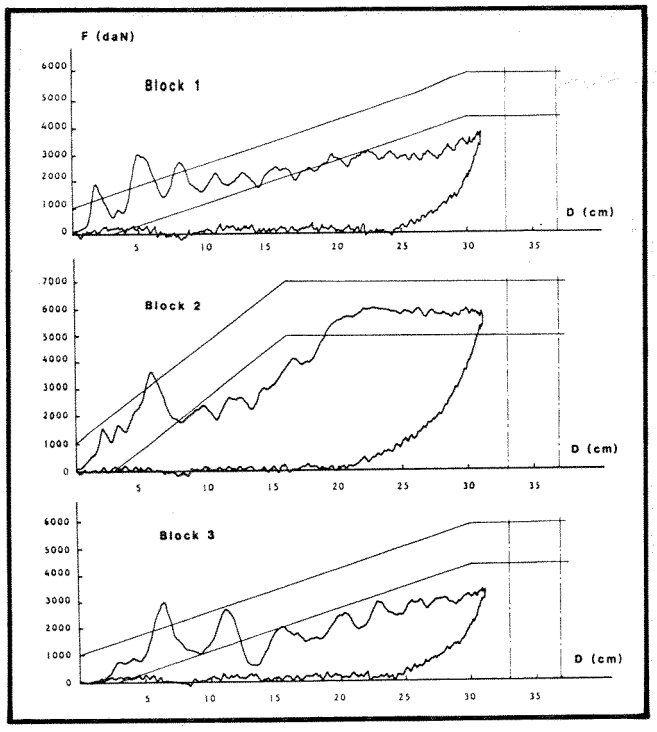

Figure 3. Force-deflection characteristics of the lower deformable part of the EEVC barrier

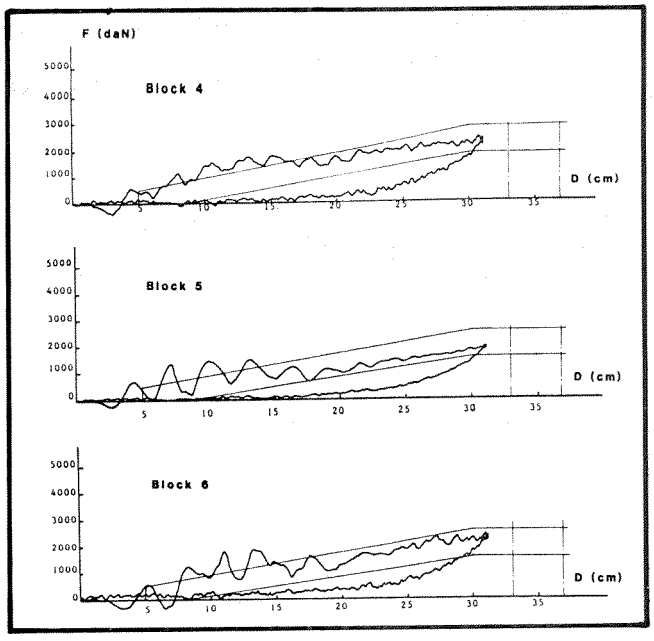

Figure 4. Force-deflection characteristics of the upper deformable part of the EEVC barrier

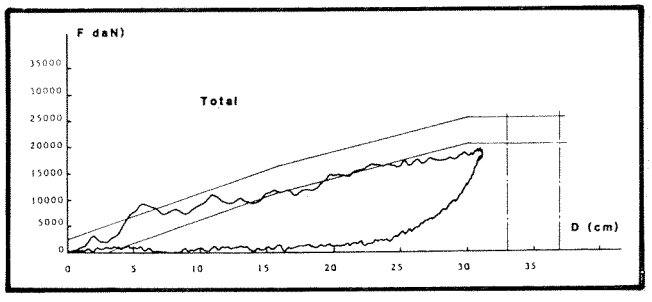

Figure 5. Force-deflection characteristics of the EEVC barrier

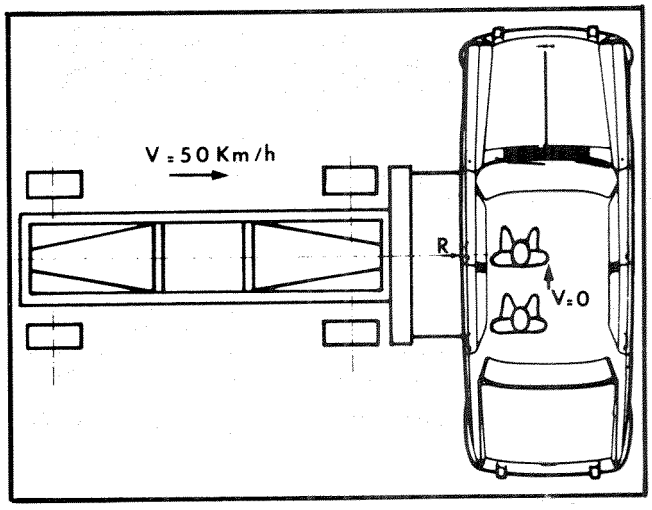

Figure 6. Collision situation in the barrier tests

The main features of this procedure are—

- Barrier impact speed: 50km/h
- Stationary struck car
- Impact angle: 90°
- Impacted side: driver (left side)
- Barrier symmetrical plane passing through R point of driver struck car

Two tests were performed with two Part 572 dummies in the impacted car at the driver and the rear left occupant seats. The third test, conducted by ONSER, was performed with the following dummies (the European dummy planned for lateral collision tests not yet available):

- Left rear sit: a Hybrid II dummy on which we note the triaxial accelerations on the head, the thorax, and the pelvis
- Driver sit: the dummy is compounded with various elements which are—
  - — Hybrid III head on which we measure triaxial accelerations (same head as the EUROSID)
  - — EUROSID neck
  - — APROD thorax on which we measure two deflections and three accelerations
  - — TNO (EUROSID) abdomen, which is able to detect a penetration

— EUROSID pelvis on which we measure three accelerations, one force at the pubic symphysis level and one force on the left iliac wing
— APROD arms

The main differences between this dummy and the EUROSID concern the thorax and arms.

The mobile deformable barrier is equipped with two triaxial accelerometers, one at the center of gravity and the other at the center of the sustaining sheet of the polyurethane foam front face.

A camera is also fixed on the mobile barrier to visualize possible shocks of the dummy heads against the struck car structure. The vehicle kinematic is studied from accelerations noted on the longitudinal and transverse axes on the A- and B-pillars at the opposite side of impact. The left front door (at the impact side) is equipped with accelerometers at the shoulder and at R point levels. Two on-board cameras help to study the passenger kinematic during impact.

Figure 7. EEVC barrier/Renault 14 lateral impact test

Test Results

Test results were analyzed to see if the barrier reproduced correctly the car deformations, vehicle kinematics, and dummy loadings.

Car Deformations

Figure 8 represents the deformations of the Renault 14 at the upper, medium, and lower levels. This figure shows a greater deformation of the car for the test conducted at UTAC. Figure 9 shows the deformations of the Renault 14 in three conditions: when impacted by the mobile deformable barrier (average value), struck by another car (average value of 10 tests with different cars), and hit by a Peugeot 305. This test was selected because the Peugeot 305 has characteristics closest to those of the barrier.

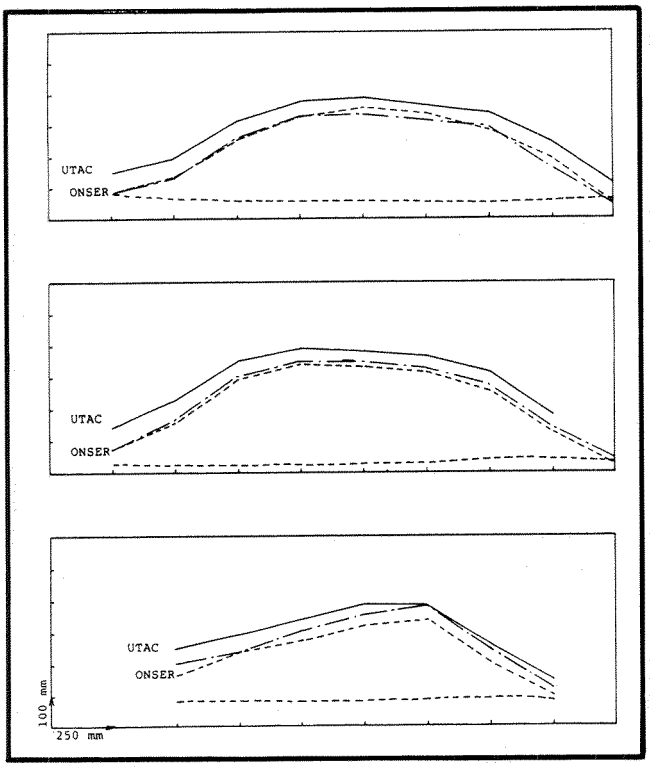

Figure 8. Deformation of the Renault 14 side when struck by the mobile deformable barrier

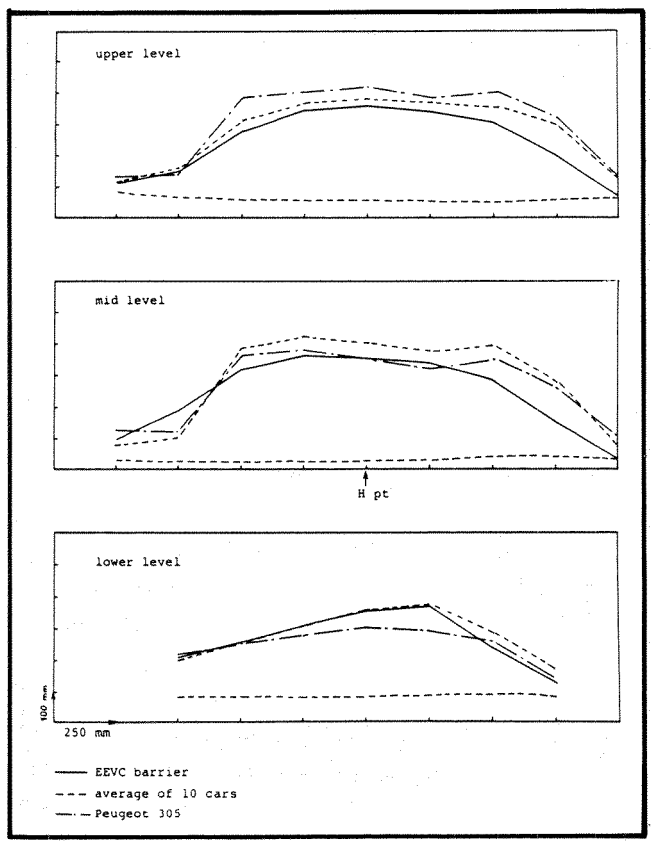

Figure 9. Deformation of the Renault 14 after side impact tests

Compared to other tests, the barrier gives correct deformations at the lower level and slightly lower at the upper level. However, differences are very low, especially in front of the driver. Figures 10 and 11 picture the struck Renault 14 in tests with the barrier and a Peugeot 305.

Vehicle Kinematics

From vehicle accelerations, it is possible to draw the speed variations versus time. The speed variation is an important factor, especially for the impacted door as it is correlated to the risk of injuries in side impact(2). Figure 12 shows the speed variation of the striking car, the struck car, and the impacted door of the struck car in the three tests with the mobile deformable barrier (the two tests conducted by ONSER give similar results) and in the test with the Peugeot 305. This figure does not show any big differences between these four tests, as indicated in Table 1. The speed ratios are in the same order of magnitude for the three tests.

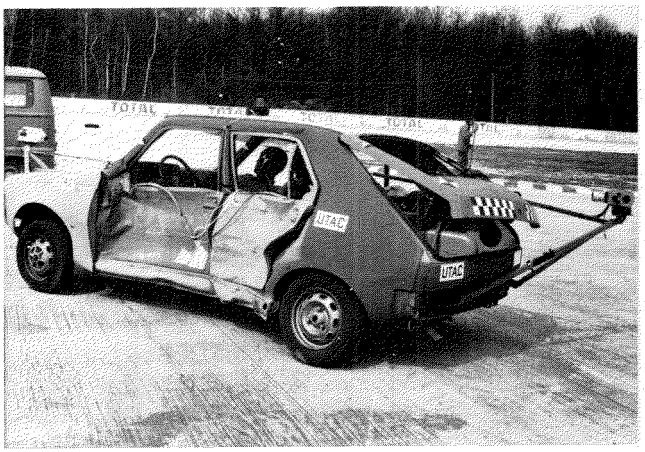

Figure 10. Renault 14 hit by a Peugeot 305

Figure 11. Renault 14 hit by the mobile deformable barrier

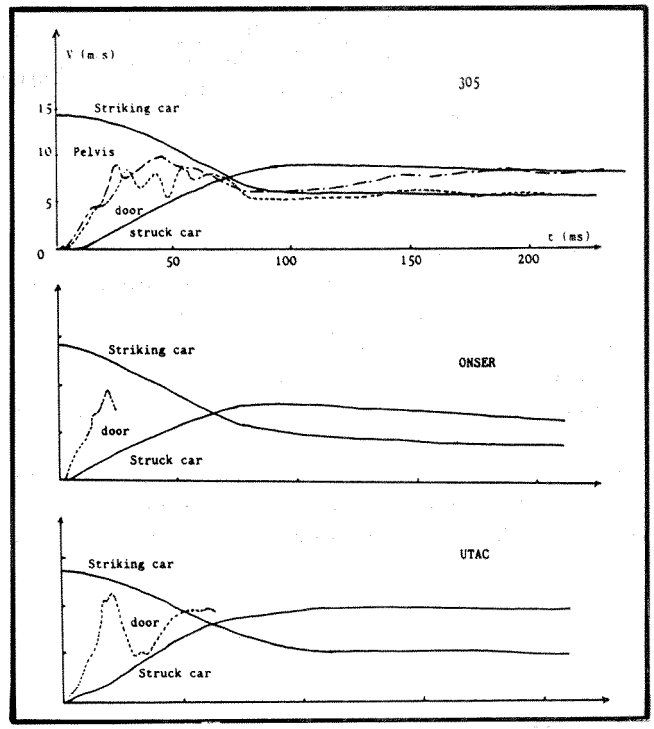

Figure 12. Speed varations in side impact tests

The distribution of deformation energy between the struck car and the impactor seems satisfactory in the car-to-car tests as in the barrier-to-car tests. If we consider the variation of the door speed, the barrier seems to give a higher slope and a higher maximum value.

Table 1. Speed ratios in side impact tests

Test	V2/Vo (%)	V1/Vo (%)	V1/V2 (%)
305/R.14	61	35	57
barrier/R.14	57	27	48
barrier/R.14	70	37	52

Vo = impact speed
V1 = striking vehicle speed at the end of impact
V2 = struck vehicle speed at the end of impact

Dummy Loadings

In each test, the dummy acceleration was recorded on the head, thorax, and pelvis. We are considering only the driver, who is more involved by the vehicle deformations than the rear passenger. Results of dummy loadings are listed in Table 2, which shows there are few variations in dummy loadings for the thorax and pelvis.

The barrier test results are closer to the Peugeot 305 test result than the average of the results of 10 tests performed with 10 different European cars.

Compared to average values, the barrier seems to increase the thoracic acceleration and decrease the pelvic one. However, the values recorded in barrier tests are in

Table 2. Dummy loadings

	Average 10 Tests	Weighted Average	P. 305 Impacting	Barrier UTAC	Barrier ONSER
Head HIC	304	241	511	141	408

Pelvis 3ms accel. (g)	106	106	85	78	84

line with those recorded in the test with the Peugeot 305, the car whose characteristics are closest to those of the barrier.

Work Done by BASt

Concept for the Full-scale Tests of BASt

The tests were carried out in the crash test facility of BASt. The measuring technique used was described fully in (3).

Figure 13 shows the test configuration of the barrier tests, which was laid down in the report of EEVC Working Group 6, "Structures"(1).

The collision speed in all tests was 50km/h. The results of the barrier tests, were compared with those of the vehicle/vehicle tests. Table 3 lists all the important test parameters. To date, two tests have been conducted with the EEVC barrier for each test configuration.

In this phase of the validation tests for the EEVC barrier, Hybrid II dummies were used since the European dummy planned for lateral collision tests was not yet available.

* test weight = curb weight + measuring equipment, without dummies

Standard measuring equipment, supplemented by six high-speed cameras, was used to measure the loads on dummies and vehicles. To determine the residual vehicle deformations, the vehicle was measured before and after each test; the points of deformation measurement are shown in Figure 14. The target points for the deformation measurements were adjusted to the R point, doorsill, and lower side window rail. The horizontal distance between the target points was 200mm. The target points on the DB 123 were located analogously.

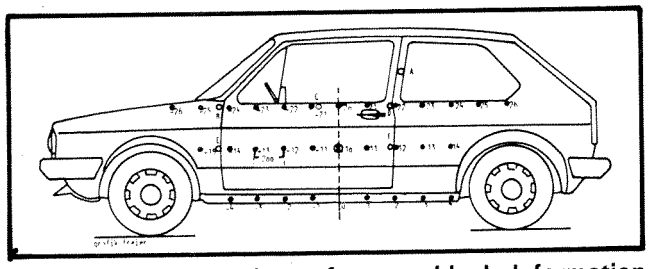

Figure 14. Target points of car residual deformation measurements

Results

The results will be used to demonstrate the differences in the vehicle and dummy loads between the vehicle/vehicle and barrier/vehicle tests. Below, the results of the barrier tests will be compared with the vehicle/vehicle tests; the mean values, particularly for the deformations of the VW Golf tests, can be regarded as the lower limit values that a test tool should achieve for a standardized test procedure for lateral collision testing.

For further comparison of different barrier designs, the results of a test series with the CCMC barrier are shown in the tables. These tests were conducted by BASt in 1982(4). The most important vehicle load values are the deformations, particularly the intrusion of the left front door of the struck vehicle into the passenger compartment, the acceleration of car body and side door, and the velocity changes thus caused.

Deformations and Vehicle Loads

In the tests with two VW Golfs, the striking car suffered a higher mean acceleration (a) and a greater velocity change (Δv) than the struck car (see Table 4). The accelerations of the side door, which are the primary determinants of the passenger load, are high (150g) and display only a small scatter.

The mean frontal deformation of the striking VW Golf was approximately 100mm, with obvious damage to the longitudinal members and outer body members (see Figure 15). On the laterally struck car, deep intrusions occurred in which the A-pillar and doorsill were ruptured and bent. The rupture of the A-pillar in the area of the windscreen frame and the deformation of the doorsill are

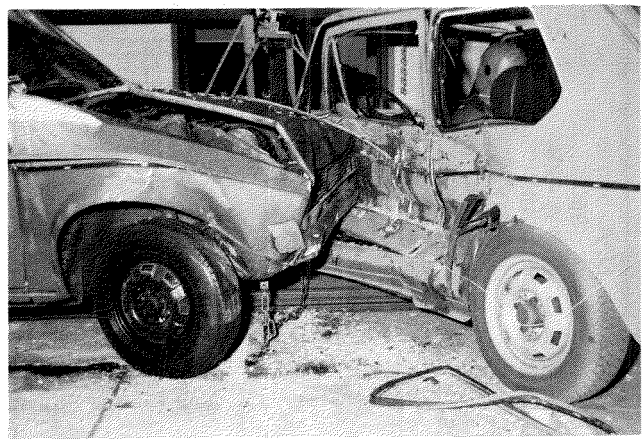

Figure 15. Deformation of the VW Golf

shown in Figure 16. The measuring rod in this illustration shows the approximate line of the original vehicle contours at the height of the doorsill.

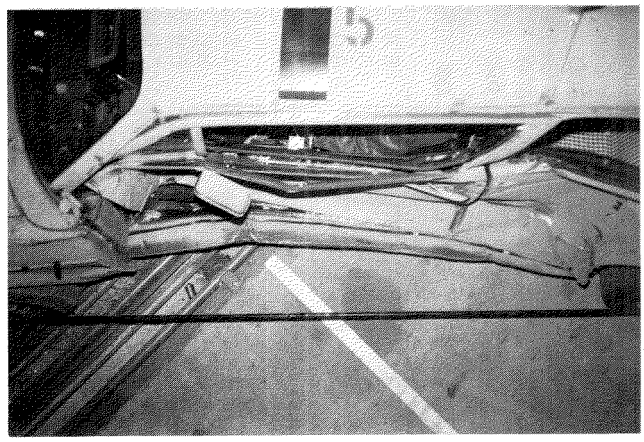

Figure 16. Rupture of the A-pillar and deformation of the doorsill of the VW Golf

The lateral deformation in the three tests with the VW Golf differed in both profile and depth. Figure 17 shows the depth of the deformation and the scatter for the three tests (in the area of maximum penetration).

These differences in lateral deformation were partly caused by the differing prior damage (corrosion) to the

□ maximum of deformation

vehicles in the area of the A-pillar. The mean intrusion on the side door—measured in the inner passenger compartment at chest height of the occupants—reached a maximum of 216mm (dynamic value); the residual intrusion was 152mm. The lateral intrusion of the A-pillar and side door led to a displacement of the steering column of approximately 90mm toward the center of the vehicle.

In the tests with two Daimler Benz W 123's, the mean car accelerations ($\bar{a}$) and velocity change (Δv) were roughly equal for both vehicles (see Table 4). With a relatively large deformation depth, the side door acceleration is unexpectedly low. This can be attributed to the greater deformation contingency of the door structure—due to the greater door thickness—and the installation point of the acceleration transducers—distance from the B-pillar.

The mean depth of front deformation on the striking vehicle was 140mm with clear damage to the lateral members caused by the hard areas of the A-pillar and rear wheel housing (see Figure 18).

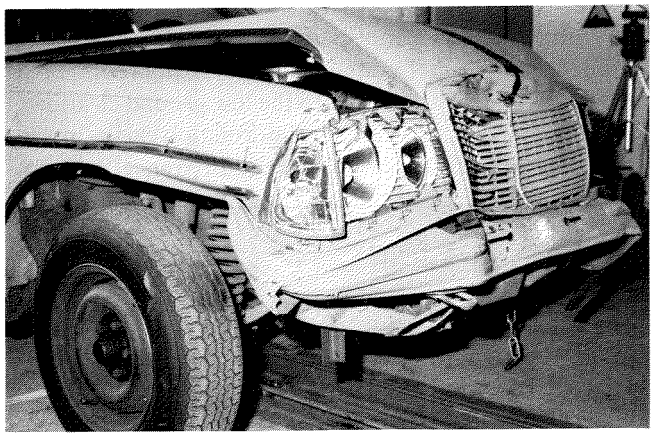

Figure 18. Frontal deformation of the striking DB W 123

The lateral intrusion in these tests displays a smaller zone of scatter than in the tests with the VW Golf (Figures 19 and 20). This can be explained by the high stability of the A- and B-pillars of the DB W 123. No complete rupture of these members occurred.

The mean dynamic intrusion of the side door reached a maximum of 299mm, and a residual intrusion of 220mm was measured (approximately 30 percent more than in the tests with the Golf). The lateral displacement of the steering wheel was, however, only 45mm.

In the tests with the deformable EEVC barrier, the struck Golf sustained higher car accelerations than in the Golf/Golf tests. The mean car load (a) was, for example, approximately 30 percent higher (Table 4). The higher vehicle loads corresponded to the considerably higher door accelerations.

The lateral deformation (measuring line -2) of the VW Golf in the impact with the barrier was of a more uniform distribution than in the Golf/Golf tests. The deformation in the area of the doorsill is considerably greater than that

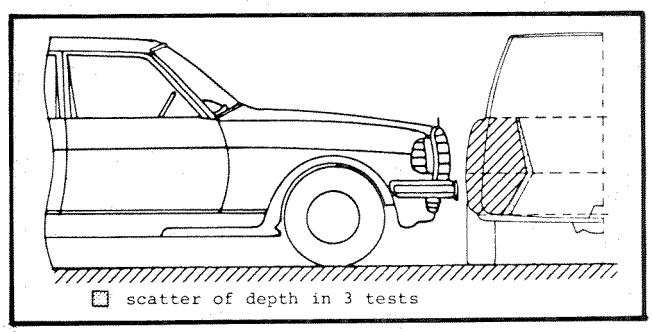

Figure 19. Deformation profile in tests with two DB W 123's from the measuring line -2 (definition in Figure 18)

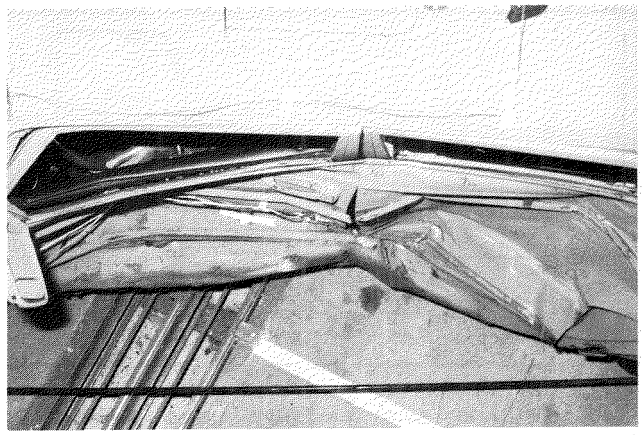

Figure 20. Lateral deformation of the struck vehicle in tests with two DB W 123's

produced in the Golf/Golf tests; the difference in penetration depths in the two tests was less in the area of the sill. The rigidities of the individual barrier elements and their ground clearance are influencing factors in these vertical deformation characteristics. Figure 21 shows the deformation profile for measuring line -2.

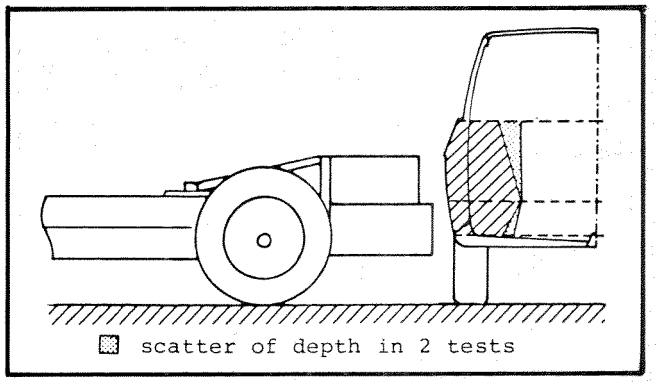

Figure 21. Deformation profile of a VW Golf after impact with the EEVC barrier for measuring line -2 (definition in Figure 14)

In the tests with the EEVC barrier and the DB W 123, a smaller scatter was also observed than is generally the case in the car/car tests. In view of the considerable difference in weight, the barrier was subjected to a greater change in speed.

The loads are therefore lower than in the tests with two DB W 123's—they correspond roughly to the level of the loads occurring during a collision between two VW Golfs, (see Table 4). The acceleration of the left-hand driver's door is low, although slightly higher than in the tests with the two DB W 123's. When the differences in weight are taken into consideration, this indicates that the foam block of the barrier is more easily deformed by the B-pillar than is the front structure of the DB W 123. The vertical deformation profile (Figure 22) during the barrier tests is very similar to that achieved in tests with two DB W 123's (see Figure 19). In these tests, the scatter of the measured deformations is low, particularly in the area of the doorsill.

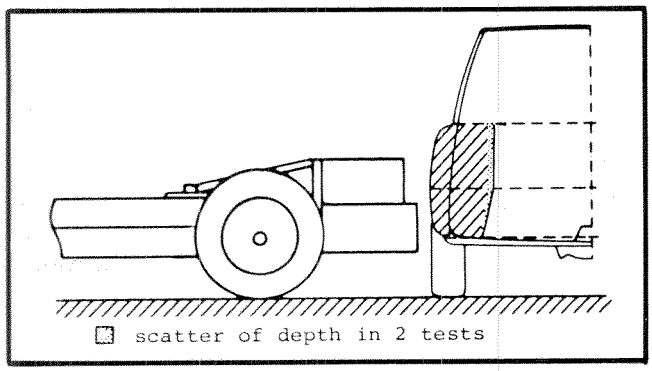

Figure 22. Deformation profile of a DB W 123 after impact with the EEVC barrier (definition in Figure 14)

For a qualitative evaluation of the differences in lateral deformation, Table 5, with a list of cumulative deformation measurements for the individual measuring points, can be used (definition in (6)). In a comparison between the Golf/Golf tests and the EEVC barrier/Golf tests, it is apparent that the mean depths of the measuring points are very similar. Also similar are the lines of maximum deformation, which, in the case of the two-door VW Golf, are approximately in the middle of the driver's door. The edge of the barrier strikes the door rabbet and hinges in front of the A-pillar and rips these out of the pillar. Whereas the VW Golf is a two-door car with a relatively rigid sidewall between B- and C-pillars, the side sectional stability of the four-door DB W 123 is relatively lower.

The low rigidity of the doors and, therefore, the only slight involvement of the A-pillar and the rear wheel housing in the distribution of the forces lead to maximum deformation in the area of the B-pillar. Furthermore, the distance between the A-pillar and the rear wheel housing on the DB W 123 is approximately 100mm greater than on the VW Golf; with the same width of barrier, this leads to a less favorable distribution of forces. The deep deformations in the tests with two DB W 123's, particularly in the area of the B-pillar at measuring line -4, are caused by the greater impact energy of the striking vehicle and by the width of the front structure. This is made particularly clear when compared with the tests using the EEVC barrier.

A comparison of the measured deformations in Table 5 shows the EEVC barrier causes the same horizontal deformation characteristics as a corresponding vehicle. The limits to this correspondence are determined by the excessive differences in mass and geometrical differences (vehicle width).

To clarify this, Figure 23 shows the horizontal deformation patterns of the struck VW Golf compared with the tests between the EEVC barrier and the VW Golf. In the upper door area, the deformation in the Golf/Golf tests is higher than in the barrier/Golf tests.

It is not possible to determine whether this phenomenon is due to the low rigidity of the upper part of the EEVC barrier or to the effect of the greater sill deformation. If the EEVC elements have a greater ground clearance, a smaller sill deformation and a greater deformation in the upper door area would be produced with otherwise constant parameters.

The deformation depth in the area of the R point important for the dummy load is equal in both test series. The deformation in the doorsill area is too high compared with the Golf/Golf tests due to the low ground clearance of the barrier. To represent the deformation curves, mean values were plotted to emphasize the differences between

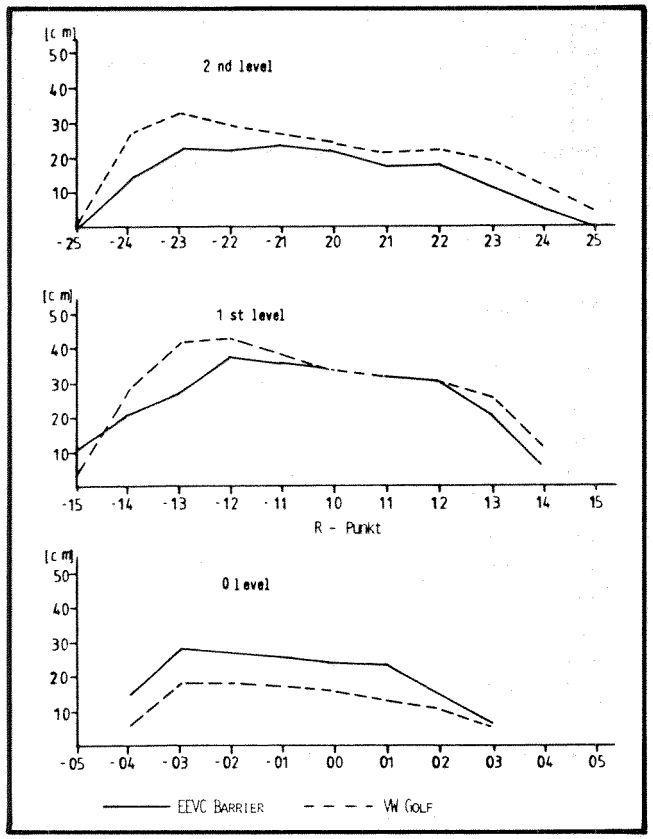

Figure 23. Mean deformation values in tests—EEVC barrier/Golf (n = 2) and Golf/Golf (n = 3)

the test series. With the exception of a few points, the conformity between the barrier tests was high in the upper door area (see also Table 5).

If one compares the horizontal deformation curves of the test series with the middle class vehicles (DB W 123), Figure 24, it can be seen that here, too, the EEVC barrier reproduces well the deformation characteristics of an impact with the same type of vehicle. As was to be expected in view of the greater vehicle mass and the consequent greater front rigidity of the DB W 123, the overall deformation caused by the DB W 123 is greater. What is unexpected is the very good conformity of the doorsill deformation, which can be attributed to the fact that the height of the sill of the DB W 123 is higher than that of the Golf and, in the event of a lateral collision, is also deformed by vehicles with greater ground clearance than the EEVC barrier. The good conformity of the sill deformation also indicates the rigidity of the lower barrier elements corresponds well with the rigidity of the average front structure of a DB W 123. The depth of deformation in the area of the middle door height shows wide deviations since the rigidities of the front of the vehicle and the front of the barrier are too dissimilar—the reason for this is probably the ground clearance of the barrier (see Figure 14). The deformation in the upper door area during a lateral collision is not normally caused by direct contact with the striking vehicle but is usually a consequence of the deformation of the door lower down. The deformation in the upper door area is therefore greater if the intrusion in the middle door area is deeper.

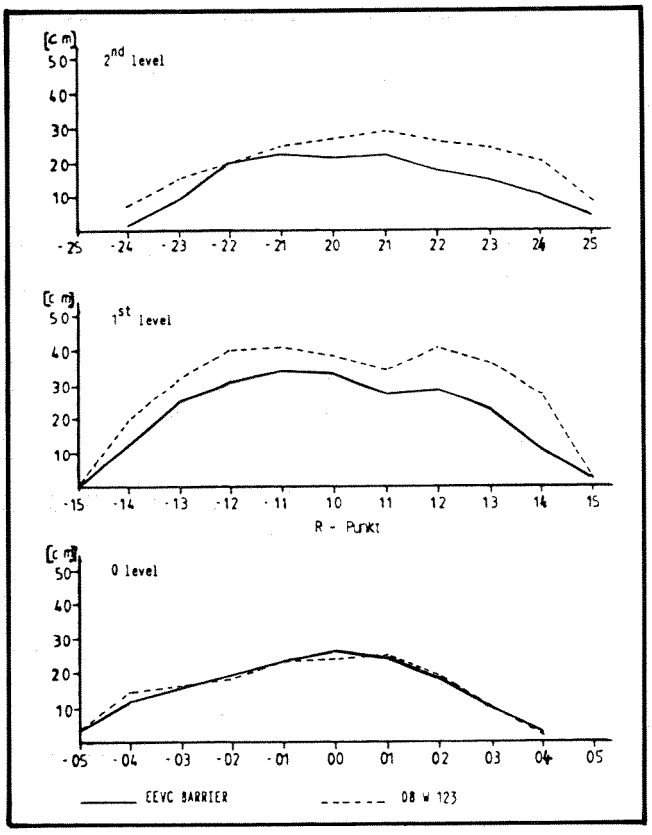

Figure 24. Mean deformation curves in tests—EEVC barrier/DB W 123 (n = 2) and DB W 123/DB W 123 (n = 3)

Deviations between the deformation values of the barrier tests are only very slight, and the reproducibility of the deformation with the EEVC barrier is, in this test configuration, very good—even better than in the VW Golf tests.

The differences in the vehicle loads during tests with the EEVC barrier and with two VW Golfs are caused primarily by the lower ground clearance of the barrier elements. This applies unreservedly to the deformation in the area of the doorsill—with additional influences of the greater mass of the barrier and the greater mean acceleration and velocity change—and probably also to the smaller deformation in the upper area of the door.

The differences in the vehicle loads during tests with two DB W 123's compared with the tests between the barrier and the DB W 123 are also large for the parameters a and Δv due to the large mass-related energy differences. The deformation characteristics are, however, very similar to those occurring during impact with a similar type of vehicle (although with a lesser depth in the middle and upper areas of the door).

The test results with the two tested vehicle types indicate clearly that the ground clearance of the deformation elements is too small:

- On the Golf, due to excessive doorsill deformation
- On the DB W 123, due to insufficient deformation in the upper area of the door

With this adaptation, the EEVC barrier has a very good simulation characteristic.

Occupant Loads

The vehicle loads described above result in the acceleration values listed in Table 6.

As can be seen from Figures 23 and 24, the deepest lateral intrusion of the side occurs in the area of the passenger's pelvis, both in the vehicle tests and barrier tests.

The highest load values were consequently also measured in the pelvis area of the driver dummy.

The obvious differences in the level of pelvis load are clearly attributable to the different depths of deformation.

Dummy kinematics and loads will generally be influenced by:

- The mean vehicle acceleration (a) and velocity change (Δv) of the struck vehicle
- The depth and speed of the intruding side
- The initial distance between the dummy and the inner panel, which affects the time of contact and thus the different speeds of side structure and dummy

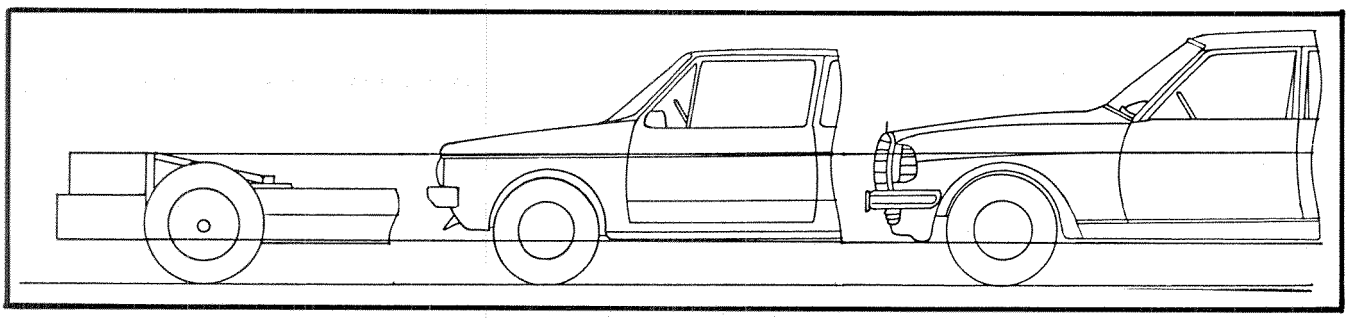

Figure 25. Comparison of heights of vehicle fronts

• The construction of side structure and paneling

When considering both test series, barrier and vehicle tests with VW Golf, only the first two parameters mentioned above can influence the differences in these tests. The sequence of the dummy kinematics is as follows: When one VW Golf is struck by another VW Golf or the EEVC barrier from the side, the intruding side first strikes the driver's seat and pushes it against the passenger seat. During this period, the dummy remains in its initial position and, after approximately 24ms (after start of crash, average for all VW Golf tests), is then struck by the intruding side. The chest and pelvis are struck almost simultaneously. The times and accelerations for the impact between the side of the vehicle and these parts of the dummy are almost identical in all tests. A slight difference was evident in the impact times for the chest with the intruding side door. During the vehicle tests, the dummy was struck by the door before it reached its maximum intrusion speed; during the barrier tests, the door reached its maximum speed before impact with the dummy (see Table 7 and Figure 26). During the barrier tests, the maximum chest acceleration of the driver dummy was reached after 35ms, in the car tests after 33ms. A greater difference in the acceleration peaks was measured for the pelvis—for barrier tests 33ms, for car tests 40ms.

These differences are associated with the deformation behavior of the door. The loads have a lesser effect on the chest than on the pelvis. The side door area at the height of the pelvis was not fitted with accelerometers. The sharp rise in the velocity curve can, however, be recognized in Figure 26 from the acceleration measured on the pelvis of the dummy. The speed in the barrier test is considerably higher.

As a result of the impact between the driver dummy and side door, the head of the dummy rotates toward the point of contact and hits its own shoulder and/or the safety belt directly behind the mounting. The resulting

* without dummies

head load was low and depended on the chest acceleration. The behavior of the chest and the head during lateral impact is determined by the design of the Hybrid II dummy; the chest and shoulder area as well as the vertebral column are too stiff for the lateral impact. In lateral collision tests with the newly developed lateral dummies, which demonstrate a more realistic behavior, the head moved through the plane of the side window(5). The load criteria for the various regions of the body were exceeded for the pelvis area (80g/3ms) in all barrier tests and one Golf/Golf test.

Due to the collision configuration (e.g., impact points), the loads on the rear passengers were less affected by the lateral intrusion. In addition, a longitudinal component was included in the direction of movement. These factors lead to markedly lower loads on the chests of the rear passengers. Due to the direction of movement toward the point of impact and also the shifting of the driver's seat because of deformations of the car floor, the knees of the rear dummy collided with the driver's seat. The loads thus caused could be measured in the chest and pelvis of the driver dummy and in the femur and pelvis of the rear seat dummy.

In the event of a head impact, the rigid, practically unpadded C-pillar and the lateral roof rail lead to high accelerations, although these do not exceed the protection criterion (HIC $\leqq$ 1,000). The kinematics and loads on the rear seat dummy were practically identical in the test series with the barrier and with the VW Golf—the slightly higher loads in the barrier tests correlated with the higher collision energy as a result of the greater vehicle mass.

In the tests with the intermediate size cars DB W 123, the characteristics of the car construction and the greater car mass of the striking vehicle produced significantly higher loads on the driver dummy (80g/3ms and 60g/3ms were exceeded in all tests for pelvis and chest, respectively). The dummy kinematic load was generally the same as in the other tests. The main difference was in the pelvis region. Whereas chest and pelvis were struck by the intruding door at the same time in all the Golf tests, the intruding door in the DB W 123 tests accelerated the chest earlier (approximately 10ms). This was caused by the seat, the side door geometry, and the resulting seating position.

A further difference involved the driver's seat, which, together with the dummy, was pushed against the passenger seat. In tests where a VW Golf was struck from the side, on the other hand, the seat displacement was almost complete before the dummy was struck by the intruding door. This means the load on the dummy during the tests with a VW Golf was not affected by the behavior of the driver's seat but was affected in the tests with the DB W 123. The effects of the impact site for chest and pelvis relative to the speed curve of the side door are shown in Figure 27.

The loads on the head of the driver dummy follow the same pattern of movements as in the other series of tests, although the head loads are higher due to the higher chest acceleration.

The loads on the rear seat passengers were also significantly lower than those for the driver dummy in these tests. The acceleration level was roughly similar to that in other test series. This may be the result of better door padding; here again, no clear interactive contact is made between the driver's seat and driver dummy. The more stable floor and the maximum side deformation

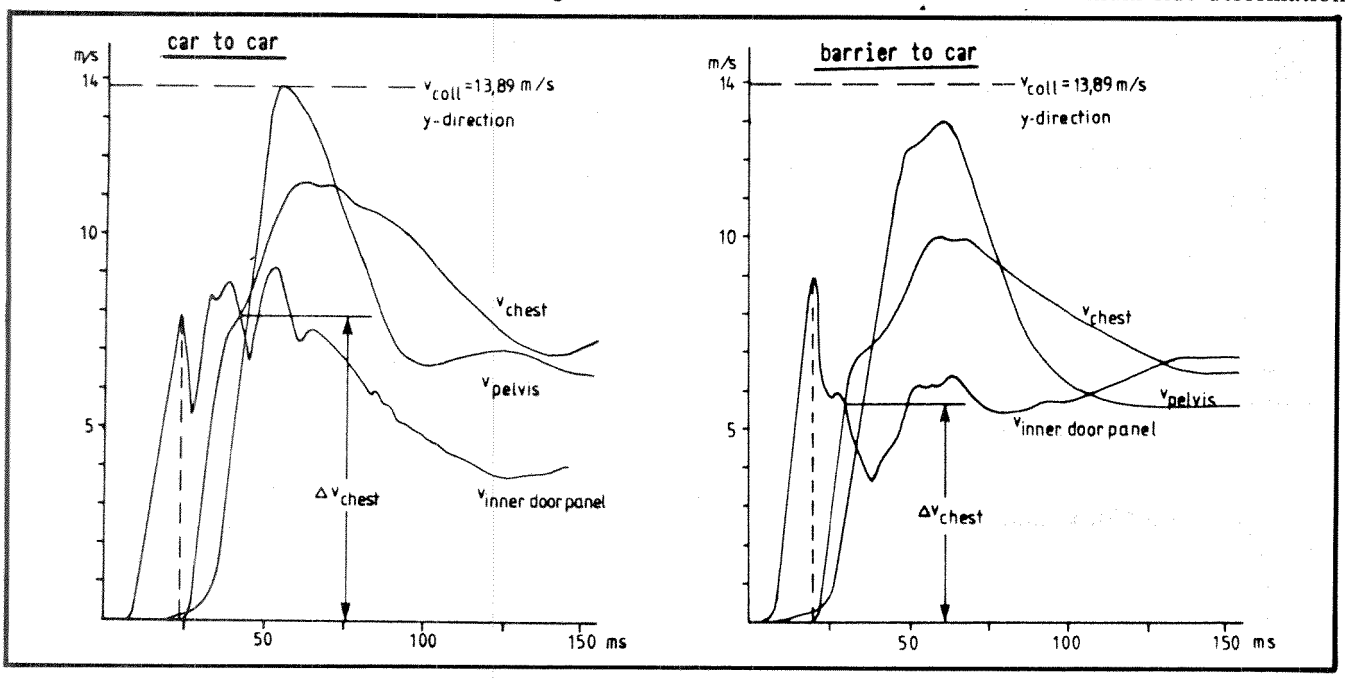

Figure 27. Velocity/time graphs for chest and pelvis relative to intruding door in test DB W 123 and EEVC barrier/DB W 123

lying further to the rear of the vehicle prevent impacts between the rear seat dummy and the driver seat.

During lateral impact of the EEVC barrier with the DB W 123, the dummy kinematics are similar to those occurring during car/car collisions, and the curve characteristic for the pelvis loads is also similar. Only the acceleration of the various parts of the dummy body is lower, and other contact times are the result of the lesser deformation depths with roughly similar deformation speeds (see Tables 6 and 7 and Figure 27).

In the following, the distribution of the accelerations over different parts of the body is compared; acceleration values with an effective duration of 3ms will be compared. Figure 28 shows the mean values from the various series of tests.

The expected distribution of the loads from head to pelvis with ascending values could be observed in all tests. The loads produced by a striking VW Golf were lower for all body parts than in the EEVC barrier tests. In contrast to the corresponding CCMC barrier tests, the EEVC barrier does not produce unrealistically high loads on the pelvis region. The greater weight and associated rigidity of the front of the DB W 123 caused high dummy accelerations not achieved in the tests with the lighter EEVC barrier. Nevertheless, the dummy loads were so high that the injury criteria for chest and pelvis were exceeded.

Summary and Conclusion

The development of a test regulation for lateral collisions as part of a type approval test is currently being promoted by ECE. Before a joint regulation can be accepted by the governments of the participating states, a more suitable anthropometric test dummy (lateral dummy) must be developed for lateral collisions and a suitable test tool selected as a standard vehicle from the existing proposals. This study was to prove the validity of a mobile deformable barrier whose parameters (e.g., rigidity and deformation behavior) were specified by EEVC, regarding its suitability in comparison with collisions between real vehicles. In this project, two tests were carried out with the EEVC barrier against the VW Golf. The results of the vehicle and dummy loads were compared with those from another test series, VW Golf versus VW Golf. In addition, a similar series of tests was carried out with the DB W 123, results of which were used to demonstrate differences in vehicle and dummy behavior. Furthermore, data from a test series with the CCMC barrier against the VW Golf are shown in comparison tables to assess the suitability of the EEVC barrier in comparison with other solutions. The most important results from the three series of tests are summarized below:

Golf/Golf Tests

- During the tests, the deepest deformation was measured in the front door area. The deformation of the doorsill on the struck vehicle was low due to the relatively high ground clearance of the striking Golf. The A-pillar was ruptured at the transition to the sill.
- The distribution of the impact speed did not produce equally high ratios to the change in velocity—the striking VW Golf sustained greater velocity changes.
- The dummy loads were comparatively low. The protection criteria were exceeded in only one test for the dummy (driver) pelvis.

EEVC Barrier/VW Golf Tests

- The barrier produced a very deep intrusion in the doorsill of the struck Golf; the profile of the deformation in the upper door area was similar but less deep. The maximum deformation was also in the front door area.
- The vehicle acceleration was greater than in the car tests. The velocity change of the struck Golf was slightly higher than that of the barrier.
- As a result of the slightly higher mass of the barrier, the dummy loads were also greater than in tests with the VW Golf. The pelvis protection criterion was exceeded in all tests.

Compared with the Golf/Golf tests, the following conclusions can be drawn as to the suitability of the EEVC barrier:

- The distribution of the various rigidity zones in the horizontal plane of the EEVC barrier conforms well to the front face of the VW Golf.

- The ground clearance of the EEVC barrier elements, designed to be compatible with future vehicle development, is too low to produce deformations comparable with those caused during a VW Golf/VW Golf collision.
- The dummy loads for head and chest in the EEVC barrier tests were of approximately the same level as in tests with the VW Golf. The pelvis was subjected to greater loads in the barrier tests, and the protection criterion (80g/3ms) was exceeded.

DB W 123/DB W 123 Tests

- In the tests, deformations in the upper door area were large and approximately the same depth as in the tests with the VW Golf. The maximum side deformation in this case, however, was in the area of the B-pillar. The doorsill deformation was significantly higher than in the Golf tests.
- The car acceleration and velocity changes were greater than in the Golf tests. The distribution of the velocity change of the striking and struck DB W 123 was the same.
- The protection criteria were exceeded in all tests for the chest (60g over 3ms) and the pelvis (80g over 3ms).

EEVC Barrier/DB W 123 Tests

- The deformations in the area of the doorsill were very similar—the areas in the middle and upper side door were deformed considerably less than in the DB W 123/DB W 123 tests. The area of maximum deformation was again in the area of the B-pillar.
- The mean vehicle acceleration of the struck DB W 123 was slightly lower than during the car tests. The mean deceleration of the EEVC barrier was approximately 1.5 times higher. The velocity change of the struck DB W 123 was considerably lower than in the car tests. On the other hand, a higher acceleration of the side door was measured that did not, however, have any major effect on the door intrusion speed.
- The similarity of the loading by the EEVC barrier compared with the DB W 123 is also indicated by the dummy loads; they are in a similar proportion for parts of the body but, as a result of the lower vehicle acceleration and deformation depth, are lower overall. The protection criteria for chest and pelvis were also exceeded during the barrier tests.

Compared with the tests using two DB W 123's, the following conclusions can be drawn regarding the suitability of the EEVC barrier:

- The distribution of the rigidity zones in the horizontal plane of the barrier conforms as well as with the Golf with the front face of the DB W 123, e.g., it leads to similar deformation profiles.
- To cause similar deformations in the vertical plane, however, the upper edge of the barrier must be raised and cause a greater deformation of the upper door area. In the critical R point area, however, it conforms satisfactorily.
- The dummy loads in the barrier tests correspond to those in the tests DB W 123/DB W 123 when the difference in the kinetic energy is regarded; e.g., they are appropriately lower. Chest and pelvis loading exceed the protection criteria.

In conclusion, the following comments can be made regarding the suitability of the EEVC barrier:

- The distribution of the rigidity zones in the horizontal plane of the EEVC barrier conforms well with the demands of such a wide spectrum as that of the VW Golf and DB W 123 as shown by comparisons of the deformation profiles.
- The ground clearance of the EEVC barrier elements is too low to produce deformations similar to those produced by cars currently on the road in small vehicles, e.g., the VW Golf tested here. If the position of the doorsill, e.g., on the DB W 123, is so high that even vehicles currently on the road cause a deep deformation of the doorsill during lateral collisions, the area of the barrier that is superfluous for sill deformation appears to be lacking in the upper door area; i.e., for a better simulation for this type of vehicle, the ground clearance of the deformation elements must be raised.
- The dummy loads in the EEVC barrier tests were, in all cases, similar to the loads caused by real vehicles and demonstrated only higher or lower values through the differences in impact energy. During the EEVC barrier/VW Golf tests, the pelvis was overloaded and the protection criterion (80g over 3ms) was exceeded. In the tests between the EEVC barrier and the DB W 123, chest (60g over 3ms) and pelvis (80g over 3ms) were overloaded.
- The EEVC barrier is capable of simulating well the specific deformation characteristics even with widely differing vehicles. The rigidity of the hard foam elements combined with the aluminum panels is a good approximation of the average vehicle structure. In view of the test results shown here, a correction of the ground clearance of the deformation elements appears to be

necessary for it to conform with vehicles currently on the road.

General Conclusions

This research involves four different European laboratories: BASt in the Federal Republic of Germany, ONSER and UTAC in France, and TRRL in the United Kingdom, under the project leadership of ONSER.

This work was split into two phases. The first phase is achieved, whereas the second phase is in progress. The main conclusions of the part of the work that is finished are—

- The force-deflection characteristics of the front element in polyurethane foam developed by Fritzmeier are close to the specification corridors. Keeping the values of foam density inside a scatter of ±5 percent and taking care of manufacturing would allow almost all the force-deflection curves to stay within the corridor.
- The frontal tests with these elements show a force peak at the beginning of the deformation. However, this force peak probably has small effect on struck car deformations and dummy loadings, as it occurs very early compared to the time of maximum crush and maximum dummy loadings.
- Investigation on alternative material showed that reusable components would be very complicated, heavy, and often damaged by the tests. They would not comply with the proposed specifications.
- The problem of the disintegration of foam was solved by covering the deformable elements with a glued fiberglass net.
- Barrier-to-car side impact tests, compared to car-to-car tests, showed that the barrier correctly reproduces car deformations as well as dummy loadings.
- The validation of the EEVC barrier is near completion, especially in tests using the EUROSID dummy as it is prescribed in the EEVC side impact test procedure. At the same time, the repeatability of the barrier is evaluated, as well as the possibility of using it to check compatability between front and side structures.

The CCMC Mobile Deformable Barrier for Lateral Collision Testing

D.R. Gebbels
Pilot CCMC Working Group Crashworthiness
(Ad Hoc Group Barriers)

Abstract

As reported at the Seventh ESV Conference, Paris, 1979, the European car manufacturers associated with the Committee of Common Market Automobile Constructors (CCMC) carried out a large program of lateral collision tests. From this data base, CCMC proceeded to develop a mobile deformable barrier (MDB) to investigate its use as a test tool. This paper describes the criteria used in MDB definition, MDB construction, and the assessment testing undertaken to date and reviews and discusses the possibilities for further harmonization of test standards.

Introduction

From 1979, CCMC has been developing an MDB to investigate its use as a realistic test tool for lateral collisions.

Importantly, it must be restated that during its early investigations into the use of side impact barriers, CCMC concluded dummies such as the Part 572 do not adequately represent the performance of human beings in lateral collisions. Therefore, MDB development will be of limited advantage until suitable progress has been made in the development of dummies for lateral collisions.

Phase I—Design Objective

The objective was to match the essential characteristics of the MDB as closely as possible to those of an average European car running on European roads in the late 1970's. A regular check was to be made, say every 2 years, to detect any trends in these characteristics so that changes could be considered. The first reevaluation of the MDB is now taking place and is discussed under Further Research. The original version was based on 1976 vehicle data and is designated CCMC-MDB76.

The essential parameters and development criteria for the MDB were—

- Mass
- Force-deflection characteristics
- Deformation zone structure (geometry)
- Deformation length
- Energy-absorbing material

The deformable part was to be designed for the most severe 90° lateral impact of the MDB against a vehicle.

Mass (CCMC76)

From 1976 sales figures, frequency distribution for unladen car masses were determined for the automobile industries in individual European countries. Weighting the basic vehicle masses with available frequencies for the vehicle types produced an unladen weight of 850kg as the average value. Allowing for vehicle occupancy of 1.5 to 1.7 (average) and the estimated shift in mass from 1976 to the date of the MDB specification, a specification for the MDB was established at 950kg.

Force-Deflection Characteristics

The force-deflection characteristics specified for 300mm deformation were determined from the test results obtained from 15 different cars into 0° full frontal dynamometric barrier at 48km/h. The dynamometric barrier information was supplied by CCMC member companies, and the 15 different car models represented some 1.5 million cars registered for the road in 1976. With consideration of geometric data, the barrier face was split into eight separate segments. The characteristics from the individual cars were weighted according to the 1976 sales figures and then averaged.

Deformation Zone Geometry

To obtain representative geometric dimensions for the deformable element, the essential geometric data of approximately 45 cars, weighted according to frequency, were determined. Figure 1 shows the representative geometry (mean value) of the front of an average European car circa 1978. Based on these findings and in conjunction with the force deflections, segmentation of the deformation zone and design dimensions were defined (Figure 2).

The front face of the barrier was specified flat, vertical, and normal to the barrier's longitudinal axis, without simulation of a bumper. The distance of the lower edge of the impact surface from the ground was set at the maximum of 300mm to allow the barrier to slide over the side doorsills of most cars.

Deformation Length

Based on the finding concerning maximum deformation values for the colliding vehicles in (1), a deformation length of 300mm was considered adequate—the MDB being originally envisaged as a test instrument for perpendicular lateral collision only. Its use under a crabbed test configuration is discussed under Harmonization of Side Impact Test Procedures.

Energy-Absorbing Material

Steel tubes, hydraulics, aluminum honeycomb, and rigid urethane foam were all considered for the energy-absorbing element. Both the hydraulics and tubes were discarded because they would require a heavy rigid front plate and such a plate would have adverse mass effects in a side collision.

After preliminary investigations and testing of aluminum honeycomb, this too was abandoned because the barrier segmentation and load deflection curves required could not be readily achieved without significant developments in the technology. Also, the source of supply for such material was limited and, with it being at a basic cost and weight disadvantage when compared to foam, rigid urethane foam was finally adopted for the energy-absorbing elements.

Material Testing

Deflection Characteristics

Quasi-static pressure tests with foams of different densities were performed to quantify the relationship

	A	B	C	D	E	F	G	H	J	K	β	α	L	M_1	M_2	P	R
CURB WEIGHT	285.2	390.4	390.8	109.0	816.4	53.5	731.9	1539.7	1433.9	746.6	5.27°	3.0°	361.7	577.1	692.0	232.3	521.5
2 FRONT OCCUPANTS	260.6	367.3	368.1	/	792.3	/	/	/	/	/	/	3.15	336.5	556.5	671.3	/	496.7

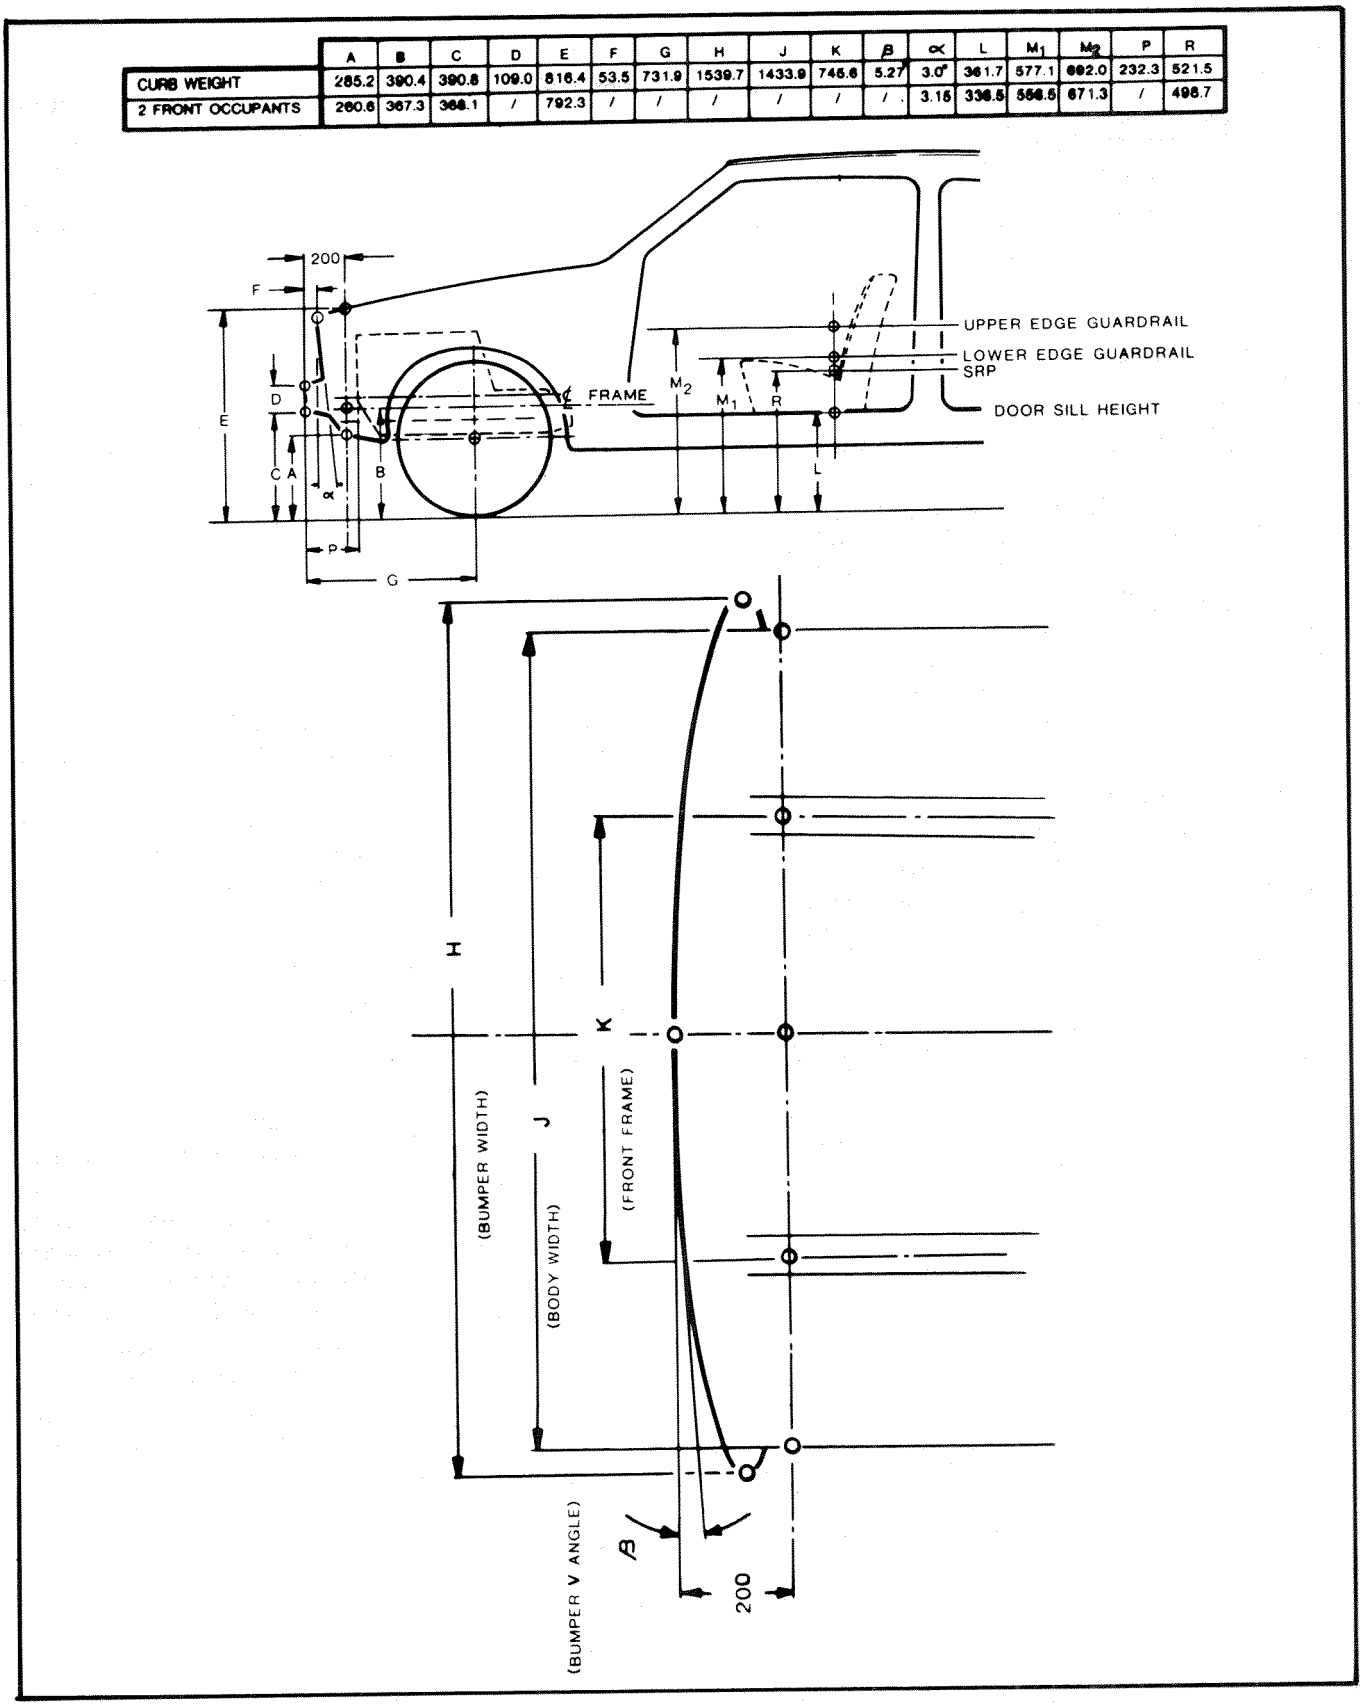

Figure 1. Geometrical car dimensions—European mean values

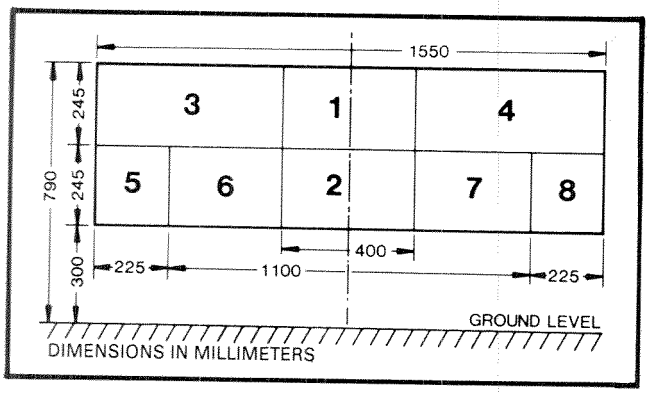

Figure 2. MDB segmented front face

between collapse force and the respective density. To obtain the necessary force-deflection, test specimens with internal sculpturing for some of the depth were made. For production reasons, the internal cavities were bored parallel to the direction of force. To adapt the foam material to the given force-deflection characteristic, each individual segment of the barrier had to comprise separate layers of different density foam with different internal cavity arrangements.

Temperature Influence

Foam samples of different density and core temperature were submitted to static and dynamic testing. The densities were 30, 70, and 96kg/m^3, and the tests performed at temperatures of 0°, +20°, and +40°C. With a density of 30kg/m^3, temperature did not have any significant influence on the force, whereas the more dense foams produced reduced forces of around 15 percent as the temperature was raised +40°C (Figures 3 and 4).

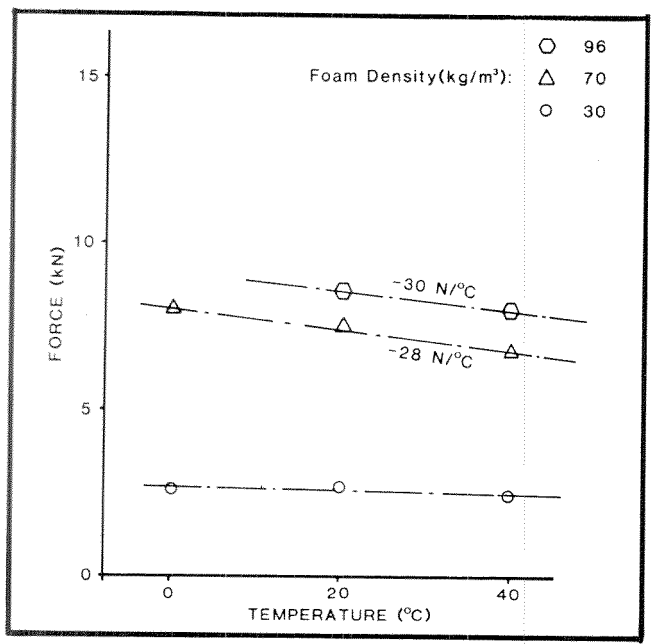

Figure 3. Temperature effects (PU foam) in static tests

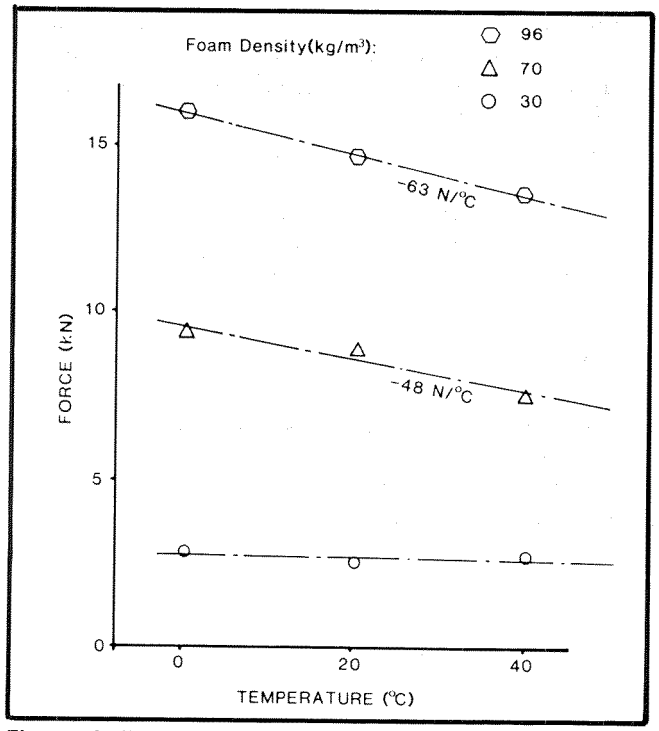

Figure 4. Temperature effects (PU foam) in dynamic tests

Consequently, to limit the effect of temperature variation to below 5 percent, a temperature range of +18°C to +25°C would be specified for the deformable zone of the MDB during a lateral collision. (This requirement is similar to that required for the anthropomorphic dummy in U.S. legislation.)

Speed Influence

Although polyurethane foam was found to be velocity-sensitive in that the collapse load was higher under dynamic loading than quasi-static, this particular criterion was not pursued in depth. Since the speed variation allowable in any test procedure would not be greater than, say, ±5 percent, it was not considered a problem. Fixed barrier tests at 35 and 50km/h impact velocities showed no differences in the force/deflection characteristics up to 300mm deformation.

Preliminary Testing of MDB Deformable Element

For the preliminary verification of the force-deflection characteristics, two differently structured MDB deformable parts were manufactured; one with three layers of foam giving a five-step characteristic, and one with four layers giving a seven-step characteristic. The constituents of the individual segments were cut from freely expanded polyurethane blocks and provided with the required

cavities by mechanical means. Tests with the two prototypes into a dynamometric barrier at 50km/h showed a good approximation to the required force-deflection curve by the three-layer variant with the four-layer version being less satisfactory. The three-layer polyurethane part was chosen for further development. Because the MDB deformable element absorbs only the energy of a 33km/h fixed barrier impact, it was mounted on an additional foam block with high stiffness.

Front Cover Plate

A flexible front cover plate was necessary to allow a continuous deformation process with different lateral stiffnesses of the impacted vehicle—to spread the forces and mitigate local penetrations. Various covering plates were tested with a 2mm aluminum plate being finally chosen.

Barrier Construction

Deformable Zone

Each segment was made from two blocks of foam glued together with internal cavities for part of their depth. Over the entire face of the MDB was glued a thin (30mm) layer of low-density foam. Onto this was stuck the 2mm aluminum plate.

To insure the temperature of the elements could be maintained between 18° C and 25° C at the time of test (as would be necessary for an outside facility in winter), the entire unit was designed so it could be installed onto the rigid chassis at the last moment before test. This was achieved by having an aluminum plate glued to the back of the foam elements so the entire assembly could be mounted easily to the rigid part of the barrier by quick-release pit pins. The entire assembly was wrapped in a thin plastic sheet to prevent foam scatter on impact. Weight of the deformable unit was 25kg.

Rigid Chassis

The frame configuration was adapted from that proposed by ISO for its barrier for side impact testing. It consists of welded steel profiles and has a front covering plate to support the deformable unit and react the deformation forces.

The chassis is equipped with two Porsche 924 rear axles so the overall height may be adjusted via the torsion bars. The suspension of both axles can be locked. The chassis is also equipped with a hydraulic brake system acting on all four wheels. The basic chassis weighs 744kg. With the deformable zone attached, the minimum barrier weight would be 770kg.

Ballast at the back of the chassis produces the specified barrier mass with a center-of-gravity height of approximately 500mm and an inertia moment between 1,500 and 2,000kgm^2 about the yaw axis.

MDB Testing

Whole Vehicle Side Impact

Since the essential characteristics of the MDB were matched as closely as possible to those of an average European-type car, circa the late 1970's, the first tests involved impacting the MDB into a car close to the established average condition. Two subject vehicles were chosen, namely the Renault 14 and VW Passat. These vehicles had characteristics closest to the European average defined in Design Objectives. Two deformable parts were manufactured. The components of the individual segments were still cut from freely expanded blocks and provided with mechanically drilled cavities.

Although CCMC members agreed that the U.S. Part 572 dummy was not designed to evaluate lateral impact protection, it was used since it was the only measurement device available at that time.

In both cases, the struck car was stationary. The impact angle was 90°, and the speed was 50km/h. The front seats of the struck car were in the 50th percentile seating position. The median axis of the impacting barrier passed through the lateral projection of the SRP point onto the outside surface of the car. Dummies were placed in both the front and rear seats on the impact side.

For brevity, only the results from the Renault 14 tests are presented here (Figures 5, 6, and 7). From these tests, it was concluded that the MDB, as designed, was capable of simulating a car-to-car side collision and that development should proceed.

Repeatability—MDB Solely

As with all crash tests that are developed to assess a vehicle's capability of protecting its occupants in accidents, it is imperative that the test procedure, inter alia, gives repeatable results. Test tools and procedures that do not provide repeatability cannot be used.

Five separate tests were run into a fixed dynamometric barrier at 48km/h (to insure complete collapse). These parts had to be manufactured under the same conditions as eventual series parts would be. For that reason, expansion moulds were prepared to maintain identical production conditions. Initially, the production of the

cavities was tried by the addition of inserts within the expansion mould.

Unfortunately, this procedure had to be abandoned for technical reasons—the foam density increasing in the area of the inserts with a resultant increase in the force level. With certain refinements to the tools later, insert-type bores were used in segments having a density of more than 50kg/m^3, which meant a considerable reduction in the mechanical treatment during production.

characteristics were specified to be made symmetrical about the centerline of the barrier. In addition, certain refinements were proposed to the separate force-deflection characteristics to make them more representative of the average European car specification.

The final specification for the deformable part as used in subsequent MDB76-to-car testing is shown in Figures 9 and 10 and Table 1.

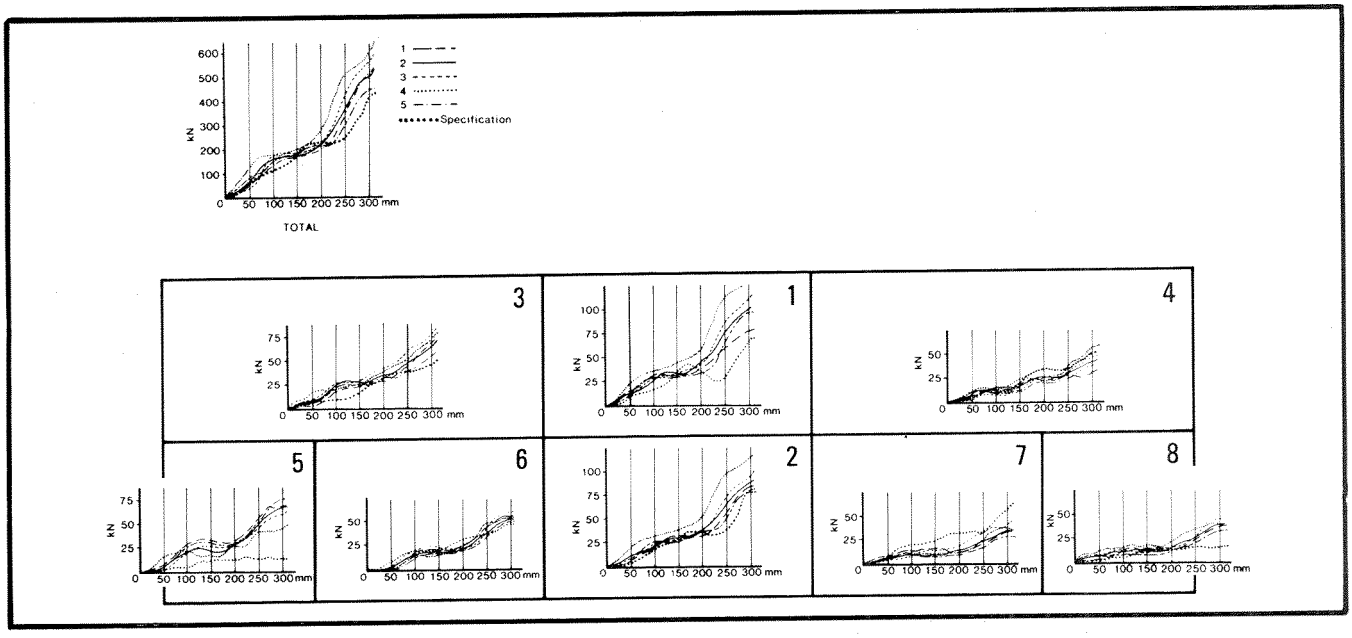

Figure 8. Segment load deflections—repeatability tests

When the five tests were evaluated, it was noted that while some segments showed deviations of as much as ±20 percent, the scatter of the overall (total) force was less than ±10 percent at 300mm (Figure 8).

After these tests, to make the barrier construction simpler and, therefore, more acceptable, the segment

Repeatability—MDB/Car Testing

To assess the repeatability of the MDB when impacted into a car, six strictly identical tests were performed with the Renault 14 as the subject car. The test protocol for

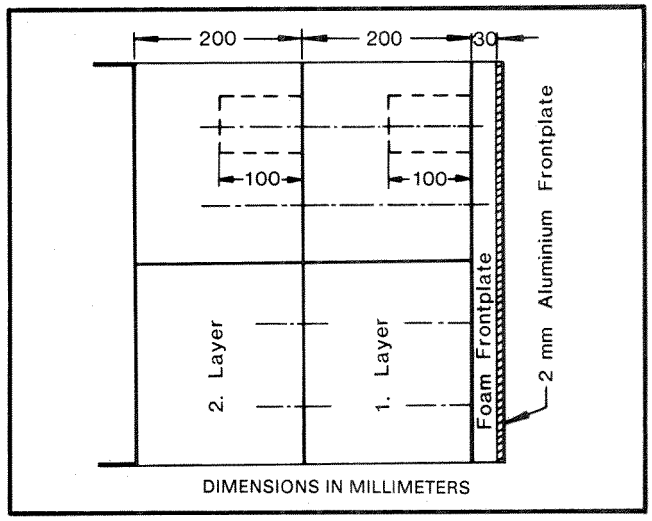

Figure 9. Final specification of MDB76 deformable part

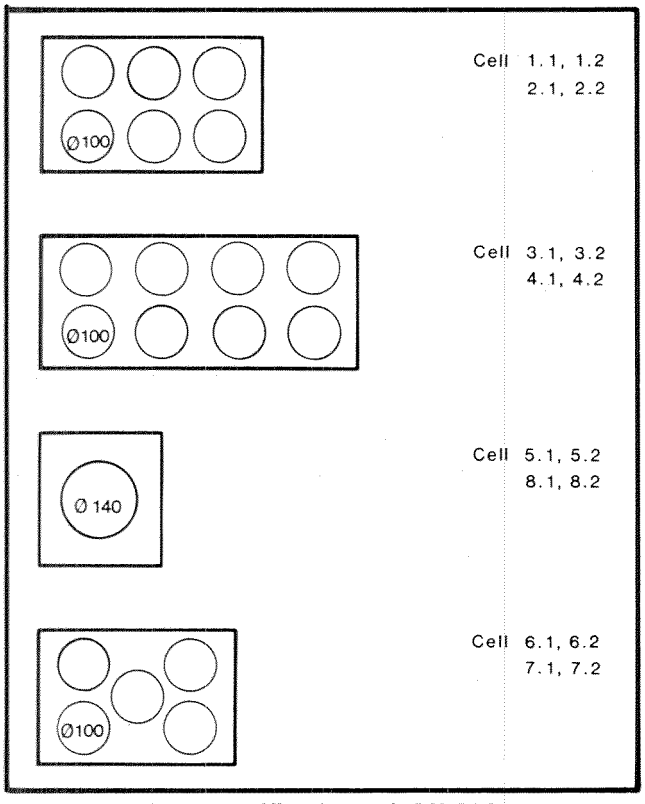

Figure 10. Final specification of MDB76 deformable part

these impacts was the same as described in MDB Testing. All impact speeds were within the range 50.2 to 50.3km/h with the subject car weight between 1,036 and 1,042kg.

As previously stated, the Part 572 dummy is not suitable for lateral collision evaluations, and so, for this part of the test program, the cars were fitted with two APROD 81 side impact dummies for simulation of driver and back-seat occupant. Since, for this exercise, the repeatability of the MDB and subsequent car deformations were the important parameters, the dummy results are not included in this report. A summary of the dummy results are, however, contained in the CCMC paper(2).

Figure 11 shows—

- The outside deformation measurement points
- Outside deformation values recorded

Figure 12 shows—

- Variations in interior intrusion at strategic points

Regarding the outside deformation of the vehicles, the damage was very similar in the six tests. Analysis of the results produced a standard deviation for maximum inside deformation of 3.14 percent and deformation at the front SRP of 1.42 percent.

These results indicated the repeatability of the MDB was satisfactory when samples from the same batch of deformable elements were used.

MDB Round Robin Testing

The MDB was then assessed by the CCMC member companies in a series of round robin tests against their

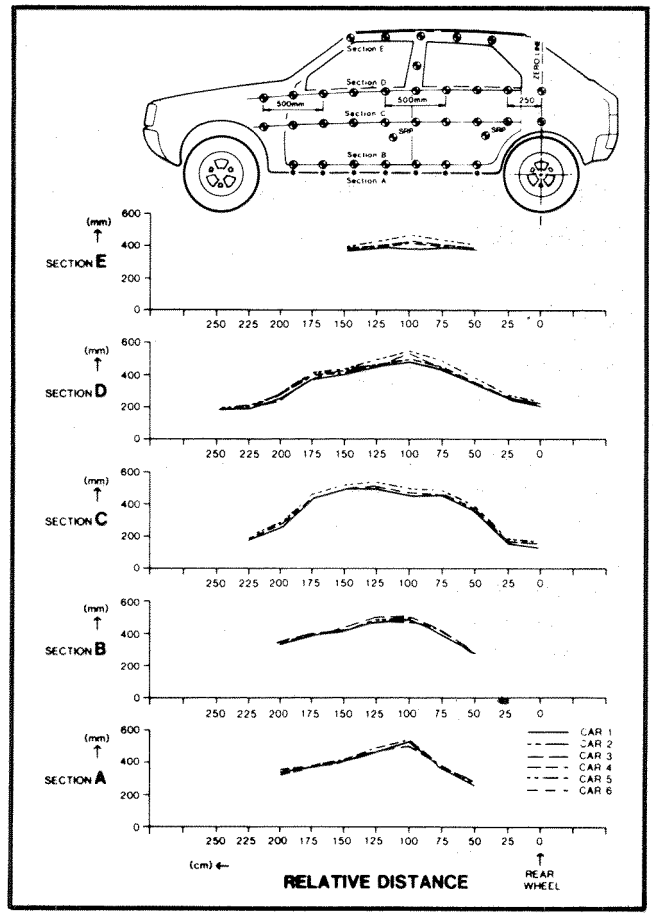

Figure 11. Outside deformations—MDB/R14 repeatability tests

own vehicle models, previously used in the earlier car-to-car and rigid barrier testing phase of their program(1). A total of 12 MDB-to-car tests were conducted, according to the test protocol of MDB Testing, but at each manufacturer's own test site. The appendix gives an analysis of these tests and compares the results with the previously conducted car-to-car tests(1).

A major conclusion from these individual assessments was that despite a lower impact energy with the MDB, the car deformation and main dummy recordings were higher than with the car-to-car tests. To improve this situation required reduction in the stiffness of the MDB deformable element. Consequently, the decision was made in 1982 to reevaluate the main MDB characteristics and attempt to get the actual values closer to the required specification.

Further Research

The testing of the barrier into European cars has shown it to need some modifications to come closer to the specification derived from 1976 data. The opportunity is being taken to establish any changes that have occurred in vehicle design characteristics during the initial evaluation period so this latest information can be considered. The member companies of CCMC have supplied data on their newer models, and a similar weighting procedure is

being used as in Phase I. Research indicates some changes have occurred, but only minor modifications will be required.

Harmonization of Side Impact Test Procedure

During the time of CCMC MDB development, both NHTSA and EEVC have been pursuing their own proposals, which vary with respect to test procedure, configuration, and MDB design itself.

The requirements of the EEVC barrier were established in the final report of Working Group 6 in March 1982 with the European community financing an evaluation program based on these requirements. NHTSA started their research program in 1977 with testing and development continuing.

Since each investigation has the same aim of improving the passive safety of motor vehicles, a proliferation of such devices and procedures is clearly not desirable or necessary, especially with the similarity in the European and the U.S. side collision accident scenes(3). The ultimate assessment criteria should be based on internationally accepted standards.

The main characteristics of the three barriers are presented in Table 2.

Mass

CCMC and EEVC have the same mass at 950kg, while NHTSA is 1,360kg. A compromise should be found, and 1,100kg is proposed.

Ground Clearance

The CCMC ground clearance will be reassessed to account for real accidents. Tests at 250mm will be undertaken during the summer of 1985.

Stiffness

With the minor modification proposed by CCMC, and the discussed stiffening of the EEVC barrier(4), the stiffness of the EEVC and CCMC element will align closely.

Test Procedure Comparisons

Configuration

CCMC and EEVC have chosen a 90° impact with a velocity direction perpendicular to the impacted car. Although it is not the most frequent impact force direction, it is the most frequent impact angle(3). NHTSA simulates the velocities of the striking and struck vehicles by having a crabbed barrier. The CCMC barrier has been assessed in this latter mode and has proved satisfactory in performance(3).

Test Velocity

Both CCMC and EEVC have used a test velocity of 50km/h. NHTSA generally uses 54km/h, taking the crabbed motion into account. This simulates the velocity of the striking (48km/h) and the struck (24km/h) vehicles in a 90° lateral impact.

Impact Point

For CCMC, the centerline of the barrier passes through the lateral projection of the SRP onto the outside surface of the car. Whereas EEVC is similar, the NHTSA point is related to the subject vehicle's wheelbase.

This brief resume of the research proposals to date shows there is a basis on which harmonization can be advanced.

Europe should consider the adoption of the crabbed impact at 90°, while the United States should consider the 90° impact for its crabbed test proposition. The repeatability and reproducibility of the CCMC MDB is such that a joint European and American research program is warranted to develop a common test procedure.

Height	(mm)	490	500	559
Width	(mm)	1550	1500	1679
Thickness	(mm)	430	500	483

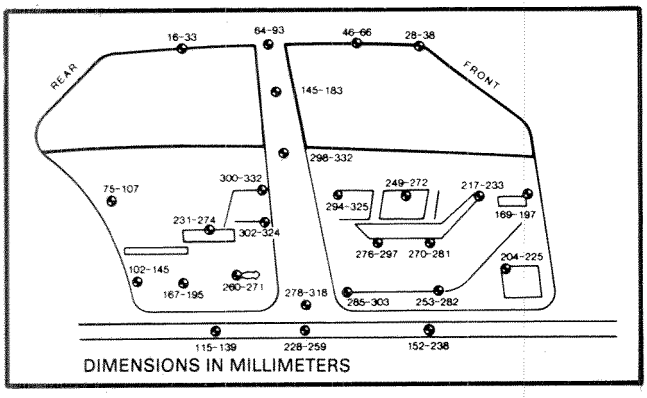

Figure 12. Inside deformations—MDB/14 repeatability tests (minimum-maximum values—six tests

The conformity and batch repeatability of the CCMC MDB have been demonstrated. Should the barrier be adopted as a homologation device, it will be very important that all deformable elements perform in a similar manner. Since a number of parameters can modify the characteristics (e.g., batch changes, transportation, storage), it is fundamental these criteria are precisely known and defined. It will be necessary to define tests that should be performed so conformity with specification is guaranteed. CCMC continues to work on these aspects.

Conclusion

1. CCMC has developed an MDB for lateral collision testing. The MDB76 version has been used by many research organizations and has proved suitable as an evaluation tool.
2. The specification is being upgraded to reflect the latest vehicle characteristics. Work on MDB calibration will continue.
3. European and U.S. researchers should collaborate more to achieve the harmonization of side impact test procedures and so avoid a proliferation of requirements. CCMC proposes to amend the mass and ground clearance of their barrier and suggests joint research should be undertaken into the use of the CCMC deformable element mounted to the U.S. crabbed chassis in a 90° impact.

Appendix

MDB Round Robin Test Results Compared With Car-to-Car and ECE Barrier-to-Car Impacts Tested in (1)

In the following diagrams, a comparison of 12 MDB tests is made with the 60 car-to-car impacts and 10 ECE rigid barrier-to-car impacts conducted earlier, all at 90°.

Analysis is restricted to the main parameters, notably:

Car		—maximum external and internal deformations —maximum internal deformation at the front SRP (Seating Reference Point)
Dummy A	Head	—3ms (milliseconds) resultant acceleration
(Part 572)	Thorax	—SI (Severity Index):3ms:contact time car door/thorax
	Pelvis	—SI:3ms:contact time car door/pelvis

Dummy A is the front-seat dummy on the impact side. This was the most critical seating position in terms of high dummy loading.

Dummy results are split:

(A*) — first impact with intruding structure
(A**) — second impact with adjacent dummy
(A) — total result

Since all the rigid barrier (ECE) tests were run at 35km/h and all MDB tests at 50km/h, only the mean values and the standard deviation have been computed for these. For the car-to-car tests, however, the speed range lay between 34 and 64km/h so the influence of impact velocity for this test type could be obtained.

Figures A-1 through A-4 show the graphical results.

The black line always shows the predicted mean value versus impact velocity from the car-to-car tests. On either side are dotted lines at a distance of one standard deviation.

The mean value of the ECE test is marked with a circle, with a vertical line showing the standard deviation.

The MDB results are shown as ellipses with the diameters giving the standard deviations measured in the two directions.

Fabrication and Validation of a Mobile Deformable Barrier for Side Impact

R. Dargaud, and
T. Bourdillon
Union Technique de L'Automobile, du Motorcycle, et du Cycle (UTAC)

Abstract

At the last ESV conference in Kyoto, the Laboratory of UTAC had proposed a work that has permitted the characteristics of a mobile deformable barrier to be defined.

After discussion at the European Experimental Vehicles Committee (EEVC) and study of proposals from different members of the Group of Rapporteurs on Crashworthiness (GRCS) of Geneva, a design of a mobile deformable barrier has been defined.

To obtain the prescribed force-deflection curves of each part of the front impactor, the use of honeycomb materials has been studied by the Laboratory of UTAC. This material was chosen because—

- The force-deflection curve is linear and constant.
- The repeatability of compression tests is good.
- The restored energy after impact is very low.
- The implementation to build the front face is very easy.
- The stiffness of the whole front impact surface is uniform.
- The visible print of the struck vehicle in the front face shows the different stiff sections of the lateral structure of the struck vehicle.

Many tests have been carried out, as part of a study contract for the "Direction de la Sécurité et de la Circulation Routières (DSCR)," against a load cell fixed barrier to verify the repeatability of deflection and effort measurements of the whole impactor. Moreover, this barrier has been evaluated during lateral impacts against vehicles.

These tests have shown that, using honeycomb to construct the front face, it is possible—

- To meet the requirements of the draft specifications established by EEVC and accepted by GRCS, especially with regard to—
  - The effort-deflection curves with an excellent repeatability
  - The amounts of energy dissipated by the different parts and the whole front face
  - The deformations of this front face
- To simulate the energy absorption of the front part of a striking vehicle

Moreover, the material permits a print in the front face, making it easier to study the lateral structure resistance of the struck vehicle.

Introduction

At the Ninth ESV Conference, the Laboratory of UTAC presented a study(1) that defined the specifications for a mobile deformable barrier. Such a barrier should be used as a striking mobile, in a test procedure, to evaluate the protection brought to the occupants of a passenger car in a lateral collision.

These specifications have been established at the request of the French Administration and are supported by French car manufacturers. The specifications of the front face of the barrier were defined after studying the frontal structures of 20 vehicles considered as performant toward frontal impact.

The characteristics of the mobile deformable barrier were defined after examining the characteristics of the vehicles. The dimensions and mass of this barrier were determined by calculating the weighted average value from the parameters measured on the 20 vehicles.

A weighted coefficient, taking into account the number of the vehicle-type registered in France in 1980, has been assigned to each parameter.

To define the stiffness of the impactor, the front structures of the 20 representative vehicles were studied in frontal collisions at 35 ± 2km/h against a load cell fixed barrier, designed to measure the contact loads during impact.

For each value of the crush, the value of the corresponding weighted average effort has been calculated. Force-deflection characteristics have been established from data provided by each of the six plates of the load cell wall. The weighted total force is defined with the same calculation.

The dimensions of the impactor of the barrier have been defined from measurements of the front parts of the vehicles.

The barrier front face was composed of six independent parts to allow the validation of the barrier against the load cell fixed barrier and to verify the stiffness of each part (Figures 1 and 2).

In the same way, European car manufacturers carried out such a study, which was presented by the Committee of Common Market Automobile Constructors (CCMC)(4). A mobile deformable barrier is defined later in this paper.

Both designs and studies carried out in Italy(5) and by TRRL(6) have been compared.

EEVC, which has been responsible for the study of a global lateral test procedure for a vehicle-type approval

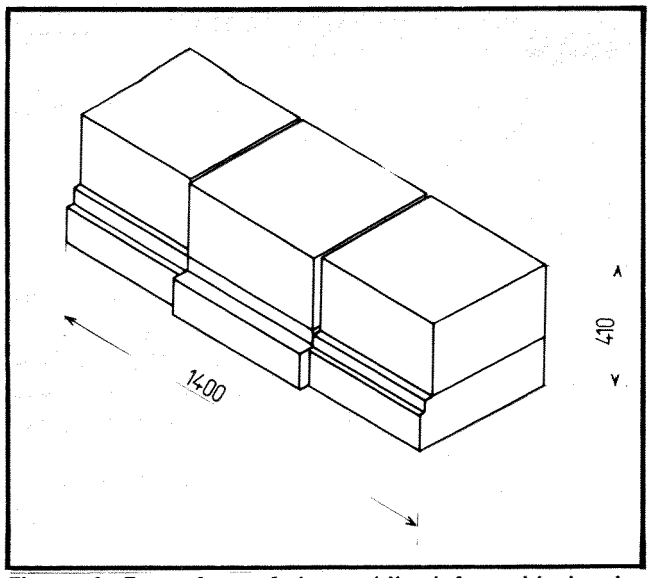

Figure 1. Front face of the mobile deformable barrier developed by UTAC

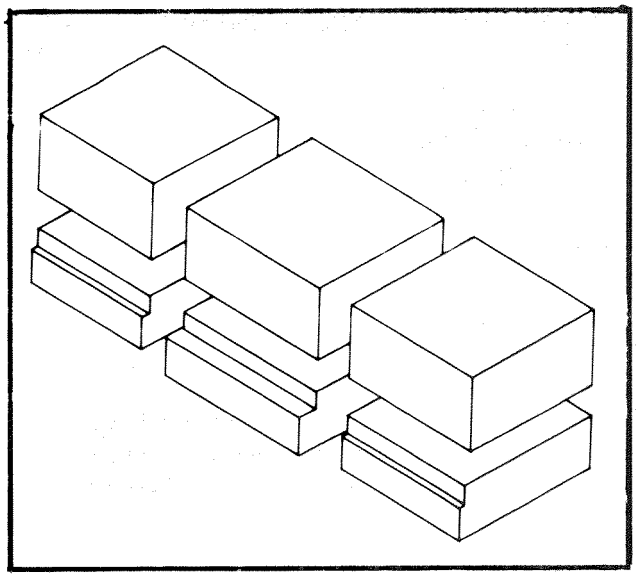

Figure 2. Front face of the mobile deformable barrier developed by UTAC

similar to the procedure proposed for front impact, has defined draft specifications for such a barrier(3).

This proposal was presented to GRCS at Geneva and has been accepted as the definition of the future European mobile deformable barrier used as a striking mobile in a vehicle-type approval test procedure for lateral impact(2).

This document summarizes the work carried out by the Laboratory of UTAC to—

- Choose a material likely to be suitable for the construction of the front face of the barrier
- Build the mobile deformable barrier according to the specifications
- Validate the front face of the barrier in frontal collisions against a load cell fixed barrier to verify its stiffness
- Validate the mobile deformable barrier in lateral collisions against a type of vehicle

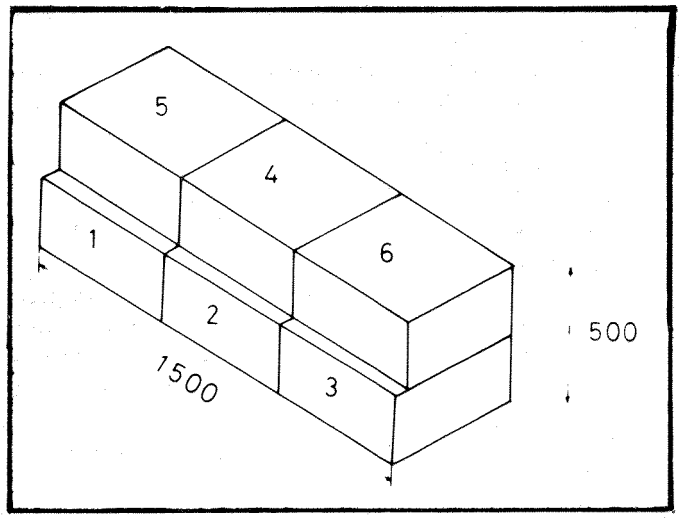

Figure 3. Dimensions of the specified front face of the mobile deformable barrier

Specifications of the Mobile Deformable Barrier

The characteristics of the mobile deformable barrier are as follows(2):

- Mass: 950 ± 20kg
- Front and rear wheel gauges: 1,500 ± 10mm
- Wheel base: 3,000 ± 10mm
- Position of the center of gravity: in the longitudinal median plan, 1,000 ± 10mm behind the front axle and 500 ± 10mm above the ground
- Distance between the front surface of the impactor and the center of gravity of the barrier: 1,800 ± 20mm

The front face consists of six independent parts. The shape and dimensions of this front face are given in Figures 3 and 4.

The front face has a ground clearance of 250mm to take into account further developments in the design of vehicles to solve the problem of compatibility between frontal and lateral structures.

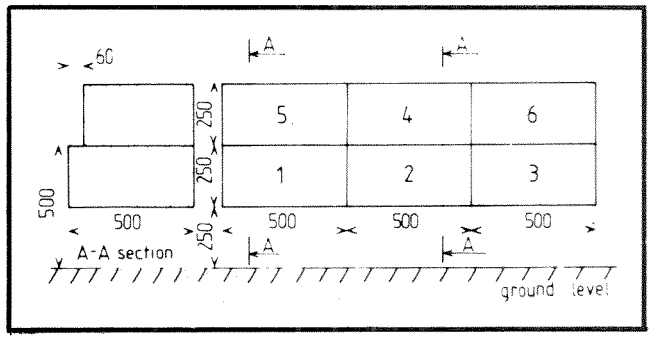

Figure 4. Dimensions of the specified front face of the mobile deformable barrier

The stiffness of the front face must meet the following requirements:

- Parts 1 and 2 on the one hand, and 5 and 6 on the other hand, must be identical.
- The force-deflection curves must be drawn in the hatched regions defined in Figure 5.
- The total force-deflection curve must also be drawn in the prescribed zone of Figure 5.

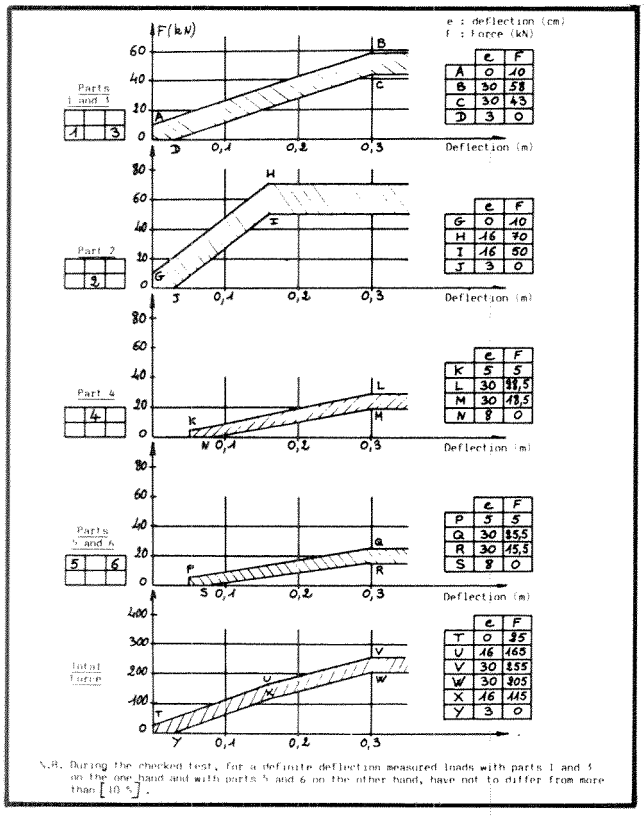

Figure 5. Specified deflection curves

The stiffness of the front face must be verified in a frontal impact of the barrier at 35 ± 2km/h against a load cell fixed barrier. The quantities of energy dissipated by each part and by the whole front face during the impact must meet the requirements prescribed in Table 1.

The deformation of the front face, measured after the impact at the level of point B (Figure 4) must be equal to 350 ± 20mm.

Comments

Meanwhile, an examination of the specifications and a study of preliminary tests show that these specifications should be modified as follows:

- The distance between the front surface of the deformable part and the center of gravity of the barrier is specified as 1,800 ± 20mm. This distance cannot be actually respected because of the dimensions of the front face and the position of the front wheels. This dimension should be raised to 2,000 ± 50mm.
- The conditions for measuring the efforts during the validation of the front face of the barrier against a load cell fixed barrier should be clearly defined. The data channel of the efforts should meet the requirements of ISO Standard 6487, and the data channel class of frequency (CFC) should be equal to 60.
- The specification relative to the deformation of the front face of the barrier is not in accordance with the nominal value of the kinetic energy (m = 950kg, V = 35km/h) and with the required effort levels. The nominal value of this deformation should be adjusted to correspond to the distance required to stop a mobile, the kinetic energy of which is equal to the nominal kinetic energy with an average effort level.

Considering the values indicated in the specifications, a value of 330mm should be adapted further.

Determination of a Material for Construction of the Front Face

The Laboratory of UTAC has studied different materials likely to be used for building the barrier front face(17).

Such a material must have the following essential characteristics:

- Its mechanical characteristics must stay constant in relation with time.
- Tests of compression with the material must show a good repeatability.
- Its force-deflection variation must be such that the specified levels of the curves may be reached. Crush force should increase linearly with deflection up to a limit, beyond which the force should be constant.
- The restored quantity of energy after crush must be low.

A first inventory examined some materials (Figure 6):

- Cardboard and structures made of cardboard
- Metallic cylindrical tubes
- Different types of foam
- Honeycombs

Table 1. Amounts of dissipated energy (kJ)

Part 1	Part 2	Part 3	Part 4	Part 5	Part 6	Total
10 ± 2	14 ± 2	10 ± 2	4 ± 1	3.5 ± 1	3.5 ± 1	45 ± 5

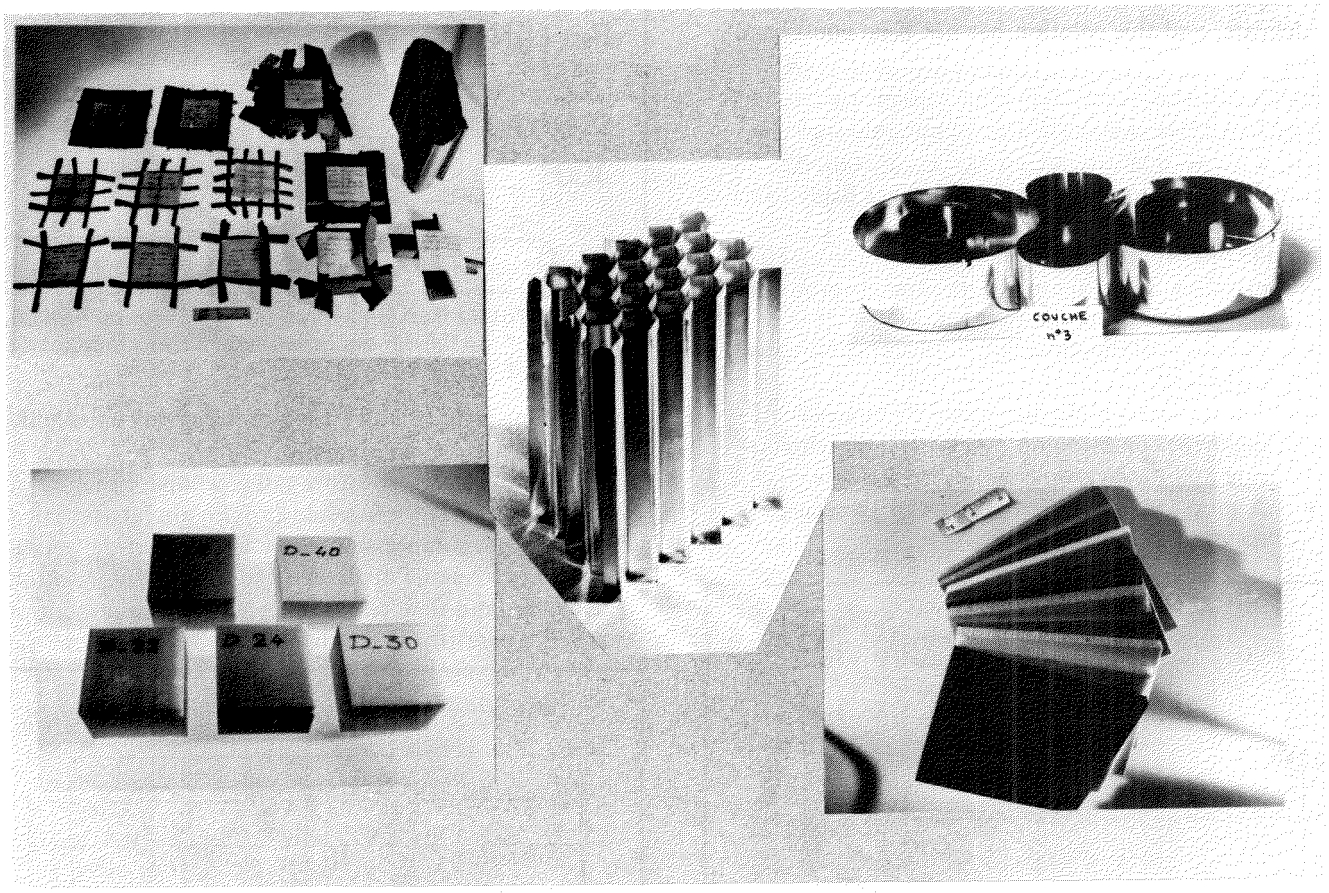

Figure 6. Various tested materials

Quasi-static crush tests of samples consisting of a stack of corrugated cardboard were carried out with a tensile-testing machine. These tests show that (Figure 7) the effort-deflection curves do not show any plateau force level, and the stiffness greatly decreases as soon as humidity increases.

Tests carried out with assemblies of structures made of cardboard showed the same failures and made this material unlikely to be worth pursuing.

Repeated crush tests with cylindrical tubes showed that the compression efforts oscillate around a mean value. However, these curves show a series of picks due to the formation of pleats during the crushing of tubes. So, the compression efforts vary to a large extent (Figure 7b). The tubes have been cut in order to weaken them and obtain the prescribed stiffness.

Some assemblies, consisting of layers of tubes and reproducing different parts of the front face, have been tested with the tensile-testing machine. It was attempted to advance with successive steps to obtain the first parts of the force-deflection curves by adjusting the stiffness of the tubes of the different layers that constitute the parts of the front face.

Some tests carried out with a tensile-testing machine showed that the force-deflection curves of an assembly, corresponding to the lower lateral parts, were inside the prescribed limits. Unfortunately, some dynamic tests showed that the measured efforts were definitely higher than the efforts obtained during the static tests, certainly because of the relative displacement of the tubes during impact. These materials are not suitable to obtain a uniformity of each part of the impactor. Moreover, the

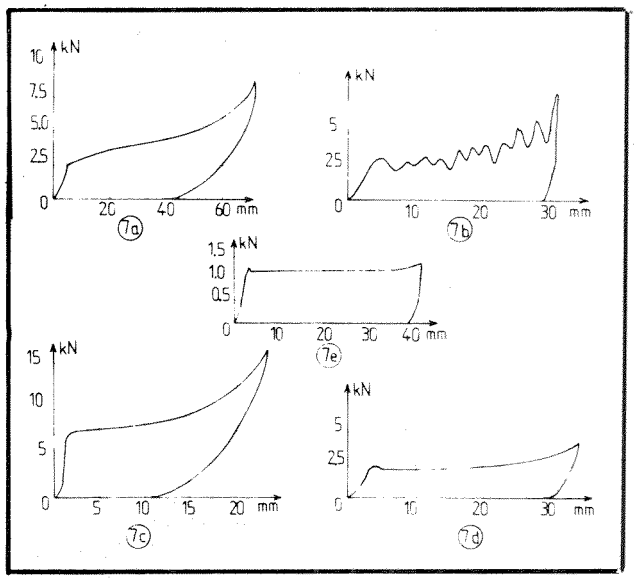

Figure 7. Force-deflection characteristics of the tested materials

labor required to build the whole front face is significant and delicate, and this solution has not been considered further.

Some quasi-static tests of flexible or semi-rigid foams showed that these materials are not suitable since they restore a large quantity of energy after compression (Figure 7c). Rigid foams were the only ones likely to be suitable (Figure 7d).

Samples of 11 types of different foams have been tested in compression after temperature and hygrometric conditioning. These tests showed that—

- The slope of the curve may vary according to the deflection.
- The mechanical characteristics fluctuate according to the conditioning, especially if the temperature and the hygrometric degree increase.
- A more or less important part of the energy is restored after impact (Figure 8).

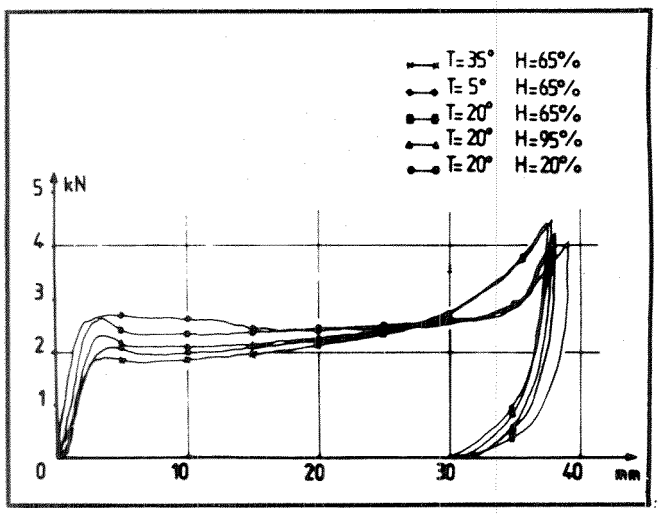

Figure 8. Crush tests of samples made of rigid foam after temperature and hygrometric conditioning

A dynamic frontal impact at 35km/h against a load cell wall of a barrier, equipped with a complete front face made of rigid foam, showed that the front face blew out and cut itself into small pieces during the impact. The collapse of the material induces a fall of the efforts, which cannot stay inside the prescribed area (Figure 9). The pieces, issuing from the burst of the front face, do not take enough part in the kinetic energy dissipation of the barrier. Therefore, a large amount of this energy was restored after impact as shown by the rebound distance of the sled, which was about 15m for the test. This was confirmed by the shape of the total force-deflection curve.

The foams also have a major disadvantage in that the makers cannot guarantee constant mechanical characteristics. These characteristics can vary about 20 percent for ordinary foams. The variations may be high, even with special foams. Considering the situation of the foam

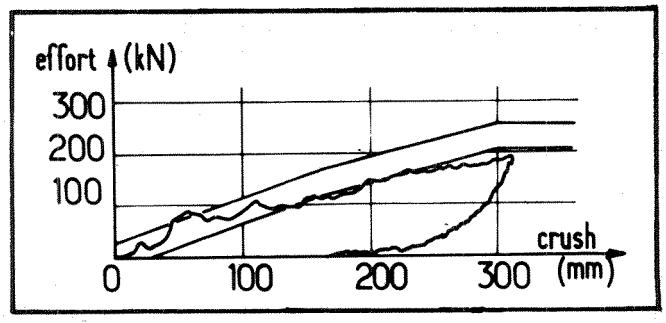

Figure 9. Total effort measured during a frontal impact of the barrier equipped with a front face made of rigid foam

manufacturing techniques, these materials are not wholly suitable as part of our study.

The honeycombs, consisting of a cellular structure of aluminim foils, have been tested also (Figure 7e). Repeated static tests of compression show their effort-deflection curves have a clean, flat plateau, their law of deformation is constant, and they restore only a very low amount of energy (Figure 10). It had been proposed to obtain the

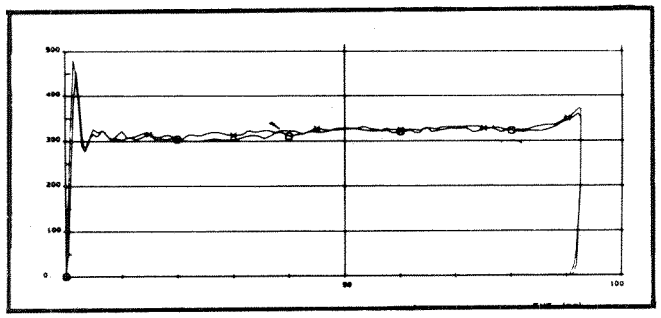

Figure 10. Quasi-static crush tests of sample of the same honeycomb type

ascending part of the curves, in making the efforts increase, by stacking honeycombs of different rates of stiffness. Unfortunately, the range of available varieties of this material is relatively limited, especially for honeycombs with low stiffness. It was decided to cut honeycomb blocks so that the sections vary according to the crush (Figure 11).

Many quasi-static and dynamic tests have been carried out with stacks of honeycombs of the same stiffness. These stacks consisted of two layers, one with a section that varied according to the crush degree. These tests showed it was possible to make some parts with honeycombs according to the prescriptions of stiffness and energy-absorption capacity and showing a good repeatability. Therefore, UTAC has decided to develop a mobile deformable barrier equipped with a front face made of this material.

Construction of the Mobile Deformable Barrier

The sled consists of a tubular steel 3,655mm × 1,065mm frame. Tubular cross members have been welded in the

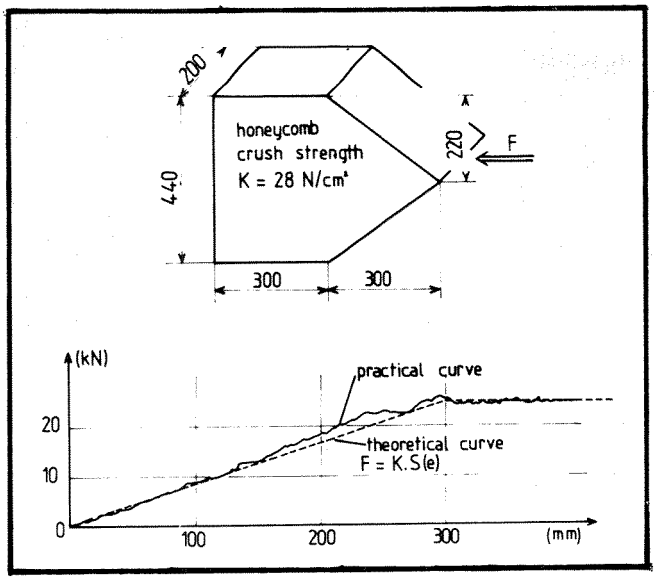

Figure 11. Crush characteristics of honeycomb with variable section

frame to strengthen it.

A 1,500mm × 500mm aluminum plate, 30mm thick, is fixed in front of the frame to support the front face. The dimensions for positioning the center of gravity have been adjusted by fixing added masses on the frame. The other specified dimensions have been respected (Figure 12). The mass is equal to 950kg when equipped.

The front face consists of six independent parts made of honeycomb. The dimensions of these parts are given in Figure 13. Steel sheets, 4mm thick, are fixed at the rear of the front face and between the different parts. The characteristics of honeycombs used for the fabrication of the front face are specified in Figure 14.

Figure 15 shows the UTAC mobile deformable barrier.

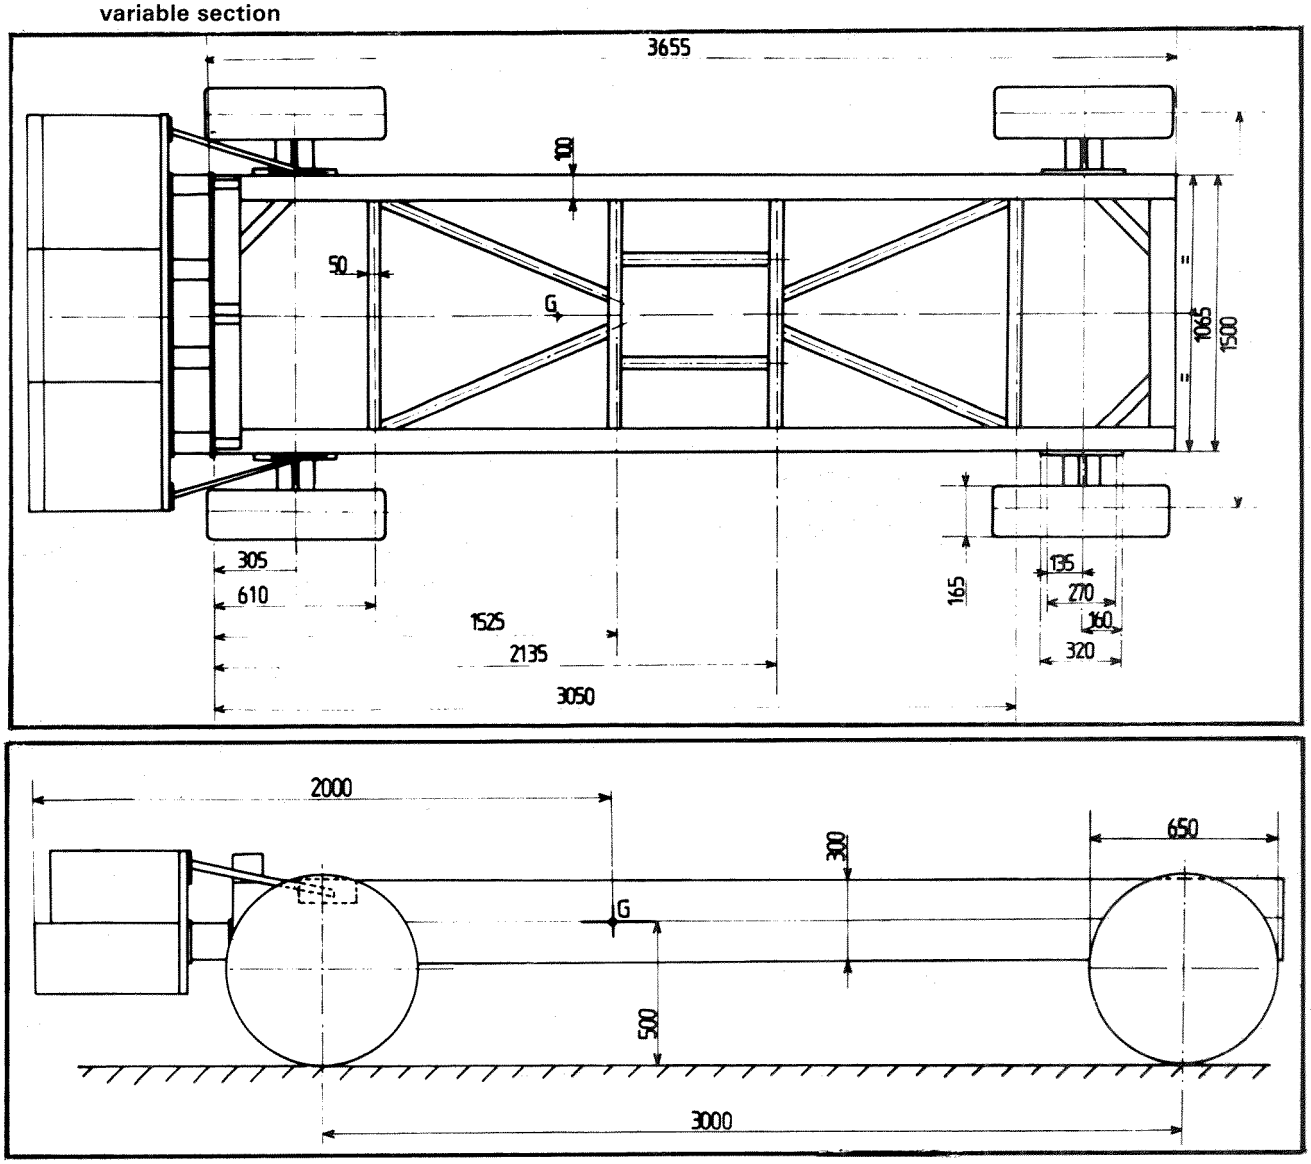

Figure 12. Characteristics of the UTAC mobile deformable barrier

Validation of the Mobile Deformable Barrier Against a Load Cell Fixed Barrier

Three tests of frontal collisions at 35 ± 2km/h of the total barrier have been carried out against a load cell fixed barrier studied and built by UTAC. Comments concerning the draft specifications were taken into account to carry out these tests.

This equipment consists of six independent plates for measuring the efforts of contact during an impact (Figure 16). Each dynamometric plate is equipped with four load cells. The signals emitted by the transducers of one plate are added through an electronic totalizer. The total effort is obtained by calculating the value of the result of these efforts.

The accelerations of the mobile barrier have been measured on the longitudinal beams of the frame, at the level of the center of gravity.

The force-deflection curves of the barrier front face have been obtained with a double integration of accelerations measured on the sled frame.

The curve is shown in Figure 17, and it is possible to compare the amount of acceleration ($m\Sigma\ell i$) of the barrier with the total effort measured by the load cell fixed barrier for one of the tests.

Figure 18 shows the force-deflection curves of the six parts of the front face obtained for the three tests. The variation of the total efforts corresponding to the various tests are also shown in Figure 19.

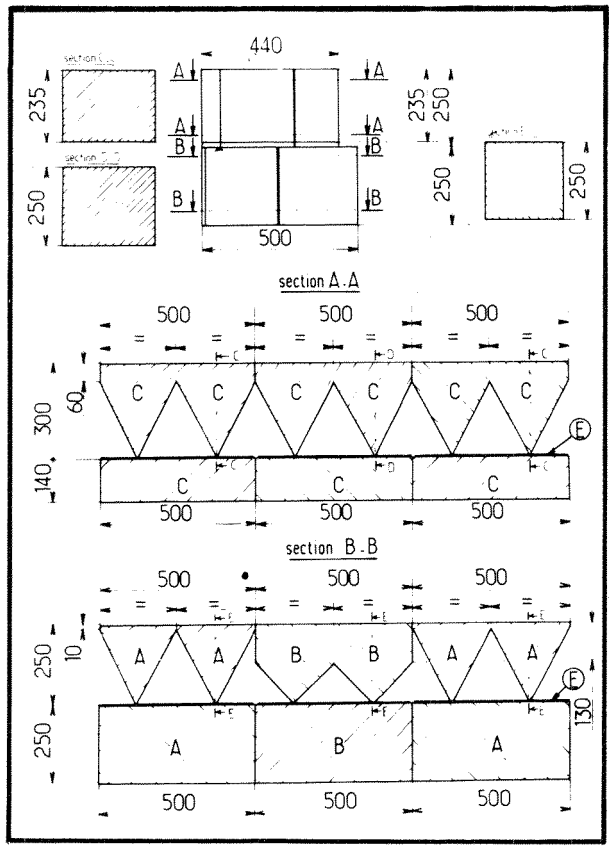

Figure 13. Detailed drawing of the front face of the UTAC mobile deformable barrier

	d (in)	e (10^{-3} in)	Crush strength (psi)
A	1/4	0,7	50
B	1/16	0,7	60
C	1/8	0,7	25

Figure 14. Characteristics of honeycombs used for the construction of UTAC barrier front face

The measurements of the different parameters have been carried out according to ISO standard 6487.

The data channel classes of frequency were—

- 60 for the efforts
- 180 for the accelerations

Figure 20 shows that the front face was uniformly crushed and the behavior of the parts with variable section was quite acceptable. The barrier impactor has not disintegrated during impact, and it was possible to verify the deformations at the level of point B, as required by the specifications.

Table 2 summarizes the main results of these tests:

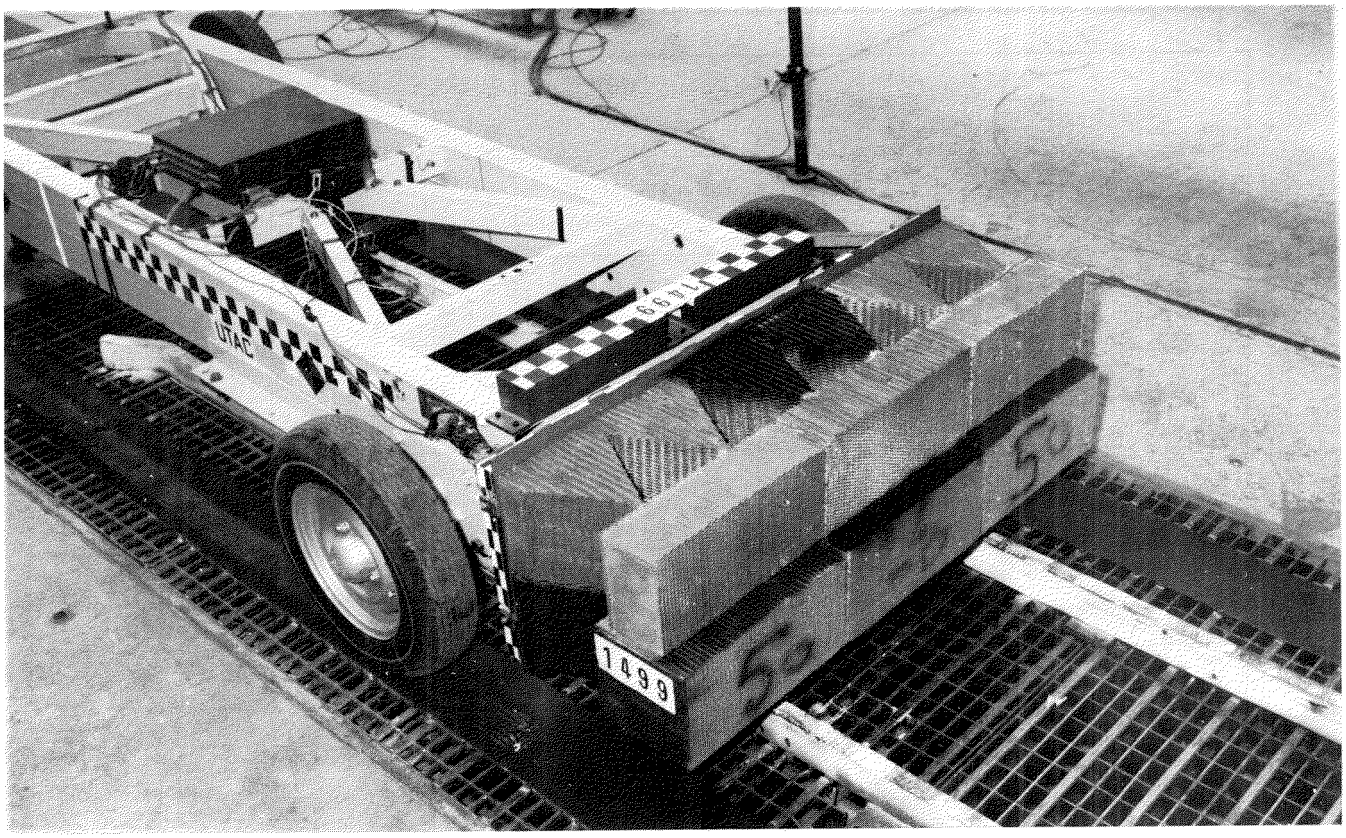

Figure 15. UTAC mobile deformable barrier

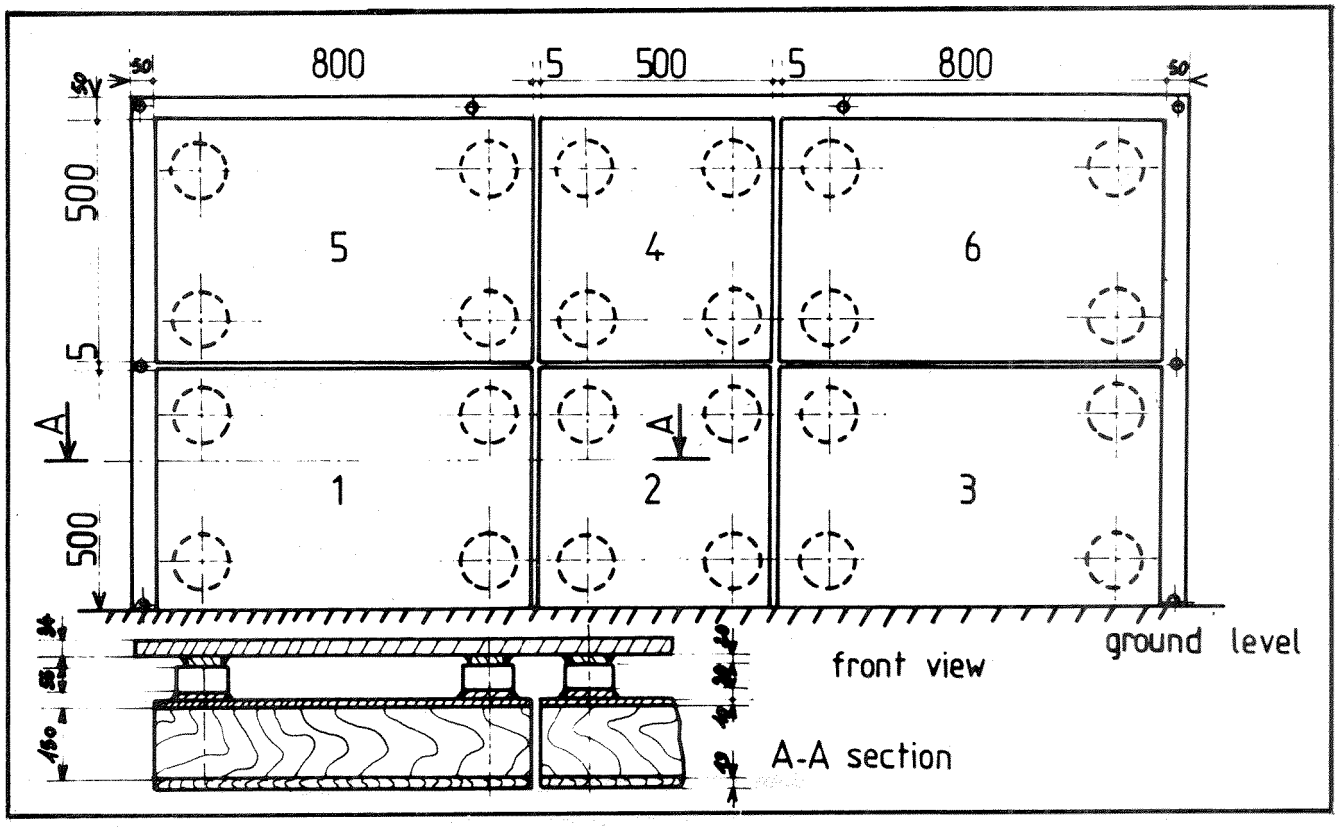

Figure 16. UTAC load cell fixed barrier

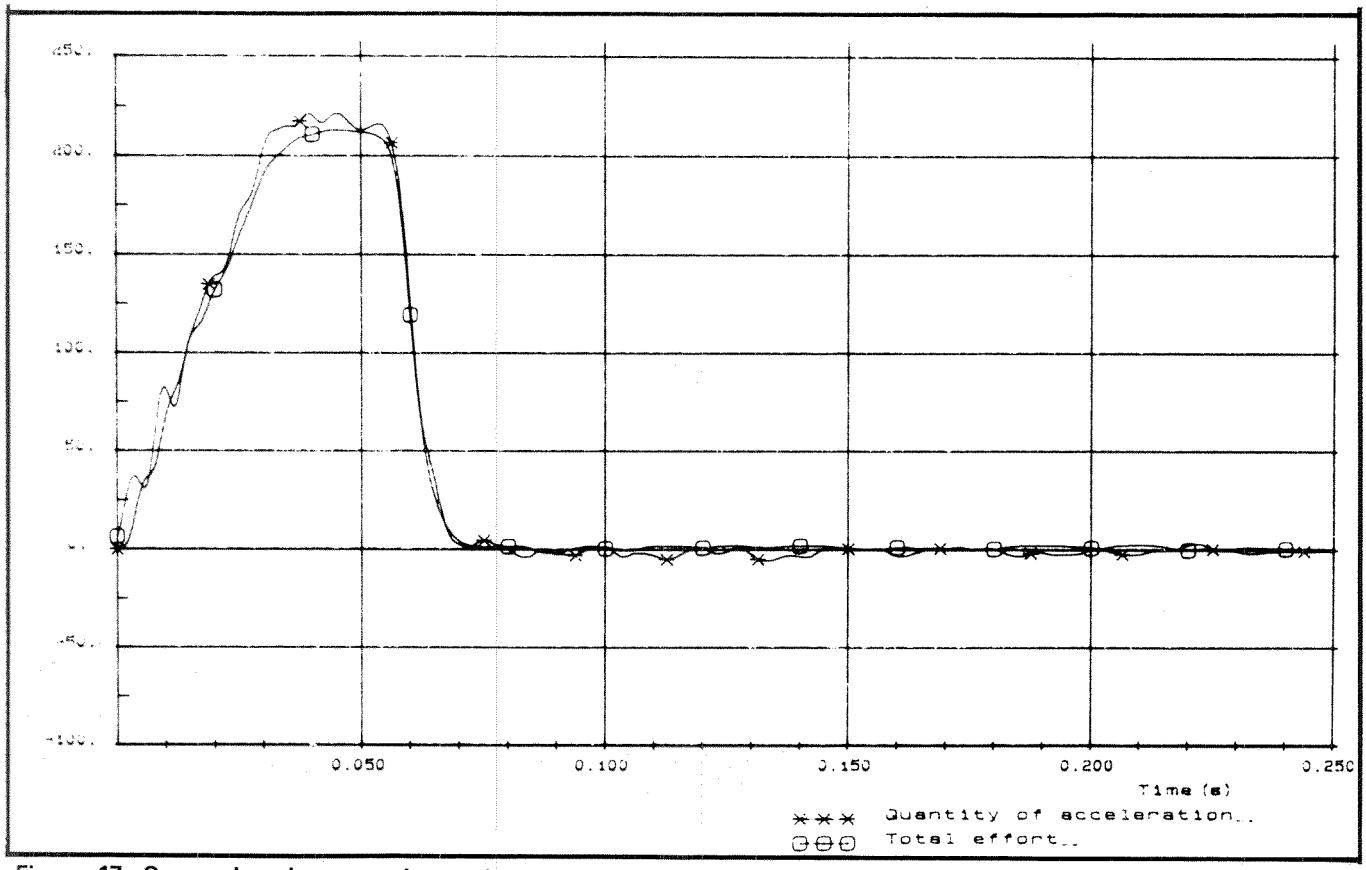

Figure 17. Comparison between the total measured force and the amount of acceleration of the barrier for one test against the load cell fixed barrier

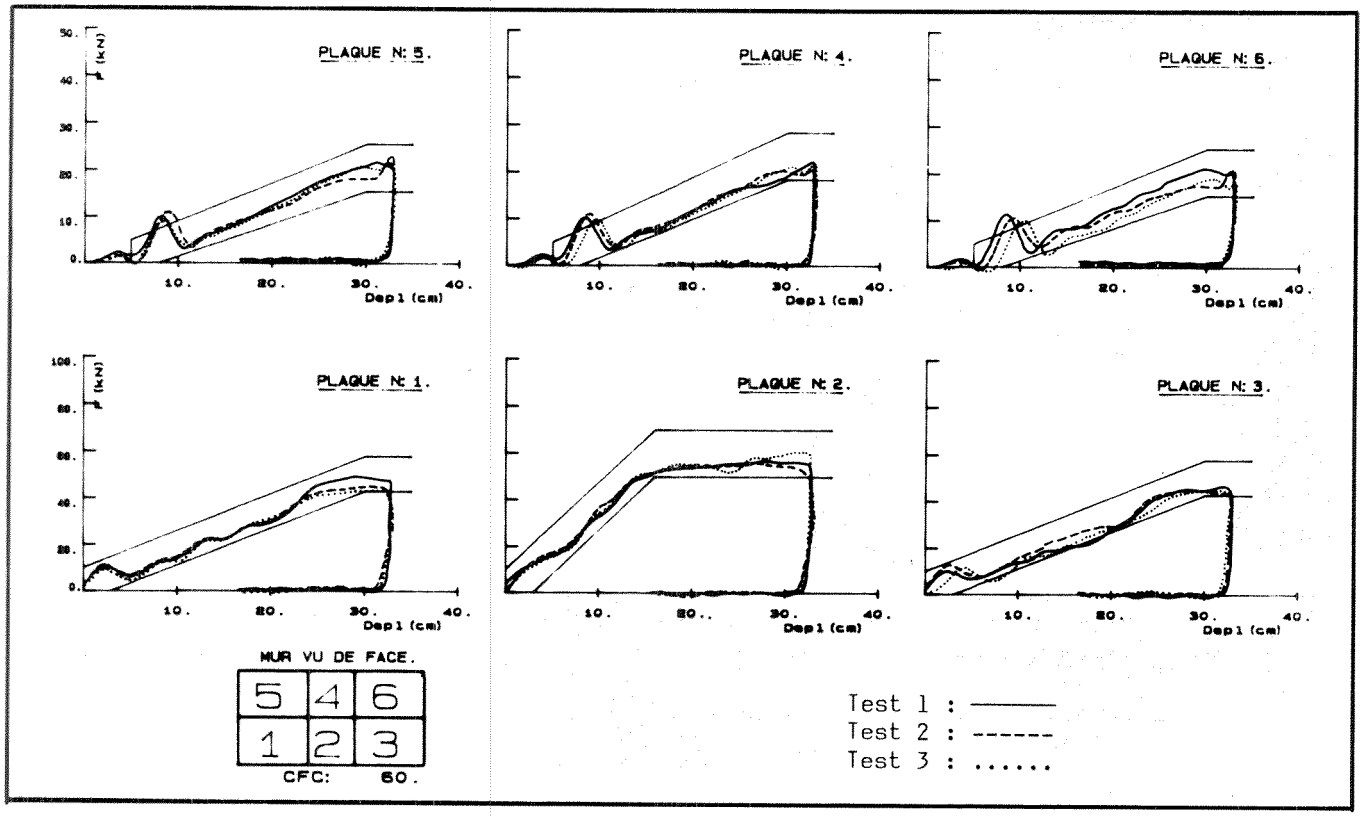

Figure 18. Effort-deflection curves of the six parts of the barrier front face obtained from the load cell fixed barrier for three tests

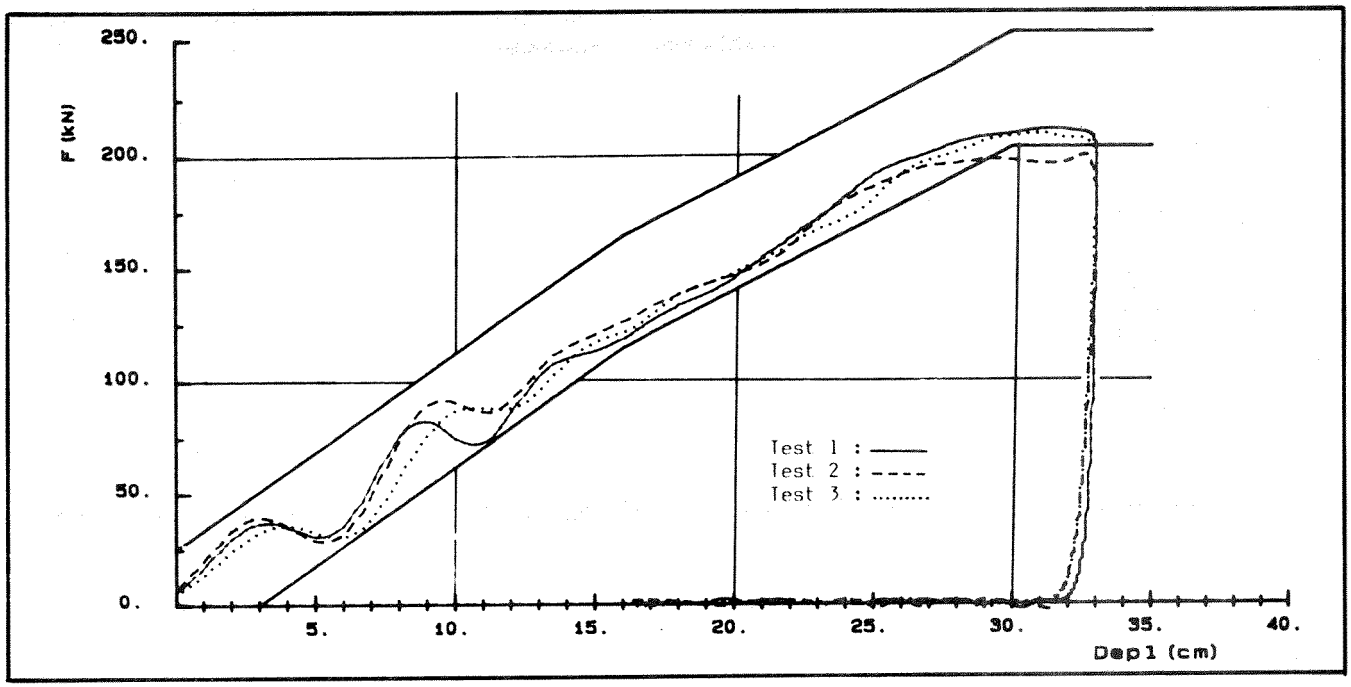

Figure 19. Force-deflection curves of the whole barrier front face obtained from the load cell fixed barrier for three tests

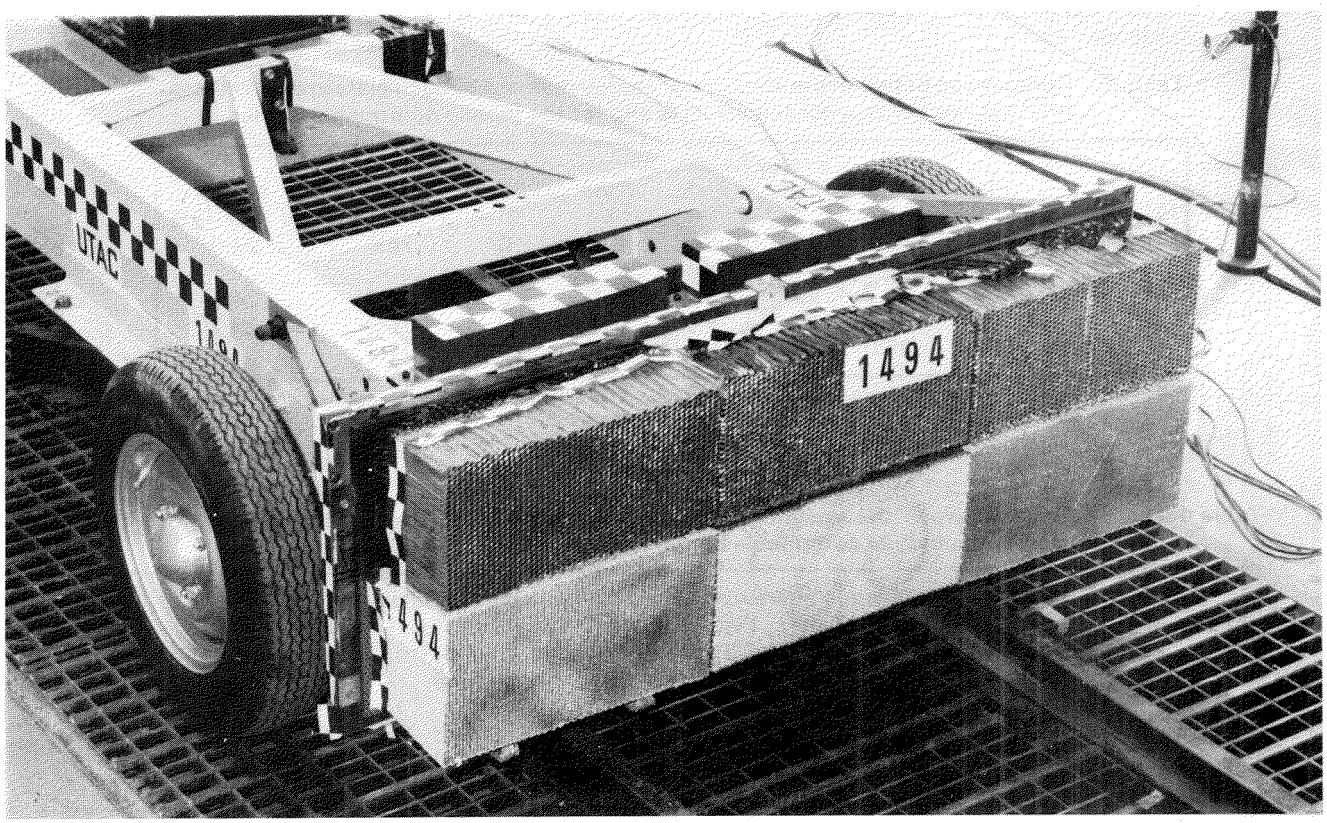

Figure 20. Barrier front face after one of the tests against the load cell fixed barrier

- The force-deflection curves of the different parts may be drawn within the prescribed zones, with the exception of the initial pick for the upper parts.
- The variation curves of the total efforts are also inside the zone while being near the lower limit.
- All the maxima of the dynamic deflections are equal to 330mm.
- The permanent deformations, measured at point B, are comprised between 290 and 315mm and are symmetrical.[1]
- The different parts have absorbed the required amounts of energy for the three tests.
- The behaviors of the front face were similar during the three tests, which confirms the excellent repeatability of crush tests carried out on structures made of honeycombs.
- The tolerances indicated for the total dissipated energy may be too close.

Table 3 shows the following:

- The amounts of energy dissipated at the level of each dynamometric plate are very close to the average weighted values obtained from the tests of 20 vehicles against a load cell fixed barrier.
- Symmetrical and identical parts absorb equivalent amounts of energy.
- During the three tests, one part absorbs the same amount of energy.

The results mentioned in Table 4 indicate—

- The average efforts, calculated for the impact duration, are constant for the three tests, for a given part.
- The average efforts obtained with the barrier are slightly lower than the average weighted values of the vehicles as shown by the force-deflection curves.

Table 2. Test results of three frontal collisions of the barrier against a load cell fixed barrier

	Impact speed (km/h)	Maximal dynamic crush (mm)	Deformation at points B (mm) left	right	Amounts of energy absorbed by each part (kJ) Part 1	Part 2	Part 3	Part 4	Part 5	Part 6	Total dissipated energy (kJ)
Specifications	35 ± 2	—	330 ± 20		10 ± 2	14 ± 2	10 ± 2	4 ± 1	3.5 ± 1	3.5 ± 1	45 ± 5
Essai 1	33,4	330	300	290	8.6	13.5	8.2	3.3	3.2	3.2	40.0
Essai 2	34.8	330	310	310	8,6	13.5	8.4	3.3	3.0	2.9	39.7
Essai 3	34.9	330	315	295	8.4	13.6	7.9	3.1	3.1	2.7	38.8

N.B. The mentioned energy amounts correspond to the energy absorbed for the deformation of the barrier front face.

Table 3. Comparison between the amounts of energy restored by each plate in relation to the total restored energy for the vehicles and for the mobile deformable barrier

		Energy for each plate/Total energy (%) Plate 1	Plate 2	Plate 3	Plate 4	Plate 5	Plate 6	Plates 1 + 2 + 3	Plates 4 + 5 + 6
Vehicles		23.7	33.1	19.2	8.9	8.1	7.0	76.0	24.0

B	Test 3	8.3	12.9	8.2	3.5	3.4	3.2	39.5

[1] The barrier arrived with a slight angle against the load cell fixed barrier for test no. 3.

These tests against a load cell fixed barrier show—

- The front face meets the requirements of the specifications.
- The behavior of the barrier is repetitive.
- The behaviors of symmetrical parts are the same.

Validation of the Mobile Deformable Barrier in Lateral Collision

Car-to-Car Lateral Collisions

Ten car-to-car lateral collisions have been carried out at the Laboratory of UTAC. For these tests, the struck vehicle, a Renault 14, was standing.

The striking vehicle impacted the tested vehicle at 50 ± 2km/h. At the moment of impact, the longitudinal median plane of this vehicle passed through the R point of the driver seat, situated on the impacted side (Figure 21).

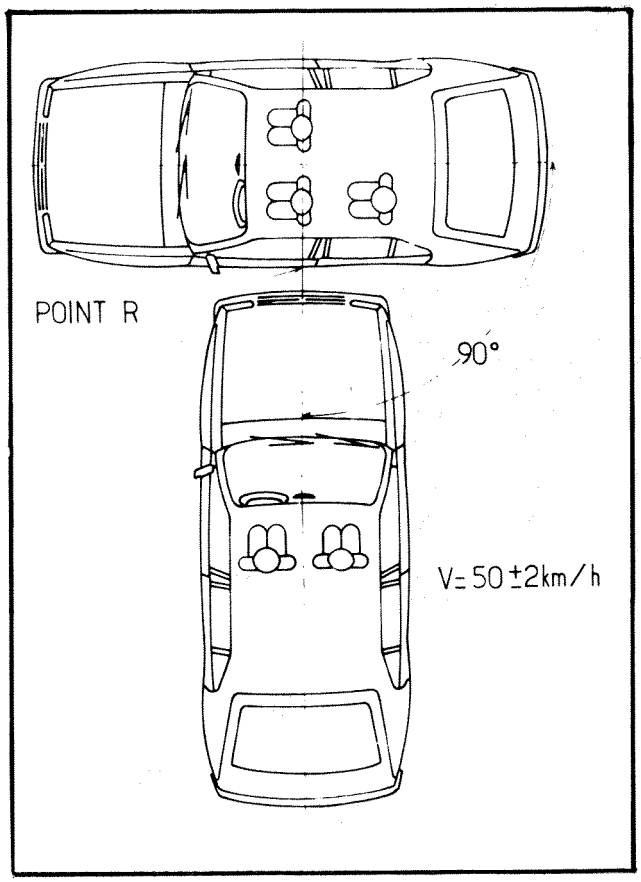

Figure 21. Lateral car-to-car impact test conditions

The front seats of the struck vehicle were positioned 50mm forward of the rearmost position. The seat backs were inclined at 25°.

Hybrid II dummies—50th percentile, calibrated according to the prescriptions of Part 572—have been positioned in the vehicles as follows:

- Striking Vehicle—Two dummies restrained by automatic 3-point belts at the front seats
- Struck Vehicle—At the front seats, two dummies restrained by automatic 3-point belts; at the rear seats, on the struck side, a nonbelted dummy

The longitudinal accelerations of the striking vehicle have been measured—

- On the engine
- On the front axle assembly
- On the structure at the level of B-pillars

The longitudinal and transversal accelerations of the struck vehicle have been measured at the level of the right A-pillar and the right B-pillar, opposed to the impact. The transversal accelerations of the inner door panel of this vehicle have been measured at the level of the shoulder and the H-point of the dummy. The accelerations of the head, the torso, and the pelvis of the dummy, situated at the front left seat of the struck vehicle, have been measured in the longitudinal, transversal, and vertical directions.

The biomechanical criteria have been calculated for this dummy.

The results of these tests are summarized in Table 5, and the deformations of the struck vehicle side during the different tests are shown in Figure 22.

Tests With Mobile Deformable Barrier

Two tests (8501 and 8502) also were carried out under the same conditions with the mobile deformable barrier (Figure 23).

The accelerations of the struck vehicle and the dummy have been recorded under the same conditions. The accelerations of the barrier have been measured on the frame of the sled.

Vehicle No. 9 had the highest coefficient (21.5 percent) for the design of the UTAC proposal.

Figure 24 shows the deformations of the side of the vehicle struck by the barrier after one of these tests.

The deformations measured after both tests have been superimposed on those obtained with the different vehicles in Figure 25.

The results of these tests are summarized in Table 6, which shows the results obtained with three striking vehicles with masses similar to the barrier mass.

Figures 26, 27, 28, and 29 show the speed variations of—

- The driver dummy chest and pelvis
- The inner door panel situated near this dummy

The curves have been superimposed on the curves obtained from the car-to-car tests.

These two lateral collisions show—

SI (1) Criteria calculated on the whole duration of the impact.
SI (2) Criteria calculated without taking dummies interaction into consideration.
(*) Values obtained when dummies' impact each other - γR and γT(3ms) calculated on duration of impact.

- The results of both tests are very similar, especially with regard to—
  - — The deformations of the struck vehicle side
  - — The parameters measured in the dummies
  - — The speed variation of the inner door panel
- These results are very close to the results obtained for the lateral impacts with the 10 vehicles, mainly with those having rather the same mass and stiffness.
- However, the deformations are higher at the level of the beams.[2]
- The movements of the dummies in the struck vehicle are very similar.
- The parameters measured in the dummies are very close to those recorded for the car-to-car tests; the head is less involved, however. Meanwhile, the speed variations of the thorax are higher.
- The inner door panel speed variation is quite significant and very close to the variation obtained when the vehicle is struck by another vehicle.

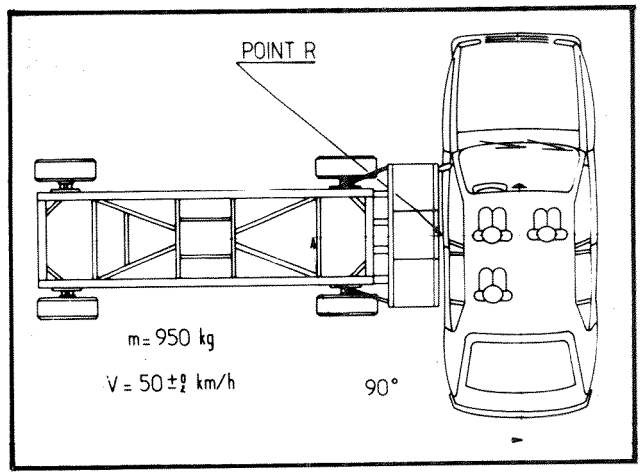

Figure 23. Lateral collision at 90°, on the driver side, with the mobile deformable barrier

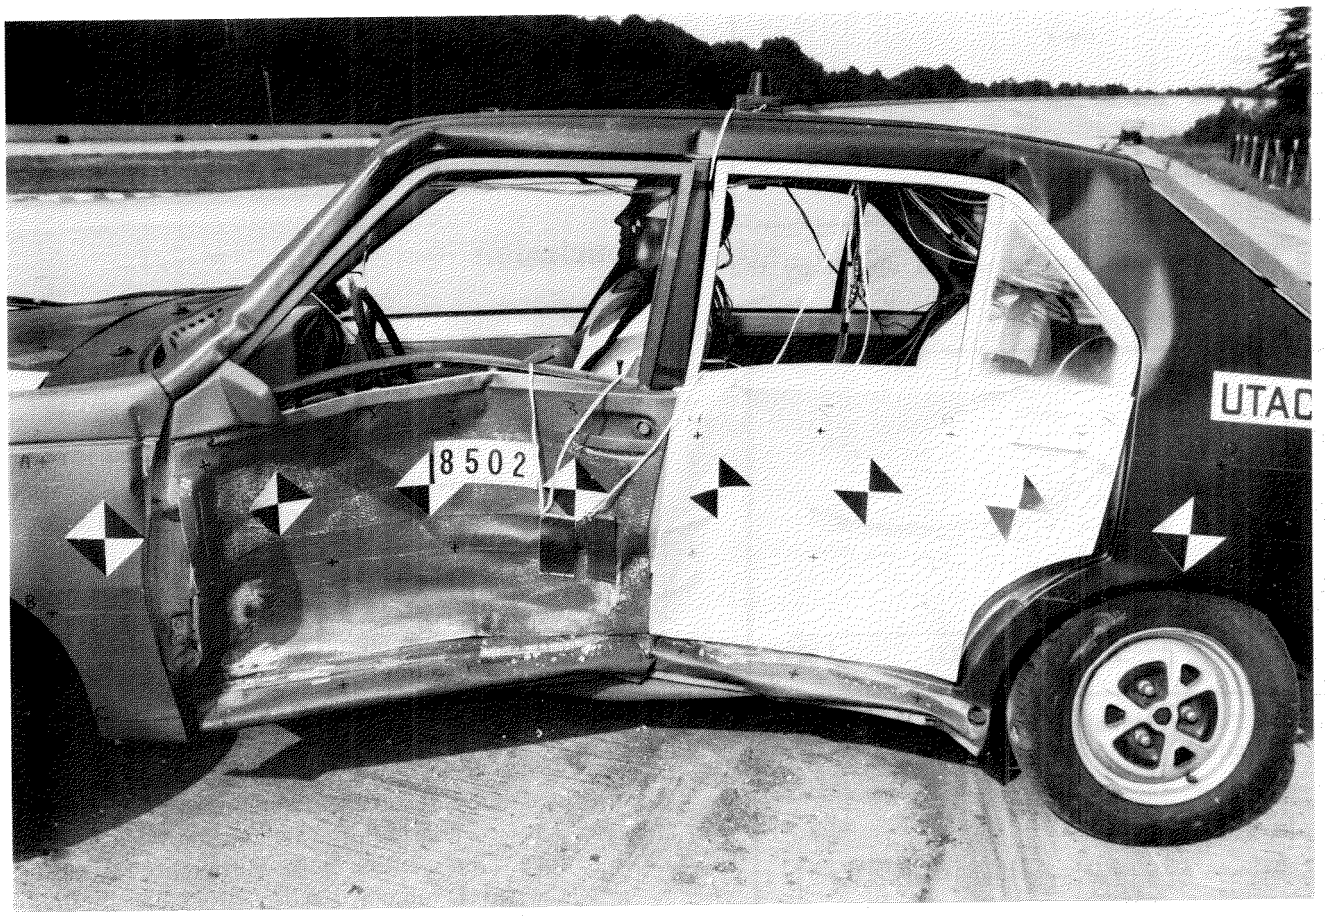

Figure 24. Lateral deformations of the struck vehicle for one of these tests

- The print of the struck vehicle, in the front face, is quite visible after test.

[2] It has been decided to reduce the height of the barrier front face from the ground to take account of future evolution in vehicle conception, which explains the downward displacement of the efforts

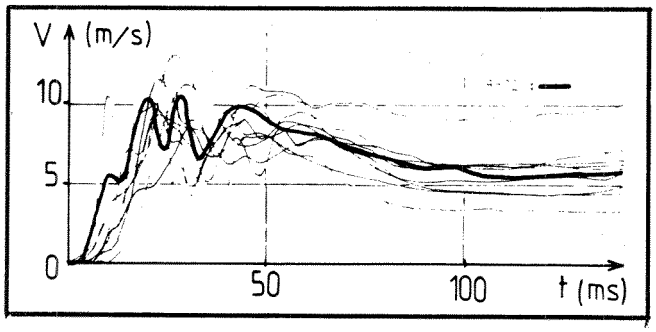

Figure 29. Inner door panel speed variations at the dummy pelvis

Conclusion

The results of the validation tests carried out against a load cell fixed barrier and against the side of a given vehicle type permit the following conclusions:

- The mobile deformable barrier meets the requirements defined in the specifications, especially with regard to—
  - — The force-deflection curves of the different parts and of the whole front face
  - — The amounts of energy restored during impact
  - — The deformations of the front face
- Tests performed with the barrier equipped with a front face made of honeycomb are very repetitive.
- The effort distribution is perfectly symmetrical.
- The front face does not disintegrate during tests and allows the deformation measurements.
- The accelerations and deformations measured on a vehicle, struck by the barrier, are very near the values obtained when struck by another vehicle. The height of the front face from the ground induces the low part of the vehicle to be more loaded.
- The behavior of occupants situated in this vehicle is also very similar.
- The print of the struck vehicle, in the front face, is quite visible.
- The mechanical characteristics of the material for the front face are insensitive to aging and atmospheric conditions.

- The fabrication and modification of the front face are easy and need no specific industrial means, especially if the force-deflection curves had to be modified.
- The barrier behavior will have to be verified during other lateral collisions against other vehicle types.

Therefore, a mobile deformable barrier equipped with a front face, made of honeycomb according to the barrier developed by the Laboratory of UTAC, meets the imperative requirements specified in the draft lateral test procedure studied by GRCS.

Taking account of these performances, this barrier will contribute to the improvement and evolution of test procedures for evaluating the protection of the occupants of a vehicle struck in a frontal impact and a rear collision.

Abstract

Vehicle-into-large-truck accidents produce a disproportionately large number of fatalities. It is hypothesized that increasing a truck's visibility or conspicuity will reduce the number of vehicles colliding with trucks. The purpose of this project was to analyze thoroughly this specific accident problem, establish information requirements of other drivers, review the state of the art of conspicuity techniques, design and conduct a series of conspicuity experiments, design a new integrated lighting and marking system, design an augmented, low-cost reflectorized system for retrofitting on large trucks, and field test the augmented system on fleets of trucks. Approximately 2,000 trucks were fitted with the augmented system, and accident rates are currently being monitored and compared with those of a matched control group of 2,000 trucks. At the time of this writing, the 2-year field study is nearing completion. About 70 percent of the total accidents expected have been analyzed, and the results thus far indicate that the trucks treated with the reflectorized systems are being hit at a lower rate than are control trucks. Increasing conspicuity, therefore, appears to be an effective method of reducing vehicle-into-truck accidents.

Introduction

Purpose

Large trucks equal to or in excess of 26,000 lb constitute less than 2 percent of the total population of vehicles in the United States but are nevertheless involved in accidents yielding nearly 9 percent of all traffic fatalities. The great majority of these fatalities are occupants of passenger cars that collide with such trucks. It would seem, therefore, that countermeasures aimed at a small percentage of vehicles could lead to a significant reduction in a relatively large percentage of fatalities. One obvious countermeasure would be the improved visibility or conspicuity of large trucks.

This paper summarizes a 3-½year project, funded by the U.S. Department of Transportation and designed to develop and evaluate improved conspicuity systems for large trucks.

Rationale

Imposing new Federal lighting and reflector system requirements would clearly impact directly on the trucking industry and indirectly on every driver. Thus, prior to the development and test of proposed new conspicuity systems, every effort was made to provide a thorough statement of the problem.

The project was composed of the following tasks and subtasks:

1. Task 1: Define and analyze the vehicle-into-truck collision problem.
   - Review relevant literature
   - Interview trucking companies
   - Analyze accident data
   - Develop functional requirements of drivers
   - Analyze retroreflective and fluorescent materials
   - Evaluate current Federal Motor Vehicle Safety Standards
2. Task 2: Design and evaluate augmented (retrofit) and new integrated lighting and reflector systems.
   - Design various conspicuity systems and conduct laboratory/field experiments
   - Design a specific low-cost augmented system for field testing on truck fleets
   - Prepare a detailed plan for conducting the field test of the augmented system
   - Design a new, integrated conspicuity system for original equipment manufacture
3. Task 3: Conduct field test of the augmented system on selected truck fleets.
   - Select conspicuity materials
   - Select truck fleets
   - Install conspicuity materials
   - Collect and analyze accident data

The following sections emphasize major findings, analyses, and considerations with respect to the above three tasks. Vastly more detailed accounts can be found in (3) and (12). As of this writing, the project is not quite completed, there being a few months remaining in Task 3 field testing. The results reported for Task 3 represent approximately 70 percent of the total accident data expected in the field test.

Task 1: Define and Analyze the Vehicle-Into-Truck Collision Problem

Analyze Accident Data

Reviews of extensive analyses of a number of accident data bases reveal that large trucks are struck about equally often in the rear and side, the latter including both sideswipes and perpendicular impacts. They are also equally often struck at night or in dimly lit environments as during the day and are struck about equally often on rural and urban roads that are both level and graded.

Rear impacts tend to occur when the truck is traveling straight ahead and moving slowly or stopping or stopped on the roadway. The following driver either (1) does not see the truck at all, (2) sees the truck but misjudges its motion and/or distance, or (3) correctly perceives the truck's dynamics and distance but not within sufficient time to avoid a collision.

Trucks are struck perpendicularly in the side most often when turning or being astride lanes, e.g., backing, making U-turns, etc., but are often sideswiped when traveling straight ahead.

In view of the foregoing, therefore, it would appear the conspicuity problem with large trucks is not restricted to nighttime conditions or specific lighting and marking systems. Trucks are apparently inadequately conspicuous during the day, and both their sides and rear ends seem in need of increased conspicuity.

Develop Functional Requirements

Based on the analyses of accidents, 19 scenarios were established that encompassed nearly every situation in which trucks are hit by cars. Each scenario was analyzed at a level of detail necessary to identify the functional requirements of truck communication systems. These scenarios included vehicle locations, directions of movement, and varying speeds. Stopping distances were computed that indicated the distances at which the driver of the striking vehicle would have to apply the brakes to stop or slow sufficiently to avoid a collision. Dynamics of both vehicles and system reaction times were included in the computations.

Scenario analysis demonstrated that a truck conspicuity system communicated general rather than specific information with respect to its dynamics. For example, the current system for indicating changes in velocity has only two states: the brake light is either on or off. The vehicle can either be stopped, accelerating, maintaining a constant speed, or decelerating, and, with regard to acceleration and deceleration, the rate of change can vary substantially. Thus, the current system relies on the driver to perceive changes in rate of closure, an extremely difficult perceptual task, particularly at night where much of the visual input is severely reduced.

The analyses of vehicle-into-truck accidents and associated scenarios clearly indicated a need for improved truck conspicuity systems that would provide drivers with the following specific information on the truck's position and dynamics:

- Presence of a vehicle
- Indication of a truck
- Distance
- Speed
- Whether it is maintaining a constant speed
- Whether is it accelerating
- Whether it is decelerating
- Whether it is stopping
- Whether it is stopped
- Whether it is backing up
- Whether it is maintaining a constant direction
- Whether it is turning

A number of techniques exist for satisfying the above functional requirements. Unfortunately, most of them would be too costly to be considered seriously at this time. Thus, less than optimal solutions must be sought that are, nevertheless, significant improvements over current systems. Such solutions must derive from an understanding of how drivers detect and identify the presence of a truck and acquire knowledge of its dynamics.

It has often been said that most accidents are wholly or principally caused by inattentive behavior. Thus, detection performance depends, at least partially, on the ability or conspicuity of a target (e.g., trucks) to compensate for inattention and penetrate a driver's field of view.

It is generally believed that luminance contrast is the major cue for detection(4). However, while luminous contrast is certainly necessary for detection, a stimulus may not attract a driver's attention in a cluttered environment. Burg and Hulbert(2) and Burg and Beers(1) demonstrated that the unique shape of a stimulus is of considerable importance in attracting attention and establishing recognition. For example, reflectors completely outlining wheels attract far more attention than do nondistinct reflectors arbitrarily located on bicycles and motorcycles.

Drivers employ subjective judgments in determining distances and dynamics of other vehicles. Carefully controlled laboratory experiments indicate that size

changes of an object moving in depth constitute the dominant cue in judging motion in depth(9,10). Apparently, the larger the object appears to an observer, the smaller the change in size necessary to detect motion(11).

The speed differences in vehicle following become increasingly important the closer the following vehicle approaches the leading vehicle. Ittleson (1951) noted that while size changes in an object provide motion cues, the judgment of distance of an object depends on a priori known characteristics of the object. Thus, if an object projects characteristics that provide no cues or ambiguous cues, no basis exists for estimating its distance. An example would be the rear end of a truck. Most drivers are knowledgeable of truck sizes and can estimate distances of trucks by virtue of that knowledge when such vehicles are well illuminated. On the other hand, when trucks are poorly illuminated at night, size cues are degraded and estimations of distance would be expected to be degraded as well.

In a laboratory setting, Jannsen(6) found that changes in size and brightness of taillights were ineffective cues in the detection of relative motion in depth. His results indicated that changes in the angular separation between taillights constituted the primary cues for such judgments. Such findings were confirmed in on-the-road studies(7,8).

In extrapolating from the foregoing, it seems apparent that the perception of movement in depth would be enhanced even more by presenting a larger target to drivers than that inherent in two taillights. In fact, Fisher and Hall(5) presented evidence that outlining the entire rear end of a truck was more effective than the simple angle generated by two taillights. As noted previously, one must assume driver inattention undoubtedly contributes substantially to degradations in the perceptual process. It seems clear, therefore, that attention and subjective judgments can be enhanced by improving perceptual cues.

Analyze Retroreflective and Fluorescent Materials

Reflective materials are obviously far less costly than lighting systems and far more easily retrofitted to trucks to improve conspicuity. Therefore, a thorough analysis of reflective materials was performed to determine their characteristics, particularly their effectiveness and durability.

Retroreflective Materials

A retroreflector directs most of the light it reflects back along the line of incidence, i.e., back toward the light source. Thus, the reflector is seen as brightest when the observer's eye is close to the light source. Retroreflectors inherently have very narrow beam patterns with respect to observation angles. At an observation angle of 1.0°, relative intensity may typically be only one-tenth that of 0.1°.

The retroreflective devices relevant to trucks include materials containing (1) spherical glass bead elements, or (2) cube corner or prismatic elements. In each case, it is the elements that reflect the incident light. The glass bead materials include those having beads partially imbedded within a supporting surface such as paint and partially exposed to the atmosphere and those having beads that are completely imbedded within a transparent material. The exposed bead designs generate greater brightnesses but are more easily damaged by abrasion and completely lose their reflectivity when wet. Newer versions of enclosed bead materials, referred to as encapsulated lens sheeting, have provided higher brightnesses while retaining protective characteristics.

With regard to prismatic-based materials, the corner of a cube forms three mutually perpendicular surfaces that will reflect light back in the direction of incidence. This principle is used in two types of reflector materials: rigid plastic and sheeting of vinyl, polycarbonate, or other plastic materials. These reflectors are typically brighter than beaded glass materials at small observation angles but exhibit a sharper decrease in brightness as that angle increases.

A number of conditions reduce the life expectancy of retroreflective materials. The top layer of reflective sheeting can be damaged by abrasion due to dust, sand, etc. Oxidation and other chemical reactions can affect the top coat, internal layers, and adhesive backing. Ultraviolet exposure can cause hazing discolor and affect properties of plastics, resins, and the adhesive backing. Physical impact (and any flexing or bending) and extreme temperatures can cause cracking. Moisture can also affect the adhesive backing and, if it penetrates inner layers, can degrade retroreflectivity.

Weather conditions can severely degrade retroreflector materials. Rain, fog, blowing dust and sand, snow, dew, and frost reduce brightness by (1) attenuating and scattering of the light paths to and from the reflector, and (2) forming a degrading optical surface on the reflector.

Empirical data regarding the durability of retroreflective materials is severely limited. It is therefore difficult to predict reflector lifetime in truck operations from available data. It would appear, however, that 5 years may be a reasonable expectation.

Fluorescent Materials

Fluorescent pigments are organic substances containing dyes capable of fluorescing in solid solution, e.g., in a paint pigment or resin binder. Such pigments convert light from the shorter wavelengths (violet, blue, green, and yellow) to longer wavelengths. The fluorescent

energy is added to normally reflected light, resulting in an effective reflection factor of 200 to 300 percent, compared to 90 percent for a bright, nonreflective color. Several manufacturers produce sheeting materials that are both fluorescent and retroreflective.

Studies on visibility and conspicuity of fluorescent colors agree that such colors are much more easily seen than are nonfluorescent colors. Fluorescent orange appears to be the most conspicuous. Of particular interest, especially when considering application to daytime truck conspicuity, is the fact that fluorescent colors are found to be more attention getting in peripheral vision than are ordinary pigments.

The most serious drawback to the use of fluorescent materials is their limited lifetime with ultraviolet exposure. Two years is a practical maximum in most outdoor situations, and useful lifetime can be as short as 3 to 6 months. Therefore, applications to truck conspicuity appear generally impractical.

Task 2: Design and Evaluate Augmented (Retrofit) and New Integrated Lighting and Reflector Systems

Task 1 demonstrated that the range of possibilities for improved conspicuity systems was very large and available empirical data were inadequate for selecting the best of the most cost-effective designs. Therefore, Task 2 consisted of a series of experiments for resolving important issues and screening out most of the possible design configurations. Prior to conducting the experiments, the following design guidelines were established for the augmented and integrated conspicuity systems:

- Truck marking and signaling systems should be standardized as much as possible across all truck body types.
- The augmented system should be restricted to reflectorization treatments to maintain low cost for retrofitting.
- Designs should have acceptable implementation costs and life expectancies.

Only 6 months were allocated to the design phase, which limited the number and types of experiments that could be conducted and the number and types of issues that could be addressed.

Design Systems and Conduct Experiments

All experiments were concerned with reflectorization designs, as little could have been added to the large body of experimental data on vehicle lighting systems within the current program scope. Thus, all recommendations concerning lighting and signaling aspects of the integrated system were based on previous research.

Six experiments were conducted. In some cases, subjects directly observed conspicuity treatments on an actual truck. In other cases, slides were taken of an actual truck and subsequently used in a laboratory setting. In still other cases, slides were taken of miniature vehicles on a 1/25 scale roadway and subsequently used in a laboratory setting.

The first experiment evaluated 45 rear end reflector treatments and compared them to conventional configurations specified by the U.S. Federal Motor Vehicle Safety Standards. Designs outlining the entire rear perimeter and mudflaps were found to be superior to all other designs with respect to conspicuity and ease of detection.

In the second experiment, 12 different patterns involving style and color were presented in pairs on a test truck to subjects at night. Alternating white/colored rectangles were found to be superior in terms of conspicuity, detail, and visible detail. The actual color was less important.

The third experiment replicated the second experiment during the day. Again, the alternating white/colored rectangle design was superior to the other designs. The actual color was again of lesser importance except when fluorescent materials were used.

The fourth experiment studied the effect of reflectorized rear end patterns on distance judgments. Seven patterns were employed. The design having the perimeter of the rear end and the mudflaps reflectorized were judged to be closest to subjects than the other designs. It was also found that the lower the reflectorized area, the closer the truck appeared.

The fifth experiment evaluated partial-to-complete perimeter outlines of the rear and side of trucks and compared them to the conventional configuration during day and nighttime illumination levels. For nighttime conditions, the complete perimeter outlines were found best for the side and rear of trucks. Essentially no differences were found between designs during daytime.

Finally, the sixth experiment evaluated partial-to-complete outlines in terms of their ability to provide rate of closure information to subjects. All experimental designs were found superior to the conventional configuration, particularly the complete rear and side outline design.

Design a Specific Low-cost Augmented System for Field Testing on Truck Fleets

The recommended augmented system design was based on the results of Task 1, the experiments described above, previous research by others, and the guidelines discussed earlier. The recommended system consisted of outlining the entire rear end and sides of trucks. The reflector pattern was a 4in-wide stripe of alternating red/white rectangles. In the case of flatbeds, a continuous stripe

around the rear and side rails was recommended. A U-shaped outline of the mudflaps was also recommended, using a 2in-wide stripe of white retroreflective material.

A variety of retroreflective and reflective materials and devices can be used, including glass bead and prismatic-type sheetings and reflex reflectors. It is considered essential, however, that retroreflector materials be hermetically sealed. Also, reflex reflectors should be of a dispersed angle prism design so that a wide angular characteristic is obtained.

Minimum and maximum SIA (Specific Intensity per unit Area) values were recommended, based on considerations of minimum intensity necessary for adequate conspicuity, the effects of temporary degradation due to dirt and grime and long-term weathering, and of glare potential. These were 250 to 300 $cd/lx/m^2$ and 500 $cd/lx/m^2$, respectively, for the stripe outlining the truck, and 200 $cd/lx/m^2$ and 300 $cd/lx/m^2$, respectively, for the mudflap stripe.

Detailed materials and installation cost analyses were performed for the recommended retroreflective design and partial configurations such as rail only, partial rail, and broken whole outline. The 1981 estimated costs ranged from a low of $34 for the partial rail treatment to a high of $416 for the complete outline treatment.

Design a New Integrated Conspicuity System for Original/Equipment Manufacture

The perimeter outline reflectorization design for the augmented system described above was also recommended for the integrated system.

Two pairs of four lights each were recommended for the rear lighting system of trucks. Each set of lights could be positioned horizontally or vertically on the lower corners of the truck. The outer (horizontal) or lower (vertical) lights represented red presence indicators. The next light represented amber turn signals. The inner (horizontal) or upper (vertical) two lights comprised red brake lights. Thus, this design not only provides separation of functions, color and size coding are also involved.

In addition to the two conventionally placed amber turn signals at the front of truck cabs, two additional turn signals were recommended on each side of the truck, one mounted on the truck's cab and one mounted midway along the body or trailer.

Amber (except for rearmost lights) side clearance lights evenly spaced every 6 to 8ft, including the corners, were recommended along each side of a truck bed or trailer. The rearmost lights were recommended to be red.

All of the lights were along or close to a truck's railing. Because of the high-mounted reflectorization, no justification was seen for high-mounted lights, including the currently required conventional three-light truck identification bar. It was believed the recommended design amply described and identified vehicles as large trucks.

The currently required intensity levels for truck signals and identification lighting appear adequate. However, a minimum area requirement of $12in^2$ should be retained for rear signals, and consideration should be given toward increasing the minimum area requirements for front and side turn signals. In addition, consideration should be given to a dual intensity system to adjust brake, presence, and turn signals to different ambient conditions, such as day, night, and fog.

Prepare a Detailed Field Test Plan for the Augmented System

A detailed test plan was prepared for field testing the recommended augmented system. Sample sizes, fleet compositions, candidate fleets, exposure data, accident rates, existing truck markings, short- versus long-haul operations, experimental and control group matching, and materials and installation costs were discussed and evaluated in detail. Two thousand trucks were recommended for the augmented system treatment, and a matched like number was recommended for a control group. A 24-month data collection period was considered adequate to demonstrate significance between the groups at appropriate alpha and beta error levels.

As will be noted in the following section, funding was insufficient for field testing the complete augmented system, i.e., full side and rear outline.

Task 3: Conduct Field Test of the Augmented System on Selected Truck Fleets

Select Conspicuity Materials

Prismatic sheeting known as Durabrite and manufactured by Avery International was selected for the field test. This selection was based on four criteria: brightness, ease of installation, durability, and cost. Durabrite more closely satisfied all four criteria than other materials. However, the cost to purchase and install this material on 2,000 trucks according to the recommended design specifications presented in Task 2 still exceeded budget. Therefore, the design specifications were modified as follows.

The recommended design was a 4in-wide stripe outlining the entire rear and sides of truck trailers. This stripe was reduced to a 2in width. And, while outlining the entire rear of trucks remained essential, only the side rail was to be treated with the prismatic sheeting. The materials cost for each vehicle was $35.

As can be seen in Table 1, the actual photometric characteristics of the Durabrite material closely approached the values recommended in Task 2. It will also

Table 1. Recommended maximum and minimum SIA values (upper) and durabrite actual values (tabled entries are in candelas/1x/m^2)

Entrance Angle	Observation Angle			
	0.2°	0.5°	0.2°	0.5°
-4°	330-500 475	150-400 325	75-125 90	38-100 62
30°	150- 220	75- 82	38- 42	19- 16
45°	75- 61	38- 42	19- 12	9- 8
	White		Red/Blue	

be noted that the colored material is labeled "Red/Blue" in Table 1. This term is explained in the following section.

Select Truck Fleets

The selection of trucking fleets for this study was a difficult and time-consuming task. Many fleets were not able to participate for a variety of reasons. Of those that wanted to participate, many had already installed reflectorized materials on their vehicles. Few fleets remained for which matched groups of control and experimental trucks could be generated. However, 4,162 trucks were ultimately obtained from three trucking fleets: Overnite Transportation, Paul's Trucking, and Ruan Trucking. These fleets included short- and long-haul, 40 to 45ft trailers. The experimental and control groups were matched as closely as possible, based on a number of variables such as exposure or mileage.

Because one trucking fleet employed a logo that included the color blue, an alternating blue/white stripe was permitted along the side rail instead of the recommended red/white stripe. However, the fleet agreed to have the recommended red/white stripe on the rear of their trucks.

The trucking fleets installed the prismatic sheeting themselves. In addition to receiving the reflector material at no cost, the fleets also received $26 per truck to cover installation costs.

Collect and Analyze Truck Accident Data

The planned data collection period was 24 months and was initiated in the middle of 1983. Approximately 3 months remain as of this writing. The 24-month period and 2,000 vehicles per group (actually 2,081 per group) were selected to provide a sample size/exposure sufficient to detect a 15 percent reduction in other vehicle-into-truck collisions in the reflectorized group with alpha and beta errors of .10 and .50, respectively.

During the data collection period, accident reports were obtained from fleet records on a quarterly basis. At the end of each quarter, the fleets' master accident logs were reviewed to identify all trailers for which accidents were reported in that period. Reports for trailers in both the reflectorized and control groups were obtained.

Each accident was coded with respect to identifying information, precrash factors, and, very importantly, the degree to which conspicuity was a likely contributing or causative factor. The conspicuity rating coding was conducted in a double-blind situation by two highly experienced motor vehicle safety professionals.

All accidents were placed in one of six classifications. The first three classifications were other-vehicle-into-truck accidents and represented high, moderate, and low likelihood that the accidents were conspicuity-related. The fourth classification comprised accidents in which the experimental and control trucks struck other vehicles. This classification permitted a test of the assumption that experimental and control groups were matched, e.g., each group should demonstrate approximately the same number of truck-into-other-vehicle accidents.

The fifth and sixth classifications were composed of accidents completely irrelevant to the study.

As of this writing, about 30 percent of the total expected accident reports have yet to be received. Therefore, only preliminary analyses of the data are presented here. The total number of relevant accidents (i.e., trucks struck by other vehicles) in the control and reflectorized groups thus far are 113 and 86, respectively. Figure 1 presents the cumulative number of relevant accidents by yearly quarter for daylight and nighttime driving. As can be seen, strong trends are in evidence, with reflectorized

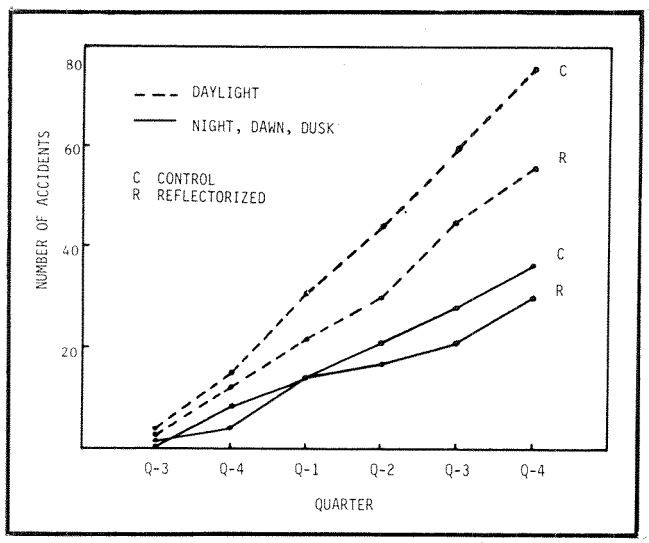

Figure 1. Cumulative number of struck trucks by quarter for daylight and nighttime driving

trucks consistently being hit at a lower rate than control trucks. Data for two additional quarters will ultimately be included in this graph, but it appears unlikely that the current trends will be altered significantly.

The relatively large difference in accident rates between daytime and nighttime driving is easily explained by the fact that the trucks were driven to a much greater extent during the day than at night. However, the difference between the control and reflectorized groups during the day is not easily explained because the reflectorization's effectiveness is primarily dependent on the light projected from other vehicles' headlights. On the other hand, the red/white and red/blue patterns do increase the conspicuity of trucks somewhat. Further analyses will be required to explain this finding more fully.

In conclusion, the field test appears strongly to be demonstrating that increasing the conspicuity of large trucks will reduce substantially the number of other-vehicle-into-truck accidents. This finding is particularly significant in view of the fact that the conspicuity treatments employed in this field test are considerably less emphatic than was recommended. Two-inch rather than 4in-wide stripes effectively reduced the recommended SIA values by 50 percent. In addition, the use of rail-only reflectorization of trailer sides equally reduced the recommended conspicuity. Thus, there is strong likelihood that even greater reductions of other-vehicle-into-truck accidents will occur with the recommended reflectorization treatment.

Motor Vehicle Manufacturers Association

Abstract

Splash and spray conditions created by tractor-trailer combinations operating on the Federal highway system have been studied and tested for many years with mixed results. Past events are reviewed briefly in this paper. In additional testing during 1983, using new state-of-the-art splash/spray suppressant devices, some encouragement was provided that these devices could work.

The 1984 Motor Vehicle Manufacturers Association (MVMA) test program was designed to develop practicable and reliable test procedures to measure effectiveness of splash and spray reduction methods applied to tractor-trailer combination vehicles.

Over 40 different combinations of splash/spray suppression devices on five different tractors and three van-trailer types were tested. The spray-cloud densities for some 400 test runs were measured by laser transmissometers and also recorded by still photography, motion pictures, and videotape. On-site observers made subjective ratings of spray density. In general, this research demonstrated that improved visibility can be achieved; however, performance varied by vehicle configuration and could not be quantitatively predicted.

This paper explores the complex relationship that exists between the amount of spray generated and various vehicle aerodynamic characteristics. Ambient conditions such as wind direction and velocity and their effect on repeatability are discussed in detail.

Background

Splash and spray generated by heavy trucks and tractor-trailer combinations on wet road surfaces have long been a source of irritation to highway users. The motor carrier industry and vehicle manufacturers recognize the condition as a major element in the public perception of trucks and the trucking industry. There is little doubt that reductions in driver visibility, regardless of reason (snow, rain, fog, smoke, or vehicle splash and spray), are important to the safe operation of a motor vehicle.

Splash and spray is not a new problem. Long before motor-driven vehicles, pedestrians and other vehicular and equestrian traffic were confronted with the splash and spray annoyance factor. Motor vehicles compounded the public irritation in the early days of soft road surfaces. Over a period of several years, driver vision was aided by windshield wipers, fender designs, and vehicle mudflaps. Mudflaps, evolving from road surface debris deflectors to mostly splash deflectors today, have been effective to a degree in reducing the total spray from the rear of trucks.

In the late 1940's, the move toward building multilane highways around the country was the beginning of road building that led into the Interstate Highway system. The advent of more and more multilane highways brought on increased traffic densities and higher vehicle speeds. Vehicle manufacturers designed new products to meet increased performance demands for the new highway system. Increased speeds, exceeding the critical speed at which splash and spray becomes an appreciable visibility problem, resulted in a more vocal public irritated by the splash and spray problem. Since the late 1960's, organizations such as the Western Highway Institute, vehicle manufacturers, equipment suppliers, MVMA, and others have tested generic concepts to reduce splash and spray. The U.S. Department of Transportation National Highway Traffic Safety Administration (DOT/NHTSA) early on proposed rulemaking with the purpose of reducing the annoyance and possible dangers of splash and spray produced by heavy trucks. However, until the relatively recent introduction of textured spray suppressing materials for flaps and skirting, no potentially practical, effective solution to the problem has been identified.

The U.S. Congress, in the Surface Transportation Assistance Act of 1982, included requirements for the installation of splash and spray suppressant devices on all new tractors, semitrailers, and trailers by January 1, 1985, and for retrofitting all such vehicles in use by January 1, 1988. Minimum performance standards for such installations were to have been established by January 1984. A Congressional amendment adopted in 1984 removed the effective dates, which are now to be determined as part of DOT/NHTSA final rules.

Prior to developing proposed rulemaking, DOT/NHTSA ran a limited number of full-scale spray reduction tests at the Transportation Research Center (East Liberty, Ohio) in which test observers visually evaluated and rated the effectiveness of reduction devices tested. The rating

results of these tests indicated that reduction device combinations previously considered effective did not consistently make a discriminate difference in subjective evaluations. Subsequent tests conducted by MVMA at the same site also failed to find consistent improvements.

In January 1984, DOT/NHTSA began another series of tests with Systems Technology, Inc., as contractor at a test site at Fort Stockton, Texas.

The methodology used was substantially that developed earlier by David Weir(1), using objective laser measurements. These full-scale tests were designed to correlate laboratory test ranking of various types of spray suppression devices on various vehicles with objective laser measurements. The results of this test project are being statistically analyzed under MVMA sponsorship.

In addition, MVMA has conducted supplementary tests duplicating the Fort Stockton approach as closely as possible. Data from these tests are useful in filling gaps in the NHTSA data and are considered important to insure that the devices requirements adopted in future DOT/NHTSA rulemaking would be practicable and effective. The balance of this paper describes the 1984 MVMA splash and spray project and the test conclusions in detail.

Project Objectives

The purpose of this project was to develop quantitative and subjective data on the splash and spray attenuation performance of different aerodynamic devices and spray reduction devices applied to heavy tractor-trailer combination vehicles. The data collected through this testing project would supplement the results of similar testing conducted under the auspices of DOT/NHTSA.

Objectives of this project were to—

1. Validate the testing performed under DOT/NHTSA auspices of several spray attenuation treatments, using the same instrumentation and test setup, and identical vehicle combinations. (Note: The DOT/NHTSA data were not available for statistical analysis for inclusion in this report. These comparative studies will be available at a later date.)
2. Test vehicle combinations not included in the DOT/NHTSA test project to determine to a greater extent than would otherwise be possible whether different types have an effect on the efficacy of spray attenuation devices.
3. Develop new and/or more extensive instrumentation that can provide more comprehensive, cost-effective, objective measures of spray from heavy tractor-trailer combination vehicles.
4. Perform statistical analyses of collected test data for the purpose of evaluating heavy truck splash and spray attenuation devices.

Test Preparation

The testing was carried out at the Texas A&M University Texas Transportation Institute (TTI)[1] Proving Grounds at Bryan, Texas. The Proving Grounds, located at an abandoned air base, provided the necessary 7,000ft runway for testing combination vehicles at 55mph. The test area (Figure 1) included a new 400ft section of asphalt surface, constructed on top of existing pavement, to duplicate the Fort Stockton surface. The asphalt mix was developed to provide a final average texture depth of 0.33in. During construction, extra care was taken to produce as level a surface as possible to eliminate water

[1] Principal investigators: D.L. Ivey, R.J. Koppa, O. Pendleton, and R.A. Zimmer.

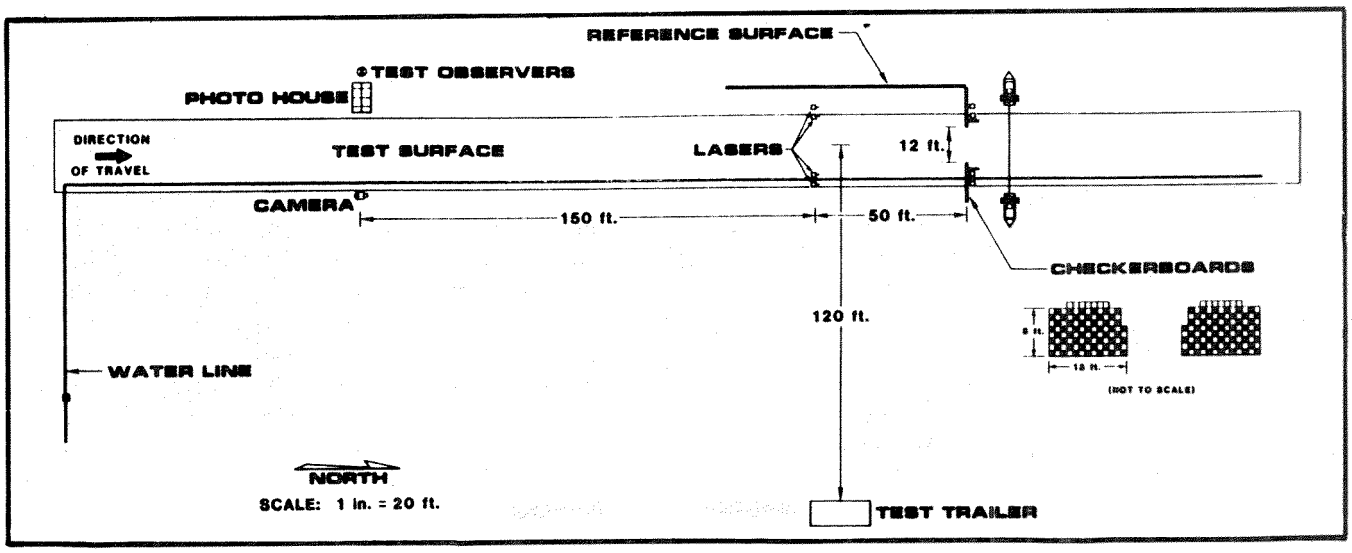

Figure 1. Test area

puddling. The new asphalt pavement was designed to have a 1 percent cross slope over its entire 400ft length. The width was 18ft to allow for a 12ft vehicle lane and 6ft for the water to stabilize.

Surface water was distributed to the pavement by a 400ft-long, 4in-diameter pipe. Water was directed to the road surface through DIN holes spaced 12in apart to provide uniform wetting. The water supply pressure was adjusted through a manifold and valve system to maintain the proper surface water depth throughout testing. Water depth measurements were recorded between each test run at 10 locations spaced along 300ft of test surface in the wheel paths by the use of NASA-type water depth gauges. The water depth throughout the entire test program was nominally 0.050 to 0.060in.

The major differences in this test project, as compared to prior tests, were the use of eight lasers for taking light transmissivity measurements and 35mm photos simultaneously on both sides of each combination vehicle as it went through the test area (Figure 2). An 8ft × 12ft black and white checkerboard target was positioned on each side of the vehicle lane.

Perpendicular to the track, 120ft from the center of the vehicle lane, a 35mm still camera was focused at a point on an 80ft × 4ft black backboard 50ft down the vehicle path from the checkerboard. The three still cameras were fired simultaneously, by means of a pneumatic trip switch as the vehicle combination entered the test area. All runs were recorded on video tape, and select runs were recorded on high-speed 16mm film.

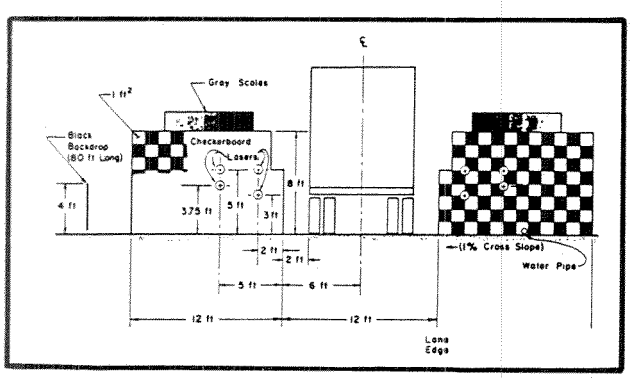

Figure 2. Test setup looking downrange

Eight low power lasers (5mw), located 50ft from the photo detectors or light meters in the checkerboard target, were used to measure quantitative spray density data. To account for crosswind, four lasers were located symmetrically on each side of the vehicle lane. The lateral and vertical placement is shown in Figure 2. The two lower positions are representative of eye levels in passenger cars, while the two higher positions are representative of eye levels in pickups and vans. The lower inboard laser positions (numbers 4 and 7) duplicate the positions used in previous test studies.

All lasers and detectors were mounted in waterproof enclosures with stable mounts (Figure 3). The sturdy mounts did not permit any motion of the laser beam due to air blast or pavement vibration, which could produce flawed data. Trial tests were run to determine effectiveness. An innovative lens system was developed to focus the 0.75in spot at the detector back to a pinpoint on the 10mm photocell. This technique eliminated the signal noise experienced in prior studies as a result of nonuniformity across the beam in addition to beam motion due to air density changes.

Signals from the detector were displayed on meters for alignment purposes and then transmitted to the telemetry system in the control trailer. These signals were then relayed via radio to the base station (Figure 4). These data were then filtered through a 5Hz, 4th order low pass filter (Butterworth), which approximates the reaction of the human eye to rapidly changing densities (Figure 5). After filtering, these data were recorded on magnetic tape, a strip chart, and the digital computer. The strip

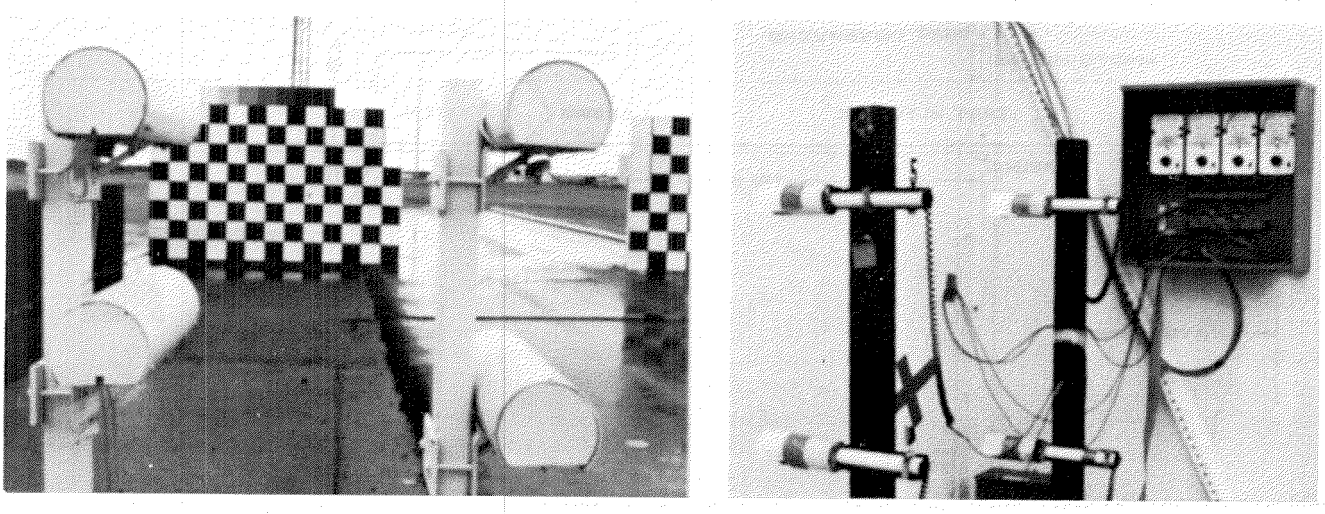

Figure 3. Laser housings and photocell detectors

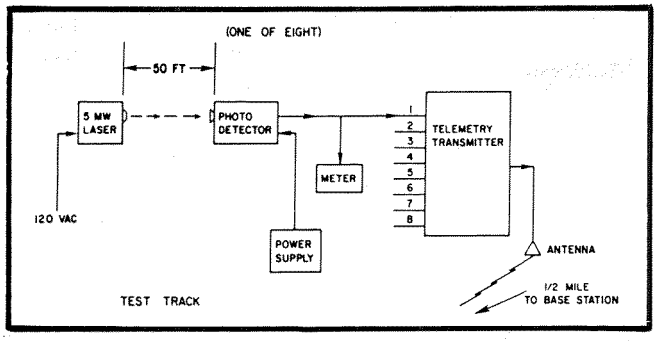

Figure 4.

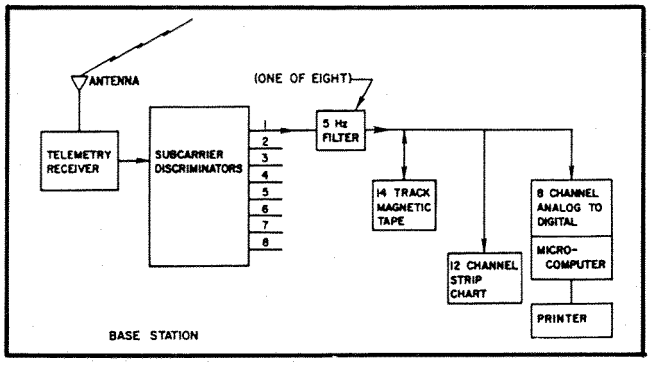

Figure 5.

chart provided instantaneous analysis of data quality, and the digital computer provided a summary printout of the minimum light transmission (based on 0 to 100 percent calibrations) from each laser. A typical strip chart trace of one transmissometer channel is shown in Figure 6, and a typical computer printout is shown in Figure 7.

End-to-end laser calibration (nominally within 2 percent of the true filter values) was achieved by inserting precision neutral density filters of 12, 25, and 50 percent in each beam and observing the digital output values.

To accommodate the greater length of the combination vehicle, the number 6 laser was relocated at a height 6in above number 7 laser and at a distance of 80ft from the detector. Thirty-six runs were made with a correlation coefficient of 0.91 between the 50 and 80ft laser positions.

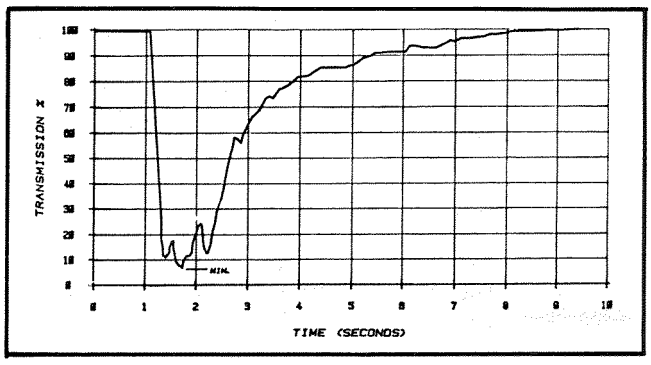

Figure 6. Typical strip chart trace

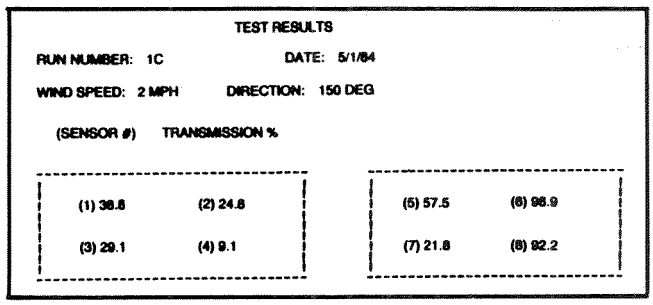

Figure 7. Typical computer printout

Therefore, in this type of testing, either a 50 or 80ft laser and detector separation could be used (Figure 8).

The effects of wind, believed to be the most significant uncontrollable variable, were minimized by taking identical measurements on both sides of the test area and by running the comparative tests within 4 to 5min. Wind speed and direction were measured prior to each test using a precision anamometer and recorded on a strip chart. Testing limits were set at a maximum wind speed of 10mph allowing for gusts up to 12mph. Ambient air temperature and relative humidity were also recorded; however, no data corrections were deemed necessary.

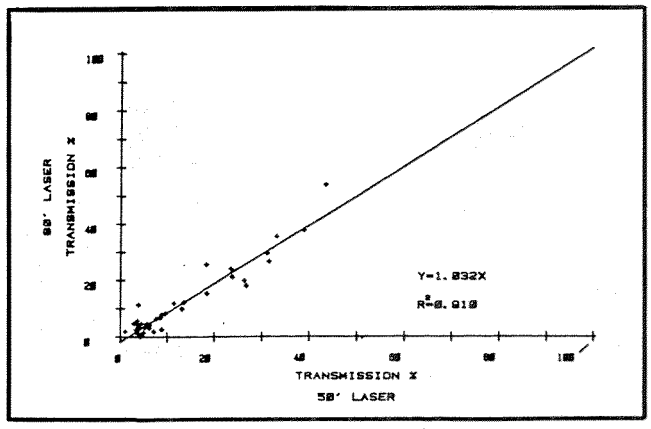

Figure 8.

As stated previously, all test runs were made at 55mph with the same driver for all runs. Vehicle speed was measured and recorded for each run by means of a standard law enforcement radar unit mounted in a vehicle positioned behind the checkerboard. The vehicle speed did not vary by more than ±1mph.

Test Plan

To assure that objective laser test measurements were repeatable from one site and one work crew to another, several DOT/NHTSA tests were duplicated using two of the actual vehicles tested by DOT/NHTSA. Refer to Figure 9 for 6×4-long nose conventional cab and single van trailer.

For this test study, the contractor was required to use three different cab types (COE, long and short conventional cabs), three van trailer types (96in-wide single, 102in-wide single, and one set of 96in-wide doubles), and two spray suppressant type devices (rear of axle-mounted flaps and vehicle side-mounted skirts). See Figures 10, 11, and 12.

Out of the series of vehicle combinations there were 47 configurations. These configurations included combinations of side-mounted skirts, treated (suppressant) flaps, and various aerodynamic devices. Each of these configurations was repeated three times for a total of 141 runs. Each run consisted of a calibration vehicle combination, an untreated baseline combination (identical to the test vehicle), and the treated test vehicle combination (Figure 13). The total number of runs for this program was 396.

Figure 9. Long nose conventional

Figure 10. COE with single van trailer

Figure 11. Short nose conventional

The calibration vehicle combination was equipped with new, plain, masticated rubber flaps (at the trailer rear only) mounted in the same location as the suppressant flaps. The baseline vehicle combination (identical to the test vehicle) was also equipped with new, plain masticated flaps (at the trailer rear only). The test vehicle combination received varying levels of suppressant devices as required by the test matrix.

The project contractor considered skirts and suppressant flaps (manufactured by Schlegel Corp. and Monsanto Co.) to be representative of the current state-of-the-art devices. These devices were installed in locations recommended by the device manufacturer. No attempts were made during this test program to vary the locations of the skirts or treated flaps. Figure 14 shows a typical front steering axle skirting and treated flap installation. Figure 15 shows a typical tractor drive axle installation (treated flap behind last axle and skirt nose of trailer mounted). Figure 16 shows a typical trailer rear installation.

Figure 12. COE with doubles

Figure 13. Calibration, baseline, and test vehicles

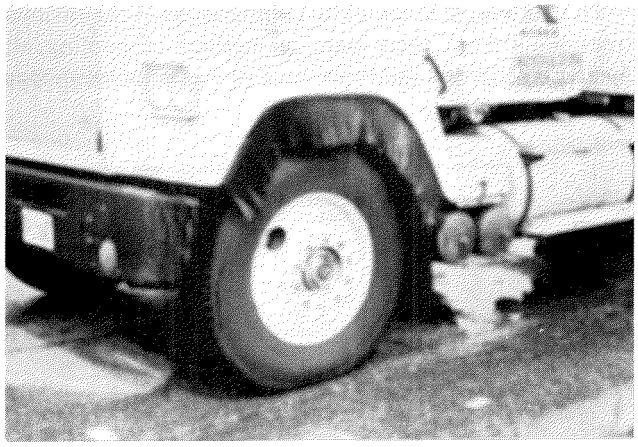

Figure 14. Steer axle installation

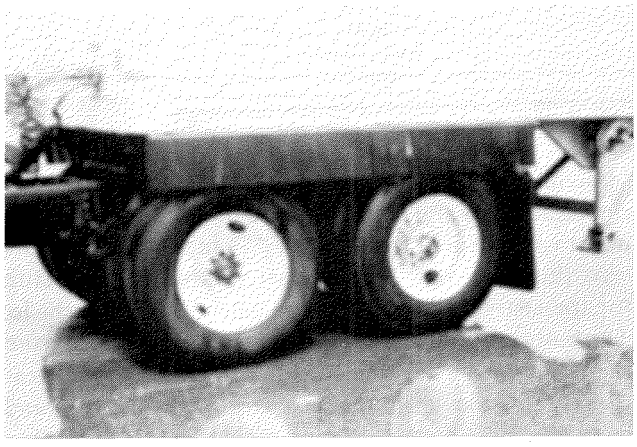

Figure 15. Drive axle installation

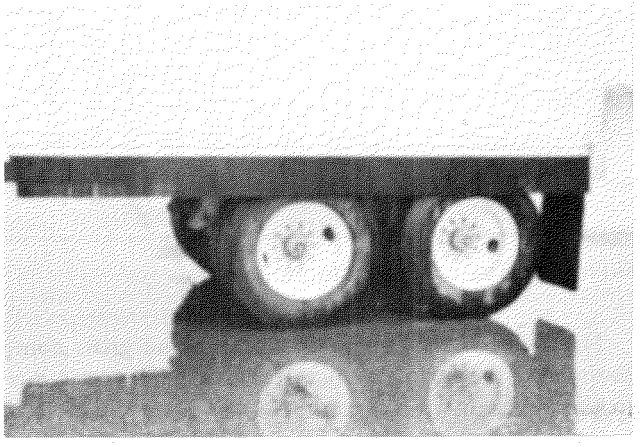

Figure 16. Trailer rear installation

The specific objectives of this test plan were designed to produce the following direct comparisons:

1. Compare the effect of aerodynamic devices
   a. Between cab configurations
   b. With various levels of suppressant devices
2. Compare the effect of suppressant devices
   a. Between cab configurations
   b. With various levels of aero devices
   c. With plain masticated flaps
   d. With varying levels of valances

Legend

Vehicle Type:

- COE = Cab-Over-Engine Tractor
- LNC = Long Nose Conventional Tractor
- SNC = Short Nose Conventional Tractor
- SV = Smooth Side Singles, Van Semi-trailer
- DV = Smooth Side Doubles, Van Trailer

Aeroaid:

- X* = Cab Roof and Side Fairings
- X = Cab Roof Only

Flaps:

- T = Trailer, behind rearmost axle
- D = Tractor, behind rearmost axle
- S = Tractor, behind front steering axle

Skirts:

- Tr = Trailer, rear axles (8')
- Tf = Trailer, nose area over tractor drive axles (8')
- SL = Tractor, front steering axle.

Figure 17.

Test Results

The still photographic records of each test run as the vehicle reached the checkerboard reference surfaces provide only a qualitative feel for the differences between the many vehicle treatments. The spray density measurements obtained during testing provided the primary basis for evaluating the effectiveness of the various spray attenuation treatments. The results of these spray density measurements are discussed in two parts as described below.

The first part of this section will discuss the results of the digitized minimum light transmission data for each sensor for the test plan as follows:

1. Data reduction and analysis
2. Correlation of sensor measurements with one another and with wind
   - Pairwise correlation analysis
   - Principal component analysis
   - Variance attributable to test conditions
3. Comparisons of conditions by grouping of setups
4. Analysis of variance and other tests of significance
   - Difference analysis of variance
   - Regression or covariate analysis of variance
   - Analysis of cases taken as treatments

The second part will discuss the results of the following special evaluations:

1. The relationship between heavy vehicle speed and the amount of spray generated
2. Observer ratings of spray clouds and correlation with spray density measurements

Data Reduction and Analysis

The actual data recorded included eight readings of minimum percent laser light transmission, wind velocity, and direction for each run; the test (T) and baseline (B) vehicles are identified and the setup number that identifies the specific spray suppressant treatment being evaluated (see Figure 18).

Note there are three runs per unique setup, that is, a combination of aeroaid, skirts, and spray flaps on the front steering axle and the tractor and trailer rear axles.

OBS	RUN	VEHICLE	SETUP	WIND	DIRECT	SENSOR1	SENSOR2	SENSOR3	SENSOR4	SENSOR5	SENSOR6	SENSOR7	SENSOR8	TRUCK

Figure 18. Typical data sheet

To make some meaningful comparisons of the various treatments from these data, a method of pooling all measurements for the three runs of a unique setup was used (see Figure 19).

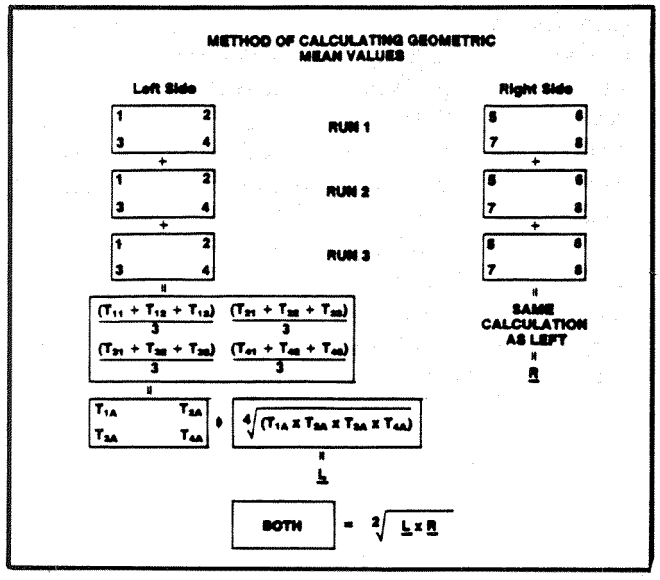

Figure 19.

Geometric mean values were calculated for left and right side lasers and then combined into a third geometric mean value expressed as "Both." Pooled measurements were thus determined for each set of three runs per setup for the test vehicle and the equivalent baseline vehicle. The baseline pooled measurements are subtracted from the test pooled measurements to provide the first indication of how the various vehicle treatments perform and compare. These data are presented in a typical bar histogram form showing the difference rank ordered from left to right in ascending magnitude for each type of vehicle (see Figure 20).

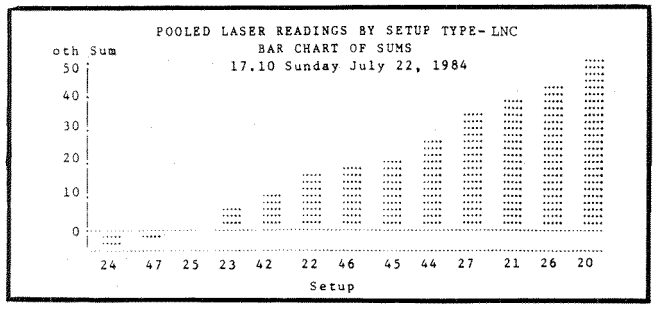

Figure 20. Typical bar histogram chart

The pooled measurements permit some gross comparisons of the various vehicle treatments. However, due to the effect of wind directions and velocity as well as limited data points, the contribution of each level of treatment could not be evaluated accurately.

Correlation of Sensor Measurements

To further study the effect of wind direction and velocity on the spray density, the use of eight different sensors in this test project permitted comparisons of various sensor measurements to determine correlation with one another in addition to wind effect.

Earlier work by Weir suggests that sensors located outboard of the "NHTSA Locations," i.e., sensors 4 and 7 in this test project, provided little additional information about the spray cloud. As shown in Figure 21, a series of correlations of sensor 4 versus sensors 1, 2, and 3 and sensor 7 versus sensors 5, 6, and 8 were computed based on data gathered on the calibration vehicle in which all eight lasers were operating. From this simple statistical analysis, it can be concluded that for comparison purposes of one treatment versus another, sensors 4 and 7 are sufficient.

Comparison	Correlation	Adjustment	MN Value*
SENSOR 4 vs.			
Sensor 1	0.796	3.48	49.81%
Sensor 2	0.89	2.56	36.64%
Sensor 3	0.86	2.37	33.95%
Sensor 4	1.00	1.00	14.33%
SENSOR 7 vs.			
Sensor 5	0.93	1.77	63.46%
Sensor 6	0.75	2.17	77.92%
Sensor 8	0.82	1.96	70.56%
Sensor 7	1.00	1.00	35.89%

Figure 21. Correlation of sensors 4 and 7 with other sensors

A more in-depth investigation and analysis of the interrelationships among the eight sensors and wind effect were conducted using the following statistical methods.

Pairwise Correlation Analysis

Pairwise correlation analysis is a bivariate statistical procedure that provides a two-dimensional description of sensor and wind relationship. Wind was selected as a single response variable representing both direction and speed.

Pairwise correlations were run among all eight sensor readings, the wind component for the calibration vehicle and the baseline vehicle separately. The results of this analysis are shown in diagrammatic form in Figure 22. Typical data plots for all sensor pairs are given in Figures 23, 24, 25, and 26.

The following observations can be made concerning these results:

1. Sensor correlation patterns are distinctly different for the right sensor (5-8) versus the left sensor (1-4). Sensors 1 to 4 have significant positive linear correlations. Sensors 5 to 8 are nonlinearly related (see scatter plots shown in Figures 23 through 26).

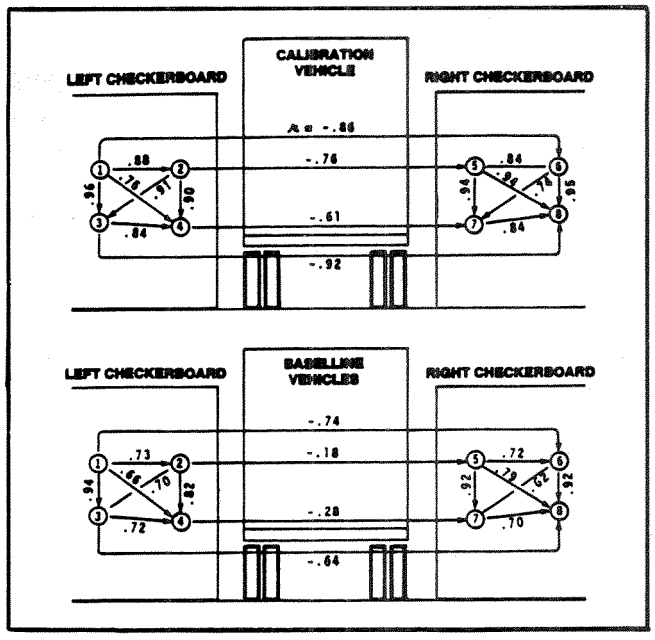

Figure 22. Pairwise correlations among sensors

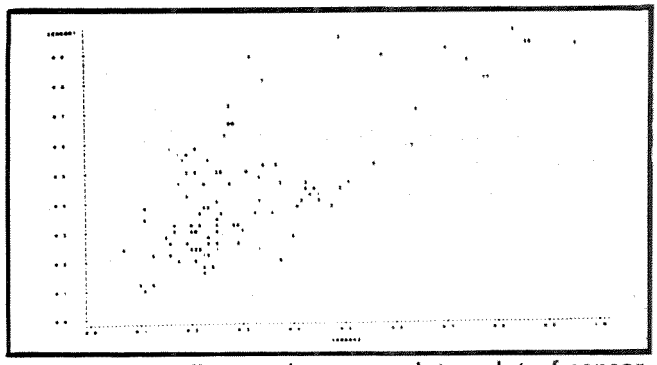

Figure 23. Baseline truck scatter plots—plot of sensor 1—sensor 2 symbol is vehicle type

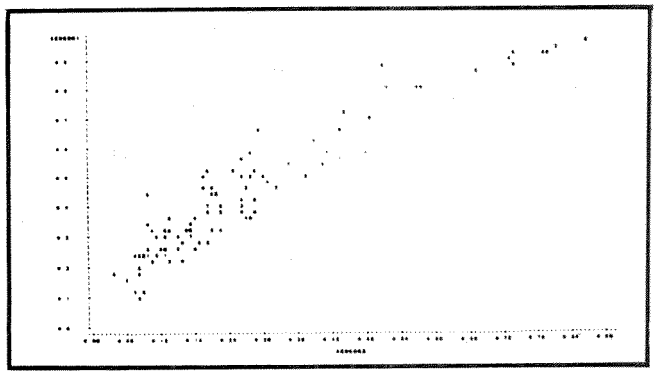

Figure 24. Baseline truck scatter plots—plot of sensor 1—sensor 3 symbol is vehicle type

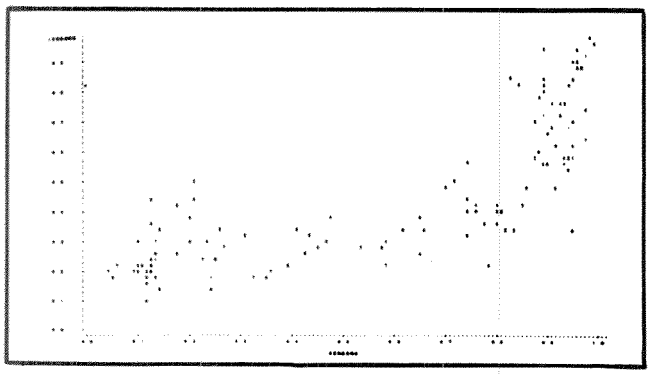

Figure 25. Baseline truck scatter plots—plot of sensor 5—sensor 6 symbol is vehicle type

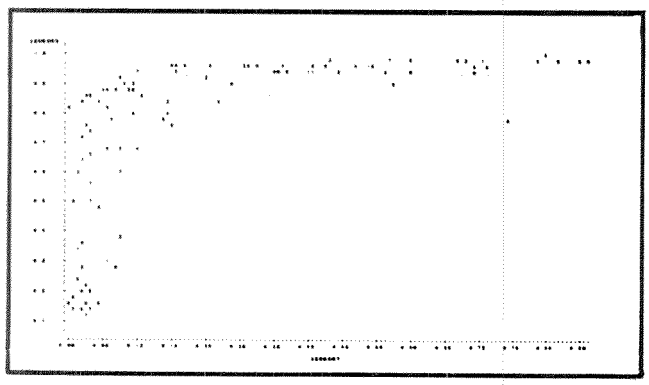

Figure 26. Baseline truck scatter plots—plot of sensor 6—sensor 7 symbol is vehicle type

2. Left sensors (1 to 4) correlate positively with the wind component and right sensors (5 to 8) correlate negatively. However, these correlations are generally lower for the inside sensors (2, 4, 5, 7). Thus, wind has the strongest effect on the outer sensors.

Principal Component Analysis

This statistical analysis is a multivariate procedure that provides a multidimensional description of sensor and wind relationships. Sensor readings and wind components are weighted and summed to provide a single response. This response reflects a significant proportion of the total variability among sensor readings and wind component variables. The magnitude and direction of these factor loadings provide information on how these variables interrelate in a multivariate setting.

Figure 27 lists the weighting factor (or factor loadings) for the standardized sensor readings and wind component for the calibration and baseline vehicles.

From the results of the correlation of sensor measurements with one another and with wind, it can be concluded that—

LOADINGS

	S_1	S_2	S_3	S_4	S_5	S_6	S_7	S_8	Wind	Prop. Var.
Calibration Vehicle										
Both	.35	.34	.35	.31	-.34	-.33	-.33	.35	.29	.83
Left	-.46	-.46	-.47	-.43					-.41	.86
Right					-.47	-.44	-.45	-.46	.42	.86
Baseline Vehicle										
Both	.38	.24	.36	.26	-.34	-.36	-.32	-.37	.33	.65
Left	-.47	-.44	-.47	-.43					-.42	.78
Right					-.46	-.46	-.44	-.48	.40	.78

Figure 27. Vehicle principal component results

1. Right and left sensors behave oppositely as evidenced by the equal but opposite signed factor loadings when all sensors are analyzed together.
2. The sensors behave oppositely with regard to wind; the left sensors are positively correlated with wind and the right sensors negatively correlated.
3. For the purposes of comparing treatments, sensors 4 and 7 are sufficient.
4. The baseline vehicle data did not reflect this behavior as clearly as the calibration vehicle data. Loadings on sensors 2 and 4 were high for the second largest factor.

Variance Attributable to Test Conditions

Throughout the test program, a third vehicle, the "Calibration" vehicle, was run with every pair of evaluation vehicles. This vehicle was equipped with plain mudflaps behind the trailer rear axle as the only spray control device, and it was left unchanged for the duration of the testing. Figure 28 presents summary statistics on this vehicle, spatially arranged to reflect sensor arrangement on the checkerboards, as seen down range (north). Wind velocity and percentage transmission level standard deviations are comparable to those for baseline and test vehicles. The summary statistics of two categories of

Figure 28. Summary statistics on all calibration vehicle runs

vehicles are given in Figures 29 and 30, respectively. The dispersion in relationship to each mean transmittance, which is expressed as the standard deviation, is indicative of the problem facing all testers of splash and spray devices: very large variation.

The large amount of variability in measurements for any given sensor is explained, at least in part, by wind velocity and direction, plus inherent variability in measurements of a complex aerodynamic phenomenon such as spray from a speeding vehicle. This variability far exceeds that acceptable for normal engineering test protocol. It is this variance that makes interpretation of limited runs on a given configuration difficult.

Comparison of Conditions by Grouping of Setups

To determine in a general overall sense if those spray reduction devices evaluated really work or are of benefit, a statistical analysis was made using the t-test of independent means. This approach to inferential statistical analysis allows a gross kind of comparison setup. The t-test for most of the sample sizes of this test project approximates a Z-distribution-test. The reader is referred to any standard text on statistics for a further explanation of inferential tests, and the t-test or Z-test in particular.

The results of the t-test of mean differences between all treated vehicles (T) and their baseline (B) vehicles are shown in Figure 31.

COMPARISON	N	SENSOR	MN VALUE	t VALUES	PROB >|t|
B	143	4	10.38%	-6.73	.0001**
T	140	4	25.33%		
B	143	7	22.28%	-8.30	.0001**
T	140	7	50.61%

102" TRAILER	30	7	56.2%	1.22	.22
96" TRAILER	95	7	47.8%		

*Significant Difference (Pr<0.05)
**Highly Significant Difference (Pr<0.001)

Figure 31. T-test—sensors 4 and 7

For both DOT/NHTSA sensors (and the others as well), a significant difference was observed. Overall, transmittance was more than twice as large for treated vehicles as compared to baseline. Sensor 4 had a mean value of 10.38 percent versus 25.33 percent for treated trucks. That this great a mean value difference could occur, and yet there was no difference between treated and baseline vehicles as measured by sensor 4, is associated with a probability of less than 0.0001. These spray reduction devices, taken overall, do indeed work.

For the purpose of evaluating the effect of the cab roof-mounted aerodynamic shield on spray reduction, the setups shown in Figure 32 were used. The t-test results

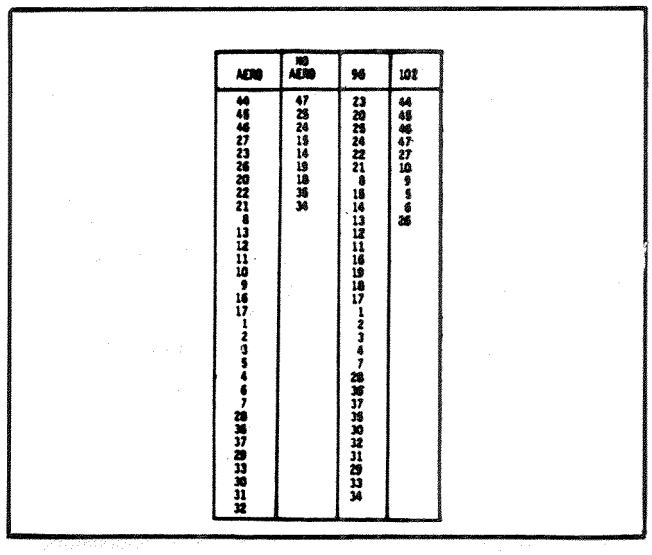

Figure 32. Setup partitioning for comparison of conditions

as shown in Figure 31, AERO versus NO AERO, indicate the differences on the left side (sensor 4) were significant, but less so on the right side. If pooled, these differences would remain significant beyond the 0.05 level; hence, it can be concluded that the cab-mounted aeroaid has a measurable effect on reducing spray. Figure 32 also provides the results of the comparison of spray levels between 96in-wide and 102in-wide trailers and indicates no significant measurable difference.

The above findings merely scratch the surface so far as making definitive statements about the many treatment strategies tested. T-tests between different individual treatments with only three runs per treatment or setup would be unproductive, and, in any case, multiple t-tests for data that could be analyzed by more sophisticated methods can be very misleading.

Therefore, analysis of covariance using several different models was performed on all the data gathered for B and T vehicles in this research project. This analysis is explained and interpreted in the following section.

Analysis of Variance and Other Tests of Significance

Individual setups were tested only three times; therefore, meaningful statistical comparison of transmissometer data is difficult. A strategy was developed to make inferences concerning the effects of different treatment combinations of flaps, skirts, and aeroaid. This strategy required the sacrifice of certain variables, namely, trailer type (which has been found to produce no significant difference) and tractor type (five different tractors). These data were simply collapsed over these two variables. Once this was accomplished, a variable called Aero can be identified as having three levels:

No aeroaid installed	= 0
Standard aeroaid	= 1
Special (Gelco) aeroaid	= S

Another variable is the treatment on the steering axle of the test vehicle, which can be called Steer:

Flaps only	= F
Flaps and skirts	= FS

A third variable is the treatment on the drive axle(s) of the tractor, which has two levels, just as the Steer variable does. This third variable is called Drive.

A final variable is Rear, which is the rear (trailer) axle treatment. Since all setups specified special flaps on the rear of the trailer, the two levels of this variable are—

Flaps only	= 0
Skirts and flaps	= S

Figure 33 identifies 10 different combinations of these variables that were tested in the setups of the test matrix. Each setup, in other words, can be classified as being one of these two cases. In Figure 33, each of the 10 cases is related to the setups that match that case.

CASE	SETUPS	AERO	STEER	DRIVE	REAR
1	3, 37	S	F	F	S
2	4, 5, 29	S	F	F	0
3	2, 36	S	F	FS	S
4	1, 6, 28	S	FS	FS	S
5	14,18,24,34,47	0	F	F	0
6	15,19,25,35	0	FS	FS	S
7	12,22,32,45	1	F	F	S
8	10,13,17,23,27,33,46	1	F	F	0
9	11,21,31,44	1	F	FS	S
10	8,9,16,20,26,30	1	FS	FS	S

Figure 33. Setups classified into 10 cases

Since, as Figure 33 shows, the few cases of flaps only at the rear covaried with the presence or absence of an aeroaid and combinations of Steer and Drive, this factor could not be extracted independently. Thus, this analysis concentrates on differences among the various combinations of Aero, Steer, and Drive. Two approaches were used. In the first, the difference between test and baseline vehicle sensor readings on equivalent runs was the dependent or criterion variable. The other involved a more direct approach for controlling the troublesome intervening variable of wind. The first analysis is referred to as the difference analysis.

Difference Analysis of Variance

A two-factor interaction analysis of variance model was used with Aero and Steer/Drive being the main effects with three levels each. This resulted in a missing cell design, since no Aero = U and Steer/Drive = (F-S) combination or levels were observed. The assumption in this experimental design is that the test and base vehicle experienced similar wind conditions. Since this was precisely the purpose of running baseline and test vehicles in close sequence, this may not be an unreasonable assumption.

Based on the considerations of relationships among the eight sensors previously discussed, four different criterion variables were developed. Each variable required a separate analysis of variance. These variables were as follows (each observation is a difference between a sensor's readings on a baseline truck pass and the equivalent test truck pass moments later):

- Variable 1—The geometric mean of all eight sensors
- Variable 2—The geometric mean of sensors 4 and 7 only
- Variable 3—The geometric mean of left sensors only (1 to 4)
- Variable 4—The geometric mean of right sensors only (5 to 8)

The geometric mean is frequency used as the measure of central tendency when the random variable of interest is a portion or percent since the population frequency distribution of such random variable tends to be skewed. The frequency distribution of the sensor arithmetic mean did show a definite skewness. The frequency distribution of the geometric mean, on the other hand, appeared to be nearly normally distributed. To further support the use of geometric mean, analyses were run using both measures, arithmetic and geometric, and there were no differences in results concerning treatment effects.

Figure 34 provides a summary of the results of this difference analysis of variance for all four criterion variables. In this table, an asterisk (*) indicates a level of significance of 0.05 under a null hypothesis of "no difference." This signifies that means that are as far apart in value as those observed, among the various levels of the factors being analyzed, have a chance of 5 in 100 of being just that—chance—rather than reflecting a real difference between treatments or combinations of treatments.

		Criterion Variable			
Factor		1	2	3	4
Aero		*[1]	*	*	*
Steer/Drive		*	*	N.S.	*
Aero X Steer/Drive		N.S.[2]	N.S.	N.S.	N.S.
Aero:	1	27.1%[3]	21.3	24.7	26.4
	S	14.3%	9.5	18.5	16.5
	0	11.6%	8.8	7.5	8.3
Steer/Drive	FS-FS	26.0	20.8	20.4	26.3
	F-FS	19.2	15.4	16.6	22.0
	F-F	17.1	12.1	19.2	15.3

NOTES:
1. $\alpha = 0.05$
2. N.S. = NOT SIGNIFICANT
3. Geometric mean difference in percent transmittance, Test vs Baseline Vehicle

Figure 34. Results of difference analysis of variance on aero and drive steer comparisons

The rows under the significance matrix help the reader understand the meaning of these findings. For criterion variable 1, in which all eight sensors are pooled, a standard aeroaid, across the board, produces consistently better results (a higher mean transmittance difference of 27.1 percent) than either the special aeroaid or no aeroaid.

The Steer/Drive combinations are consistent for all but variable 3, as can be seen in Figure 34. The most effective combination is both flaps and skirts for all axles, and it is significantly better than just flaps alone on these same axles. Note in this table that the interaction between the levels of aeroaid treatment and axle treatments is uniformly nonsignificant. This means that whether or not an aeroaid is installed has no differential effect on the efficacy of the wheel treatments; the percentage change (in this case improvement), associated with the use of an aeroaid, works as a constant on whether wheel treatment is installed. It should be noted that the standard aeroaid condition occurred with greater frequency in this data set; i.e., there were 63 standard aeroaid runs as compared to 30 special and 27 nonaero conditions.

Regression or Covariate Analysis of Variance

To address more directly the effects of wind, a second method of analysis was undertaken, with the dependent or criterion variables being the transmissometer readings for baseline and test vehicles considered separately. In this analysis, the crosswind vector component of wind is entered as an independent variable just like treatments on the test vehicles. Other independent variables in the model were, as before, Aero and Steer/Drive axle combinations. This model essentially fits separate linear regression lines for the four ways of pooling sensor data used in the difference analysis for each factor level combination and tests for the equality of slopes and intercepts. Since baseline vehicles had no treatments, these lines should be equal in slope and intercept. If the slopes are equal for test vehicles, this implies that treatment combinations shown in Figure 33 can be compared at any wind value and result in the same conclusions. If, however, slopes are not equal, this finding would suggest that a treatment was better under some wind conditions than under others. Inequality of intercepts means that the treatments were not equal with regard to the amount of spray recorded, and thus different treatments can be rank ordered with respect to the extent of spray control.

Figure 35 summarizes the findings of these analyses, organized as before with respect to the four different

		Criterion Variable

Figure 35. Results of regression analysis of variance on aero and drive steer combination

methods of pooling sensor observations. Baseline vehicle geometric mean readings are also included in this table for comparison with test vehicle geometric means.

In this analysis, wind is not a significant covariate either by itself or in interaction with other factors for criterion variable 1 or for variable 2. These, it will be remembered, are (1) laser readings pooled over all eight sensors, and (2) sensors 4 and 7 only pooled by taking their geometric mean. In the section Correlation of Sensor Measurements, the correlational analysis of sensor readings with wind for the baseline and calibration vehicle runs, it was determined that sensors on the left and right correlated oppositely with wind; hence, the fact that wind is not a significant covariate for sensor readings pooled on both sides of the vehicle should not be surprising. That wind (really the crosswind vector) should be a significant variable for criterion variables 3 and 4 is also not surprising, since these are left-only and right-only sensors, respectively. These geometric means were greatly influenced by wind velocities and directions from one period of time to another, and thus wind is a significant covariate. This relationship was, however, the same for all factor levels as evidenced by the lack of interaction of wind with any of these factors.

The slopes and intercepts of the lines for all factor level combinations of the baseline vehicles were equal, indicating that the baseline vehicles' pooled laser readings were essentially equivalent for all runs.

The results for the test vehicle responses, as summarized in Figure 35, show that wind was a significant covariate for the right and left responses, criterion variables 3 and 4, but the slopes of the regression lines were the same for all factor levels. Thus, equivalent conclusions regarding treatment effectiveness will result at any wind condition. This figure again shows that for criterion variables 1 and 2, the standard aeroaid was superior to either the special aero or no aeroaid.

When left-only sensor 3 and right-only sensor 4 are used as the dependent variable, the results are not as straightforward. For the right-only sensors, there was a significant interaction between the kind of aeroaid treatment that was used and the wheel treatment used. The main effects of wheel treatment closely parallel the findings of the difference analysis of variance; the fuller the treatment of tractor axles, the better the results.

As a supplementary analysis, the single factor of rear axle (on the trailer) with two levels—flaps only versus skirts and flaps—was studied, using test vehicle data only. The results show a significant difference between these two conditions for all but the right-only sensors, with skirts and flaps superior to flaps only on the rear axles (see Figure 36).

	Criterion Variables			
	1	2	3	4
Rear: Flaps & Skirts	49.9	27.6	50.4	89.5
Flaps ONLY	37.0	21.4	36.9	87.4

Figure 36. Results of regression analysis of variance on effects of skirts on rear axles

Analysis of Cases Taken as Treatments

A difference approach can be taken for the data of this study, if each of the 10 cases identified in Figure 33 can be taken as an individual treatment. Through analysis of variance methods and criterion variables identical to those described in the previous section, it should be possible to make some overall statements concerning the relative efficacy of these generic installations on vehicles. In addition, an analysis of covariance was performed on these data.

Figure 37 summarizes pooled laser readings for the 10 cases, plus pooled case readings for their equivalent baseline vehicle runs. The pooled transmissometer variables are (1) the geometric means of all eight sensors, and (2) the geometric mean of sensors 4 and 7 only, just as before. A study of this table will show some differences among the various cases, and a quite evident overall superiority of test vehicles over their equivalent baselines.

	Conditions				Variables			
					1		2	
CASE	Aero	Steer	Drive	Rear	T	B	T	B
1	S	F	F	S	39.6%	29.7	17.2	13.9
2	S	F	F	0	49.9	31.2	24.9	13.3
3	S	F	FS	S	36.4	34.6	14.2	14.5
4	S	FS	FS	FS	53.3	31.4	28.8	12.3
5	0	F	F	0	33.1	26.5	16.1	11.1
6	0	FS	FS	S	42.1	24.0	23.5	13.9
7	1	F	F	S	52.0	23.5	28.1	8.8
8	1	F	F	0	44.5	24.2	25.4	8.9
9	1	F	FS	S	54.3	26.3	31.9	8.6
10	1	FS	FS	S	57.1	24.0	35.0	8.8

Figure 37. Summary of pooled laser readings by cases

The following methods of analysis were used to determine treatment effects:

1. Analysis of Differences—In which the dependent variable was the difference in laser readings, sensor by sensor, between the test and the baseline vehicle on a given run. A one-way analysis of variance and a duncan multiple range test were run using 10 cases as the independent variable (each case is a level in this fixed model). Data were analyzed by separate wind directions defined as either a positive or negative value according to the crosswind vector. Another

analysis was performed with only those observations in which a crosswind component of equal to or less than ±2mph was recorded ("no wind").

2. Regression Analysis—Which is similar in approach to the differences analyses discussed earlier and yields little more definitive information. A separate regression line was developed for each of the 10 treatment combinations (cases). These regression lines were then compared for equality of slope and intercept.
3. Analysis of Covariance—In the analysis of covariance regression, model wind was considered by fitting lines for pooled laser readings versus wind (crosswind vector) for 10 test cases and their equivalent baseline runs. Hence, 20 lines of regression were fitted simultaneously and then tested by equality of slopes and intercepts. Since this procedure involved multiple hypothesis testing (40 parameters being estimated), in order to have an overall significance (α) level of 0.05 for rejecting the null hypothesis of "no significant difference," individual slopes and intercepts were tested at the level of 0.001.

Criterion variables used in these analyses were the usual four described previously, plus a special category consisting of each sensor taken individually (no summary by pooling). Duncan multiple range tests were then used to evaluate the significant differences found among many of the 10 cases in the difference analysis.

Figure 38 identifies cases in rank order of efficacy in attenuating spray from left to right for criterion variables 1, 2, 3, and 4. Those cases identified in each row corresponding to an analysis such as "All Winds (considered)" are cases significantly better than their baseline equivalents but not differing significantly among themselves. Case numbers in parenthesis are cases that mark the threshold from significantly better than base to no better than base (in some instances worse).

Geometric Mean of All Sensors		Geometric Mean of Sensors(4&7)	
All Winds:	10 9 4 7 2 8 6 1 3 (5)	All Winds:	10 9 7 4 8 2 6 1 5 (3)
No Sig. Wind:	10 4 9 6 7 8 2 1 5 (3)	No Sig. Wind:	10 9 6 4 8 7 2 1 5 (3)
Sig. Wind:	9 2 10 7 4 1 8 6 3 (5)	Sig. Wind:	9 2 10 7 4 1 8 6 3 (5)
Geometric Mean of Left Sensors(1-4)		Geometric Mean of Right Sensors(5-8)	
All Winds:	2 7 10 9 8 1 4 6 3 (5)	All Winds:	4 9 10 7 8 1 6 2 5 (3)

Figure 38. Rank order of cases

In Figure 38, first results are shown for all data (all winds) for variables 1 and 2. Then results by comparing data generated under low or no wind versus significant wind are given. For left-only and right-only sensor data, where directionality is obviously of interest, rankings of cases are shown for the all winds considered analysis (all winds) and for only those observations in which wind is significant (greater than ±2mph, crosswind vector).

These findings can be interpreted as follows. Cases 10, 9, and 7 were uniformly superior across all wind directions and types of pooling of laser readings. Cases 3 and 5 were generally least effective in attenuating spray.

Turning to an analysis of individual sensor data, Figure 39 provides rank order information. Treatment difference responses that are underlined are significantly different than those that are not underlined and are significantly greater than zero. Cases 10 and 7 again were consistently selected, although case 2 was ranked as one of the best treatments by sensors 1 through 4 but not by sensors 5 through 8. Conversely, case 4 was ranked very highly by sensors 5 through 8 but not by sensors 1 through 4.

(Individual Sensors:)										
S1	10	8	2	9	7	1	4	3	6	5
S2	2	7	10	6	9	8	4	1	5	3
S3	7	2	10	9	8	4	3	1	6	5
S4	7	2	10	6	9	8	1	5	4	3
S5	4	9	7	8	10	6	1	2	3	5
S6	7	10	9	1	4	8	6	2	5	3
S7	9	4	8	10	7	6	1	3	2	5
S8	7	9	10	4	8	6	1	2	5	3

Figure 39. Rank order of cases by individual sensors

In summary, a standard full treatment of flaps and skirts on every axle, together with a standard aeroaid (case 10), provided the best overall results in spray attenuation. Leaving the steering axle without skirts but installing everything else (case 9) is next most efficacious, followed by a treatment in which skirts are retained only on the rear of the trailer. Case 2, which has no skirts but does have cab side fairings in addition to a special cab roof-mounted aeroaid, produces highly wind-dependent effects. The aeroaid is very critical, since the cases without it perform erratically to poorly (cases 5 and 6).

Relationship Between Speed and Spray Generated

Special speed tests (in increments of 5mph from 35 to 60mph) were conducted using various levels of suppressant devices and plain rubber flaps. It can be concluded that speed and spray generation are linear and that combination vehicle speeds over 60mph will produce unacceptably high levels of spray.

Observer Ratings and Correlation to Objective Measurements

To better correlate observer ratings and objective laser measurements, the relationship between spray density and observer contrast sensitivity was investigated. To this

end, a vision contrast test system marketed by Vistech Consultants, Inc., was used along with an artificial rainmaker. Observers, plus a single laser beam, were used to rate four levels of transmission: 100 percent (no water), 60 percent, 40 percent, and 20 percent. Predictably, contrast discrimination falls off rapidly with increased density of spray or as the fineness of the target patterns increases. An evaluation of the computed percent change in contrast sensitivity of the laser compared to observer ratings demonstrated a high degree of correlation (.92). Based on these findings when a condition of 40 percent laser transmittance was reached, observer contrast discrimination had fallen off by a factor approaching two.

It can be concluded that when spray obscures light to below 40 percent transmissivity, loss of observer contrast sensitivity results. Such a controlled test does not reproduce the dynamic situation of a driver attempting to pass a truck with all of the variables of wind, speed, aerodynamic effects, windshield, windshield wipers, etc. Therefore, a conclusion that treated vehicles must achieve a threshold level of 40 percent or above for the motoring public to perceive improvement cannot be substantiated.

Innovative Instrumentation

Within the scope of the research objectives of this project, the University of Michigan Transportation Research Institute (UMTRI) conducted a limited study of advance instrumentation for measuring the effectiveness of heavy truck splash and spray suppression devices.

Visibility is a subjective measure that can vary greatly between observers. Thus, to measure the effectiveness of spray suppression devices, it is desirable to select a quantity that can be objectively measured, preferably with simple instrumentation, and that exhibits a reasonable correlation with visibility. The transmissivity of the spray cloud along the side of the vehicle is the quantity that has been measured in several previous studies. The rationale for selecting this measurement, together with a general discussion of the problems involved in measuring the effectiveness of spray suppressors, follows.

Two schemes were considered practical for potential field implementation:

- The use of expanded collimated laser beams (2in diameter or larger) to obtain spatial averaging over a larger area of the spray field than obtained with the raw laser beam
- Photometric measurement of laser light scattered or reflected by the spray field

Because eight laser transmissometers were implemented at the start of the field test program, no further consideration was given to the multiple laser transmissometer scheme. Laboratory experiments were performed relating to the expanded laser beam and the light-scattering measurement schemes. These experiments were intended to define the hardware requirements for potential field implementation.

The generation and use of an expanded laser beam up to 6in in diameter were shown to be simple and straightforward. Beams 12 to 15in in diameter could also be easy to generate and apply. By virtue of averaging over a larger area of the spray field, the expanded laser beam arrangement may provide a useful enhancement of the laser transmissometer scheme. Thus, field evaluation of the expanded laser beam transmissometer appears worthwhile.

Photometer measurements of the light scattered as a beam of light passes through the spray field do not appear to have practical application for measuring the visibility through the entire spray field along the side of a vehicle. A photometer focused on the beam would receive power from only a small area of the spray field. However, such methods could provide a useful measurement of local spray density.

In a scattered light-measuring system, the light level received by the photometer is several orders of magnitude less than received in a transmissivity-measuring system. Consequently, a modulated light source and a sensitive bandpass-tuned photometer must be used to detect the scattered light separately from the ambient light. Using a 10mW laser light source, with 100 percent modulation, a tuned photometer with a sensitivity of at least 50pW is required. Of course, a less sensitive photometer would be adequate with a proportionately higher powered light source, and the light source does not have to be a laser. A search of literature indicated that bandpass-tuned photometers are not readily available as standard test instruments. Although the design of such a photometer is straightforward, such a task was not included in this research project.

Summary of Findings

Based on the analyses of the extensive data collected in this test study and the results previously discussed, the following seem warranted.

Vehicle Performance

- When equipped with an aeroaid, skirts, and treated flaps at each axle, most tractor-trailer combinations demonstrated improved mean light transmissivity over the equivalent baseline (untreated) vehicles, by a factor that can approach two. The prime contributor in reducing spray is the cab roof-mounted aeroaid.
- Flaps alone are insufficient to reduce spray reliably, although they can help. Skirts on the trailer rear axle are more important than skirts on the axles farther forward on the vehicle.

- Any improvement varied with vehicle/trailer configuration and, depending on baseline performance, improvement can be expected but not quantitatively predicted.
- The relationship between vehicle speed and spray density is an approximately linear one. Above 60mph, the effectiveness of any treatment was totally negated.
- Insufficient replications of treatment combinations were made to permit adequate statistical analysis of the relative contribution of specific treatments at various locations or the effect of wind condition on treatment effects.

Equipment/Procedure

- Computer image digitization of spray cloud density appears to be a viable alternative to costly and stationary laser instrumentation.
- Use of eight lasers versus two provided little additional information about the spray cloud.
- Expanded laser beam transmissometers, up to 15in in diameter, appear feasible and allow spatial averaging that will reduce received output fluctuations caused by large water droplets.
- Photometer measurements of scattered light are feasible for measuring localized spray density but not throughout the entire spray field.
- No correlation methodology or procedure exists to relate the improvement in light transmissivity to improved visibility as perceived by the motoring public.
- Under controlled conditions, the contrast sensitivity of an observer is substantially impaired when a laser transmissivity of below 40 percent through a spray cloud is reached.

An Evaluation of the Obstacle-Avoidance Capabilities of Articulated Commercial Vehicles

Paul S. Fancher
The University of Michigan Transportation Research Institute

Abstract

Analytical methods are used to evaluate the braking and steering performance of tractor-semitrailer, truck-full trailer, double, and triple combinations that have mechnical properties corresponding to current design and usage practices in the United States.

Introduction

Drivers of articulated commercial vehicles are expected to stabilize directional response, avoid rollover, and judge stopping capabilities under various operating conditions. This paper examines the extent to which the design and configuration of combination vehicles influence (1) the nature of the driver's control tasks, and (2) the fraction of the tire-road friction that can be used in successfully avoiding obstacles and resolving traffic conflicts.

The purpose of this paper is to describe analytical approaches used for evaluating the steering and braking performance of heavy trucks in a current project sponsored by the National Highway Traffic Safety Administration (NHTSA)(1) in the United States. In that project, the sensitivity of vehicle performance to parametric changes in component characteristics will be evaluated. An ultimate goal of the NHTSA project is a vehicle dynamics handbook for straight and articulated heavy trucks. The approach described will be used in formulating the vehicle dynamics handbook.

Description of the Methodology

The results presented are based on models developed during studies supported by the Motor Vehicle Manufacturers Association (MVMA), the Federal Highway Administration (FHWA), the State of Michigan, and NHTSA. Table 1 provides correspondence between open-loop vehicle maneuvers, computerized models, and published references. Simulated vehicle maneuvers have been used to make design evaluations similar to those that might have been obtained from typical vehicle tests.(19,20,21).

Braking in a Turn								X

For most of the maneuvers employed here, a performance signature is obtained for each type of vehicle. Then, performance measures are evaluated at safety-relevant levels of the performance signatures of the various vehicles. For example, in a steady-turning maneuver, the roll angles of the vehicle's unit increase as the lateral acceleration of the turn increases. At the limit of performance, one of the vehicle's units rolls over at a level of lateral acceleration called the rollover threshold. In this case, the roll angle versus lateral acceleration graph is the performance signature and the rollover threshold is the safety-relevant performance measure.

A family of maneuvers and associated performance measures (see Table 2) has been selected for assessing the influences of changes in vehicle properties on steering and braking performance(1). The steady-turning maneuver is used to examine three aspects of performance, namely, roll, tracking, and handling. Constant deceleration braking is used to evaluate friction utilization and braking efficiency. The other maneuvers are transient in nature in that they involve changing from one path to another.

Some of the maneuvers are open loop such that a test driver would perform predetermined control actions

Table 2. Performance signatures and measures for various maneuvers

Maneuvers	Performance Signatures (or Operating Condition)	Performance Measures
Steady Turning		
a. Roll	Lateral acceleration versus roll angle	Rollover threshold
b. Tracking	(360m radius at 88kph)	Offtracking
c. Handling	Handling diagram (22,6) and critical speed versus lateral acceleration (23)	1. Steering gain at 80kph 2. Critical speed at 0.3g
Constant Deceleration Stopping	Friction utilization and deceleration versus pressure	Braking efficiency at 0.4g
Low-speed Cornering (In-Town Corner)	(12.3m radius, 90° corner)	Maximum offtracking
Transient Turning (Ramp-Step Steer)	Steering wheel angle (200°/s to 28°)	Lateral acceleration response times (50% steering to 90% of steady state)
Obstacle Evasion (Rearward Amplification)	Transfer function: lateral acceleration of last unit to that of the first unit	Maximum rearward amplification (steering frequency < 0.5Hz
Responding to External Disturbances	Transfer function: steering control to equivalent disturbance input	Maximum closed-loop steering gain
Braking in a Turn	(2s braking pulse while following a 360m turn at 80kph)	Open-loop: maximum changes in yaw rate and sideslip Closed-loop: deviation from a reference yaw rate

independent of the instantaneous position or path of the vehicle. Constant acceleration maneuvers are inherently of this type. Transient maneuvers may have either open- or closed-loop versions. In this case, the ramp-step and low-speed cornering maneuvers are treated in an open-loop fashion. Obstacle evasion and braking in a turn are investigated using both open- and closed-loop analyses, and the response to external disturbances is studied through closed-loop calculations.

Open-loop results serve to define the accident-avoidance capabilities of the vehicles. In this study, a driver representation(24) is used to steer the vehicles to attempt to follow preselected paths in simulated closed-loop situations. These closed-loop analyses aid in understanding the influences of open-loop vehicle properties on the predicted performance of the driver/vehicle system.

Performance Signatures and Measures

Steady Turning

Roll

Equilibrium values of roll angle are a function of lateral acceleration, as illustrated in Figure 1. This performance signature has a discontinuity in slope at the point (0.36g) where the semitrailer's inside wheels lift off the ground. The maximum value of lateral acceleration, the rollover threshold, occurs at 0.39g when the tractor's inside rear wheels lift. Above 0.08rad of roll angle, the slope of the curve (lateral acceleration versus roll angle) becomes negative, indicating points of unstable equilibrium.

The roll performance signatures of vehicles with full trailers include additional acceleration versus roll angle curves for each full trailer. Nonlinear spring characteristics

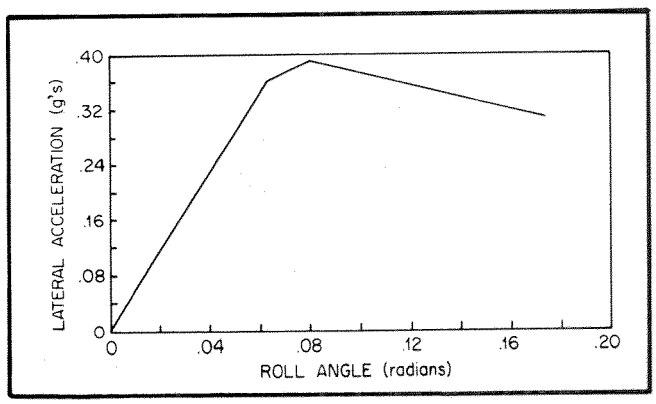

Figure 1. Roll performance signature

and free play when leaf springs go into tension cause more complicated-looking characteristics than those shown in Figure 1. Nevertheless, the rollover threshold is readily identified as the maximum attainable level of lateral acceleration before rollover of any unit of the vehicle.

The first row of Table 3 provides first-order estimates of the rollover thresholds of fully laden versions of various types of articulated commercial vehicles commonly employed in the United States. (Table 4 presents prototypical values of fundamental parameters describing the basic vehicles.) In addition to the ratio of center of gravity (c.g.) height to track width, these estimates are influenced by those conditions that allow the c.g. of the sprung mass to translate laterally—specifically, low suspension roll rates, free play, and low roll center heights(9). Accident data have been used to show that small changes in rollover threshold can have a large influence on the number of rollover accidents for heavy vehicles having values of rollover thresholds in the vicinity of those given in Table 3(10).

Tracking

Ideally, the trailing units in an articulated vehicle would be expected to follow exactly the path of the front axle of the towing unit. Practical vehicles come close to achieving this type of performance at highway speeds on highway curves. However, small deviations from the path of the front axle have caused trailer wheels to strike curbs and other roadside obstacles and thereby precipitated rollovers or control difficulties. Recognition of this danger has prompted the recommendation of a tracking test(21).

For a given length of vehicle, low-speed maneuverability is enhanced by adding articulation points. The addition of articulation points will greatly reduce low-speed offtracking. However, this improvement in low-speed offtracking contributes directly to the amount of outboard offtracking at high speed.

A specific turn has been selected as being representative of a high-speed exit ramp. The simulated maneuver is performed at a velocity of 88km/h (55mph) on a flat turn with a radius of 360m (1,200ft). The outboard offtracking attained by the end of the last trailer has been selected as the performance measure.

Figure 2 is a parameter sensitivity diagram showing the influences of (a) the cornering stiffnesses of the tires, and (b) the wheelbase of the third trailer on the high-speed offtracking of a typical triple combination employing 8.1m (27ft) trailers. The abscissa values of +1 and -1 represent deviations from the baseline values of wheelbase and cornering stiffness. These deviations are equal to ±½ of their baseline values. At low speed, the offtracking on a

Note: The triple (2-S1-2-2) is the same as the double except that it has another full trailer

360m (1,200ft) radius turn would be 0.19m (0.62ft) toward the inside of the turn. As speed is increased, the offtracking decreases to zero and then increases toward the outside. The basic triple is predicted to track more than .57m (1.9ft) outboard in a maneuver requiring 0.17g at 88km/h (55mph).

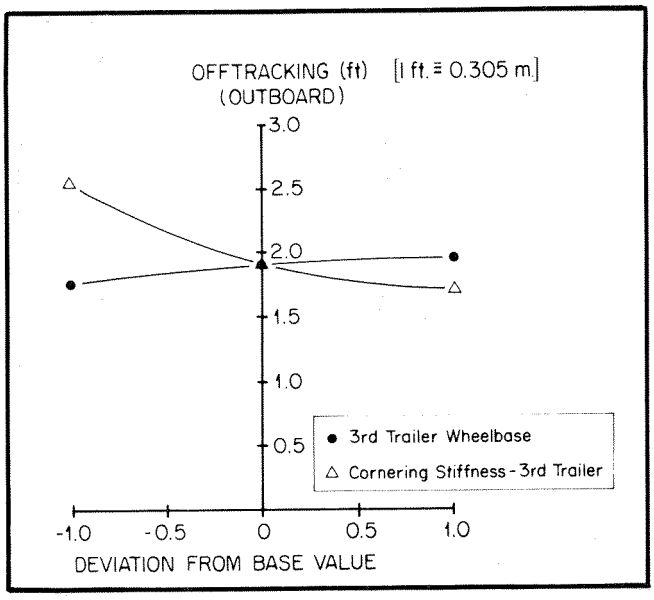

Figure 2. High-speed offtracking, parameter sensitivity diagram

The +1 value of deviation represents the cornering stiffness typical of radial tires, the 0 value corresponds to bias-ply tires, and -1 represents lug-type tires. Although lug tires are not usually used on trailers, the parameter sensitivity diagram shows the adverse effect of low cornering stiffness.

The triple tracks outboard of the double by an amount equal to the contribution of a full trailer since the double and triple are made up of identical units. The triple has by far the largest offtracking among the basic vehicles (see the second row of Table 3).

Handling

In this context (i.e., steady turning), handling refers to the response of the towing unit to steering inputs. Handling diagrams(22) (see Figure 3a) have been constructed at 80km/h (50mph) to obtain performance signatures. The handling diagram contains a handling curve that displays steady-turning properties as a function of lateral acceleration, yaw rate, forward velocity, and a reference front-wheel angle (in this case, steering-wheel angle divided by steering-gear ratio).

Vehicles with tandem axles on the tractor or the first semitrailer do not have a unique handling curve applicable at all speeds(6). However, vehicles without tandem axles do have special handling diagrams analogous to those

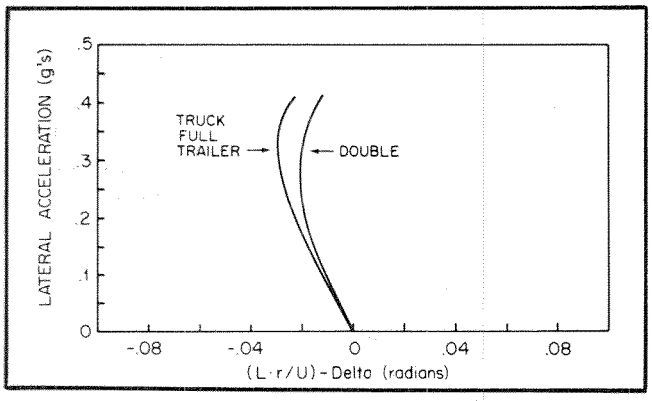

Figure 3a. Handling diagram

used in the study of passenger cars. Figure 3a contains handling curves for a truck-full trailer and a double combination. The handling curve for the double is applicable to all speeds since this double has single-axle suspensions. The truck in the truck-full trailer combination has tandem axles at the rear of the truck. For the truck-full trailer, the handling curve only applies at 80km/h (50mph) because, due to the tandem axles, the effective wheelbase changes with velocity(6). The wheelbase used in Figure 3a is the distance from the front axle to the center of the rear suspension of the towing unit (i.e., the truck).

In the handling diagram, an oversteer condition is indicated by a positive slope of the handling curve. For vehicles that become oversteer at lateral acceleration levels below their rollover thresholds, critical speeds have been computed. For these vehicles, a stability boundary can be plotted in a space defined by critical speed and lateral acceleration (see Figure 3b). This stability boundary is a special type of performance signature that provides an indication of the conditions under which the driver has to control an unstable vehicle.

For the baseline vehicles, the results indicate that all of them remain stable at speeds up to 88km/h (55mph) and lateral acceleration levels below 0.3g. The third row of Table 3 lists the critical speeds obtained at 0.3g of lateral acceleration. The fourth row indicates the lateral acceleration levels at which the vehicles become neutral steer while traveling at 80km/h (50mph).

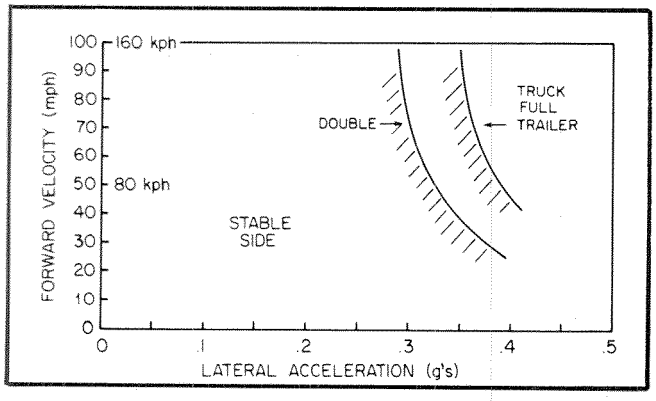

Figure 3b. Critical speed versus acceleration

For vehicles with full trailers, the handling results are similar to those that would have been obtained if the full trailers had been removed. That is, conventional dollies nearly decouple the full trailer from the unit towing it because the lateral force at the pintle hitch is very small compared to the tire forces acting on the towing unit(14). For example, the handling results for the double and triple are practically identical to those obtained if only the tractor-semitrailer portion of these vehicles were to be analyzed. (The handling results for the double and triple are also identical to each other since these vehicles employ the same tractor-semitrailer as their towing unit.)

At turning levels above 0.15g, lateral load transfer has an important influence on truck tire characteristics. The curvature of tire cornering stiffness with respect to vertical load becomes especially important for the drive axles of the lead unit since a large portion of the lateral load transfer takes place at these axles on typically suspended heavy vehicles in the United States. Given a bias in roll stiffness distribution, the level of oversteer at high g levels depends to a large extent on the curvature of the tire characteristics. The results presented here are for vehicles with typical bias-ply truck tires, having a moderate amount of curvature in their characteristics. However, sudden transitions to large oversteer may take place for tires with considerable curvature in the relationship between cornering stiffness and vertical load.

Constant Deceleration Braking

The performance signature selected for constant deceleration braking is a family of curves (one for each axle) showing the friction, required to avoid wheel lock, displayed as a function of treadle pressure (see Figure 4). Also superimposed on this plot is a graph of deceleration

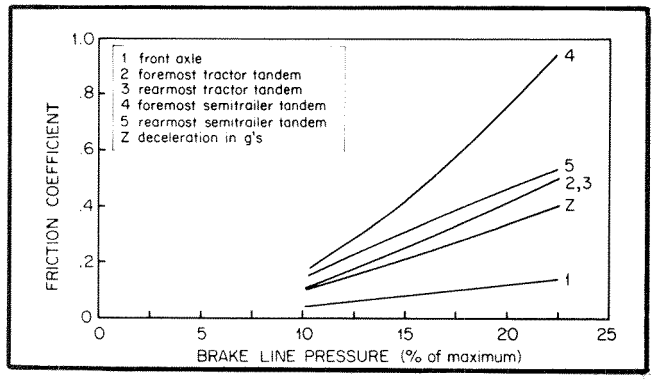

Figure 4. Friction utilization and deceleration, empty tractor-semitrailer (interaxle load transfer for the semitrailer's tandem equal to 20 percent of the braking torque divided by the tandem spread

in g's versus treadle pressure. Braking efficiency is the ratio of deceleration divided by the highest required friction coefficient (i.e., the results for axle 4 in Figure 4). The braking efficiency at 0.4g has been used to provide the performance measures listed in row 5 of Table 3. These results indicate that empty heavy vehicles have braking efficiencies that are less than 0.6.

In the example shown in Figure 4, the brake torque acting on the tandem suspension of the tractor does not cause interaxle load transfer. Hence, the curves labeled 2 and 3 coincide in Figure 4. Curves 4 and 5 do not coincide because, in this example, a significant amount of load is transferred from axle 4 to axle 5 during braking. The effect of this interaxle load transfer is to reduce the braking efficiency at 0.4g from 0.59 for a vehicle without interaxle load transfer to 0.43 for a vehicle with a semitrailer whose tandem suspension has a large amount of interaxle load transfer (for American suspensions).

Transient Maneuvers

Tractrix

The term tractrix pertains to the path of the axles of a semitrailer while it is turning a corner at low speed. To evaluate transient offtracking at low speed, articulated heavy vehicles are treated as a train of semitrailers in which the path of each hitch is the general curve followed by the attached semitrailer.

The trajectories (tractrices) of the various axle sets of a truck-full trailer are shown in Figure 5. The center of the steering axle is assumed to follow a 90° turn with a radius of 12.3m (41ft). The rear axles of the truck are treated as a single axle. The dolly axle does not offtrack far from the path of the truck's rear axle (see Figure 5). The rear axle

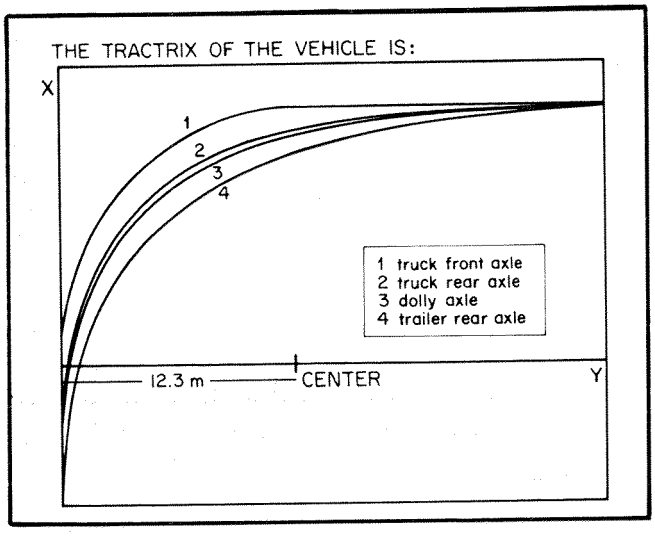

Figure 5. Tractrices for a truck-full trailer

of the trailer has a maximum inboard offtracking of 2.9m (9.6ft), which occurs when the rear axle has turned through 59°.

The maximum offtracking of the rear of the last unit has been used to quantify low-speed turning performance of the prototypical vehicles (see Table 3, row 6).

Ramp Step Steer

This maneuver is used to establish the quickness of the lateral acceleration response of the first unit in a combination vehicle. Response times are measured between the time when a rapid steering input reaches 50 percent of its final value and the time when the lateral acceleration response reaches 90 percent of its steady-state value. The magnitude of this response time depends on vehicle loading, speed, and the amplitude of the steering input. The results given in Table 3, row 7, are for low-amplitude steering-wheel inputs (28°) applied to fully laden vehicles traveling at 80km/h (50mph) on high-friction surfaces. The response times of the basic vehicles range from 0.79 to 0.98s.

The lateral acceleration response time is believed to relate to the manner in which drivers correct for external disturbances. A computational method, similar to one used in vehicle testing(25), has been developed by MacAdam(26) for assessing closed-loop response to external disturbances. Results from these computations for the basic vehicles indicate that drivers, represented by a delay time of 0.25s and a preview time of 1.5s, will increase the magnitude of the influences of external disturbances, occurring at approximately 3rad/s, by a factor of approximately 2. These results are sensitive to driver-control characteristics (delay time and preview time). Shorter delay times and/or longer preview times will reduce the gain of the closed-loop response.

Obstacle Evasion

The obstacle-evasion maneuver is based on traffic conflicts in which another vehicle stops or suddenly pulls out in the path of a heavy truck. The truck driver is assumed to attempt to avoid a collision by suddenly swerving into another lane. Vehicle performance in this type of situation depends on the period of the maneuver and the forward velocity of the vehicle. Quick maneuvers, in which the major steering activity occurs within 2s, have been found to excite amplified responses at the last units of combination vehicles with full trailers(15).

These amplified responses, referred to as rearward amplification, have been studied in both time and frequency domains. The frequency domain approach has been found to be effective because (1) the worst frequency, the one causing maximum amplification, can be readily observed, and (2) the magnitude of the amplification

determined by linear methods has proven to be a good indicator of the magnitude of amplification predicted by nonlinear analyses(15).

Rearward amplification not only has tracking or swept-path implications, it also indicates situations in which full trailers with high c.g. loads are likely to roll over. Since the rollover threshold is expressed in terms of lateral acceleration, the ratio of the lateral acceleration of the last unit divided by the lateral acceleration of the first unit of a combination vehicle has been used to quantify rearward amplification. In the frequency domain, this ratio is displayed as the amplitude of the transfer function between the motion of the c.g. of the towing unit and the motion of the c.g. of the last unit (see Figure 6). The maximum value of this transfer function has been selected as a performance measure for this maneuver.

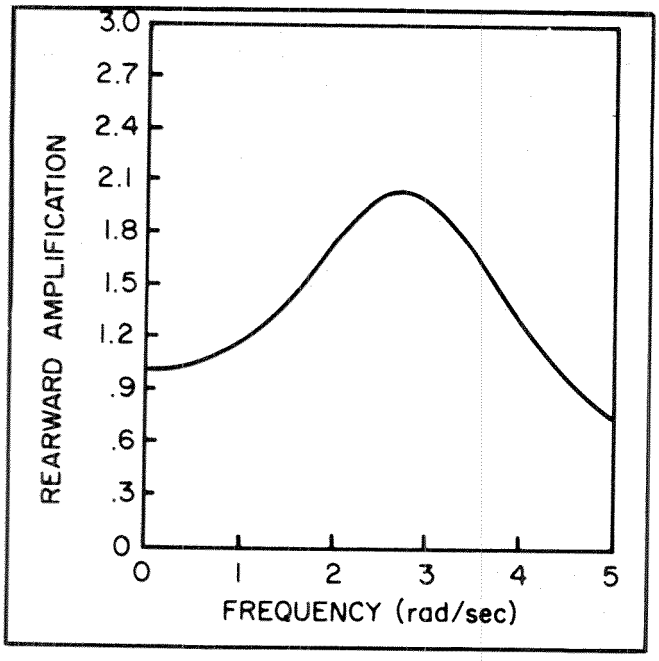

Figure 6. Rearward amplification for a basic U.S. double

The results, given in row 8 of Table 3, indicate that tractor-semitrailers have small amounts of rearward amplification compared to vehicles with full trailers. To first approximation, rearward amplification is a cumulative property consisting of the product of transfer functions between (a) unit c.g.'s and hitch points, and (b) hitch points and unit c.g.'s from the front to the rear of the vehicle(27,5). Hence, vehicles with more units tend to have higher amplifications.

For example, the basic triple is obtained by adding a full trailer to the basic double. The rearward amplification of the triple is approximately equal to the rearward amplification of the double multiplied by (a) the transfer function from the c.g. of the first full trailer to the pintle hitch between the first and second full trailers, and (b) the transfer function from that pintle hitch to the c.g. of the last full trailer(5). The rearward amplification of the triple exceeds that of the double by a multiplicative factor that depends primarily on where the last pintle hitch is located, the length of the last trailer, and the ratio of the weight of the last trailer divided by the sum of the cornering stiffnesses of all of the tires installed on the last trailer(5).

Sensitivity analyses have shown that rearward amplification may be reduced significantly by (a) reducing speed (the results given here are at 80km/h (50mph)), (b) increasing the wheelbases of full trailers, (c) reducing the distance from the center of gravity of a unit to the pintle hitch installed at the rear of that unit, and (d) increasing the cornering stiffnesses of the tires.

To produce a closed-loop version of the obstacle-evasion maneuver, a path is selected to represent the choice made by the driver in an attempt to avoid the obstacle. Driver-controlled path following is then used in the simulations(24). Preliminary results for a maneuver in which the driver attempts to suddenly translate the basic double by a lateral distance of 1.2m (4ft) while traveling at 80km/h (50mph) show a rearward amplification of approximately 1.5 if the driver has a 2s preview and is allowed an additional 2s (a total of 4s) for completing the 1.2m (4ft) displacement. However, the last unit will not experience more than 0.1g of lateral acceleration in this case where the driver can use a long preview time. If the preview is shortened to 1.0s and the total time for clearing the obstacle is 1.6s, corresponding to a maximum lateral acceleration at the tractor of 0.27g, the lateral acceleration of the last unit exceeds 0.7g during the rollover of the last trailer. These closed-loop results are interpreted to mean that rearward amplification is not a problem if the driver can foresee the obstacle to be avoided. However, if drivers are forced to take emergency evasive actions to resolve traffic conflicts at highway speeds, fully laden (high c.g.) full trailers are likely to roll over.

Braking in a Turn

Combined braking and steering maneuvers are difficult to control on a poor, wet road. When braking is applied while turning, the driver may lose directional control momentarily or wheels on individual axles may lock up, leading to jackknifes or trailer swings.

From an analytical point of view, braking in a turn is difficult to treat because it involves all the dynamic modes of vehicle motion. The tires are required to produce both longitudinal and lateral force. On even moderately slippery surfaces, demand for high deceleration may result in a lack of side force. The critical levels of performance, where loss of control may occur, are significantly altered by many vehicle characteristics. The interaction between longitudinal and lateral tire forces is

clearly critical, but data describing the influences of longitudinal slip on lateral force and slip angle are not generally available.

Not only are the basic results difficult to predict, but suitable performance signatures and performance measures are difficult to select. In open-loop testing, the disturbances in yaw rate and sideslip shortly after braking have been used to quantify the magnitude of the directional control problem presented to the driver(28,29).

Closed-loop results have been predicted for vehicles equipped with antilock brakes(30). In that situation, the simulated driver does not need to modulate brake pressure. However, information is not available to use in predicting how drivers will modulate brake pressure when the vehicle does not have an antilock system.

Currently, our plans are to perform open-loop calculations for empty and fully laden vehicles turning at 0.11g at 80km/h (50mph) on poor, wet roads (skid number at 65km/h is 28). (See (30) for a discussion of tire properties applicable to turning and braking on a poor, wet road.) The maximum deviations in yaw rate, sideslip angle, and articulation angles (where appropriate) will be used to quantify the influences of the disturbances caused by braking. The brakes will be applied suddenly and fully. At the end of 2s from the initiation of braking, the brake pressure will be released. The maximum deviations occurring (a) when the brakes are applied and (b) after the brakes are released will be used as performance measures.

Given the above braking disturbance, closed-loop simulations will also be run to study driver/vehicle system performance during braking in a turn. If the results of these calculations (both open- and closed-loop) are significant, they will be included in the previously mentioned vehicle dynamics handbook.

Conclusion

The constraints that vehicle characteristics place on the obstacle-avoidance capabilities of the driver/vehicle system have been evaluated using performance measures derived from computations based on open-loop maneuvers (see Table 2). Closed-loop calculations are now being used to examine control difficulties that may develop in obstacle-avoidance situations.

These results provide information that should necessarily be considered by persons specifying and assembling articulated commercial vehicles. However, these results are not sufficient in themselves to provide the guidance needed to assemble a satisfactory combination vehicle.

In particular, two further steps need to be taken. First, a synthesis procedure is needed to define the sequence of choices (priorities) so the vehicle will satisfy its functional requirements—for example, low-speed maneuverability in small areas. Second, guidance is needed to aid in deciding the tradeoffs between conflicting performance requirements.

The two main areas in which tradeoffs are required are (1) compromises between high- and low-speed tracking, and (2) the choice between longitudinal and lateral force capability in combined braking and steering maneuvers. With regard to tracking, the addition of articulations within a given overall length can increase overall maneuverability, but it also increases high-speed offtracking and rearward amplification. In combined braking and turning, truck brakes in the United States have traditionally been able to override the lateral force potential of all tires except those on the front axle. The driver is expected to steer out of difficulties although it may be difficult or nearly impossible to avoid jackknifing on slippery surfaces.

Adjustable or adaptive components are being developed to resolve situations that currently require compromises and tradeoffs. For example, antilock braking systems have been and are being perfected. Also, new types of dollies are being considered. Ideally, these dollies would change their characteristics depending on vehicle speed and the type of maneuver the driver wants to perform. If properly developed, these automatic systems will aid the driver in avoiding control difficulties while, at the same time, not limiting the driver's abilities and responsibilities for safe vehicle operation.

Test Procedures and Evaluation Criteria for the Handling Characteristics of Heavy Commercial Vehicles

Klaus Rompe and
Bernd Heißing
Institute for Traffic Safety, TÜV Rheinland e.V., Cologne, Federal Republic of Germany

Abstract

In the years past, quite a number of relevant test procedures, including appropriate criteria of description, have been conceived to describe objectively the handling characteristics of passenger cars and passenger car-trailer combinations. Because of the various design principles of commercial vehicles and the ever-increasing advances of vehicle combinations insuring optimum utilization of space, i.e., single trucks or buses, truck-trailer combinations, semitrailer combinations, articulated buses, platform road trains, and short coupling truck combinations, the handling characteristics of these vehicles are definitely more distinct from each other. A description of the handling characteristics as compared with existing designs will be of great importance to the classification of new vehicle combinations. This paper gives a survey of the measuring procedures applied so far and the findings as published on the handling characteristics of heavy commercial vehicles. This approach is compared with measurements taken by the authors for a 16t truck[1], a 38t truck-trailer combination, and a special type 38t semitrailer combination. Against this background, the transferability of the test procedures, which have previously been applied to passenger cars only, and the required restrictions under their application to heavy commercial vehicles is illustrated and evaluated on the basis of the measurement results obtained. Any measuring variables and criteria of description that are of significance to this particular class of vehicles are detailed.

Current Status of Test Procedures

The registration regulations as applicable to commercial vehicles are specifying requirements to be accommodated by mainly two areas of the handling characteristics complex, viz., straight line braking and mobility in turning. Since these procedures have been applied for quite a long time, they will not be treated further in this paper. The examples detailed in the sections to follow are rather related to the lateral dynamics and the combined lateral and longitudinal dynamics of heavy commercial vehicles.

[1] In charge of the German Federal Minister of Transport

Table 1 is a survey of the measurement results available in the literature on the driving behavior of heavy commercial vehicles throughout the past decade. From this, it can be gathered there are basically five eligible test procedures:

1. Steady state turning to determine the understeer/oversteer behavior as a function of lateral acceleration or driving speed.
2. Braking during steady state turning to determine the yaw stability and steerability.
3. Lane change to determine the steering effort and the effect of a lane change as an excitation function for yaw angle oscillations.
4. Step steering input to determine the promptness of vehicle response.
5. Frequency response measurement to determine the extent and promptness of vehicle response as a function of the steering angle input.

Figure 1 shows the required measuring variables illustrated by the example of a truck-trailer combination. There is evidence that the standard variables referring to the towing vehicle such as steering angle, driving speed, lateral and longitudinal acceleration, and yaw velocity are needed and so are corresponding measuring variables referring to further elements of the combination and the relative yaw angles at the different joints or couplings.

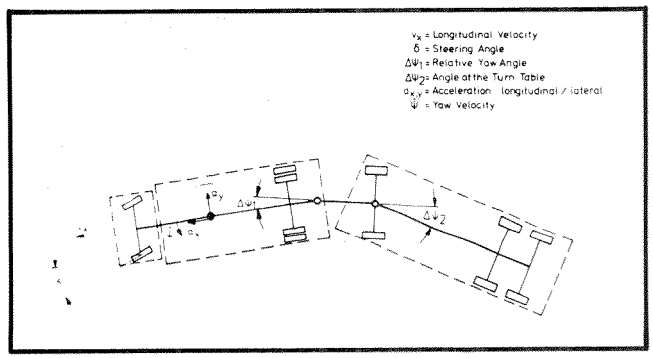

Figure 1. Commercial vehicle measuring variables

Steady State Turning

Steady state turning is to provide data on the steering tendency, i.e., on the driving course as a function of steering angle and lateral acceleration. The conditions for implementation relating to passenger cars are specified in an ISO standard(22).

Figure 2 illustrates the characteristic curves of a steering angle increase over the lateral acceleration

expressed as the difference between the steering angle δ_H minus the steering angle needed to drive on a circular path at the smallest lateral acceleration $\delta_{H,Ack}$. This variable, also known as understeering index, permits turning maneuvers on different but constant radii to be illustrated together. While the understeering tendency is distinct for all the loaded single vehicles illustrated in the upper part of the figure, it was found to be comparatively small for individual trucks. Besides, Figure 2 shows that a trailer will not always bring about a significant change in steering characteristics. The handling characteristics are rather governed by both the steering characteristics and the yaw angles acting at the single joints.

Figure 3 illustrates the steering angle and side slip angle of the towing vehicle of a loaded 16 to 22t truck. Also illustrated are the yaw angles at the coupling point $\Delta_{\psi 1}$ and at the turn table $\Delta_{\psi 2}$. While the side slip angle of the towing vehicle increases with the lateral acceleration, the two yaw angles and hence the trailer's position to the towing vehicle remain almost constant. A deviation of

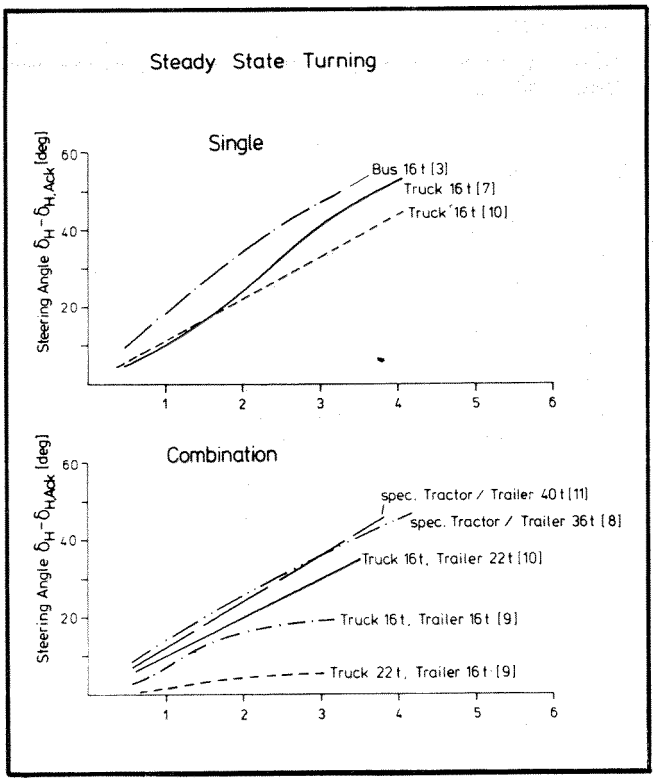

Figure 2. Steering angle increase — $\delta H - \delta H,Ack$ as a function of lateral acceleration a_y during steady state turning (all vehicles with maximum permissible weight)

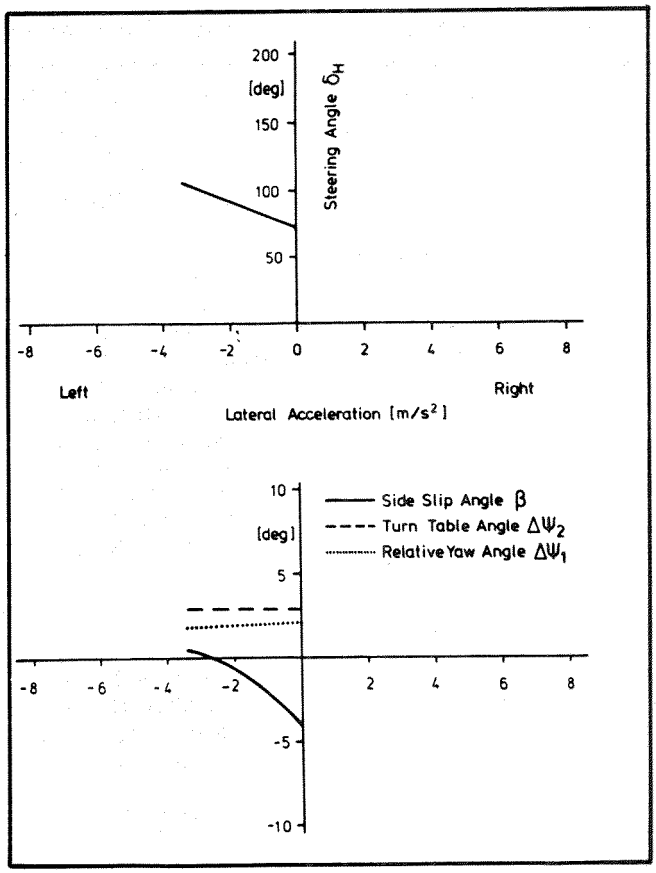

Figure 3. Steering angle, slide slip angle, yaw angle, and ring mount angle of a truck-trailer combination (38t) during steady state turning (truck with trailer), R = 105m, maximum permissible weight, dry road surface)(10)

the trailer from the circular path or a lateral displacement of the trailer was observed. This phenomenon is stated to be a criterion for the evaluation of steady state turning, e.g.,(2).

Another important criterion is the maximum physically obtainable lateral acceleration during turning. It is naturally highly dependent on the respective center-of-gravity height. Table 2 is a listing of maximum values, as measured by the various authors, for the vehicle types when driving on a dry road surface.

As loading in driving tests is generally of a low center-of-gravity height, for more practical purposes, the actual values are assumed to be slightly lower. One will see that the values obtained for single vehicles and combinations are in reasonable agreement and that the maximum physically obtainable lateral acceleration will in an average decrease under loading conditions by about $1 m/s^2$. When comparing these values with the values of modern passenger cars, one will find a lateral acceleration of 6.1 through $8.2 m/s^2$, which will decrease only slightly with increasing load(27).

Braking During Steady State Turning

The test procedure of braking during steady state turning was designed to yield information about the extent to which a vehicle's steering behavior is influenced by the simultaneous acting of braking forces. The criteria for evaluation are measuring variables that describe the

Table 2. Maximum lateral acceleration during turning on a dry road surface (7, 8, 9, 10, 20)

Maximum Physically Obtainable Lateral Acceleration			
Vehicle Type		unloaded	loaded
Bus		$4.7 m/s^2$	
Truck	16-22t	$4.4\text{-}4.5 m/s^2$	$3.6\text{-}4.2 m/s^2$
Truck-trailer Comb.	38t	$4.1\text{-}4.5 m/s^2$	$2.9\text{-}3.4 m/s^2$
Semitrailer Comb.	38t	$5.5 m/s^2$	$3.9\text{-}4.2 m/s^2$

capacity to keep the course, yaw stability, and steerability with distinct decelerations. The draft standard provided for passenger car braking during turning(23) has to be adapted for heavy commercial vehicles, especially in terms of starting conditions, because the physically obtainable lateral accelerations are lower during turning and deceleration takes more time to set in.

The time functions plotted in Figure 4 relating to yaw velocity Ψ, lateral acceleration a_y, side slip angle β, braking pressure p, and deceleration a_x were determined for a 16t truck with permissible total weight(10). With a mean deceleration, hardly any deviations were observed in comparison with a passenger car. Unlike this, the vibration of lateral acceleration was found to be distinct with great decelerations. This can be attributed to pronounced pitching motions resulting from the initiation of braking forces. This behavior of the truck tested persisted when it was coupled to a trailer.

The evaluation functions are established by deriving reference values from the time functions, which were measured in single tests at the respective deceleration levels. Such reference values are synchronous values obtained from the single tests, e.g., 1 or 2s after brake application over the respective deceleration. For minor variations in the starting conditions to be equalized, the yaw velocity and lateral acceleration are related to the original values, and the variation of the side slip angle as compared with the initial state is plotted. A reference curve is used for evaluation purposes. The underlying principle is that a vehicle will continue to travel exactly along the initial radius even after brake application and that deceleration and side slip angle will remain constant during the braking maneuver.

Figure 5 shows the evaluation function of the lateral acceleration for an unloaded 16t single truck, a loaded 16t and a 22t truck, and a special type 40t semitrailer combination with antilock system (ABS)(10,11). Experience has shown that an initial lateral acceleration of $2 m/s^2$ and an evaluation instant of 2s after brake application at an adequately high initial driving velocity are fit for the purpose. The lower half of the figure illustrates also the yaw angles at the coupling point $\Delta_{\psi 1}$ and the turn table $\Delta_{\psi 2}$ of the combination truck. The increasing locking tendency of the truck with increasing deceleration will result in growing yaw angles. With the towing vehicle nearing the limit of steerability, the decreasing yaw angles point to the almost straight position of the unit. In the ABS vehicle a control device will preclude this limit from being reached. This will lead to a minor increase of yaw angles between the elements of the combination when coming under the influence of

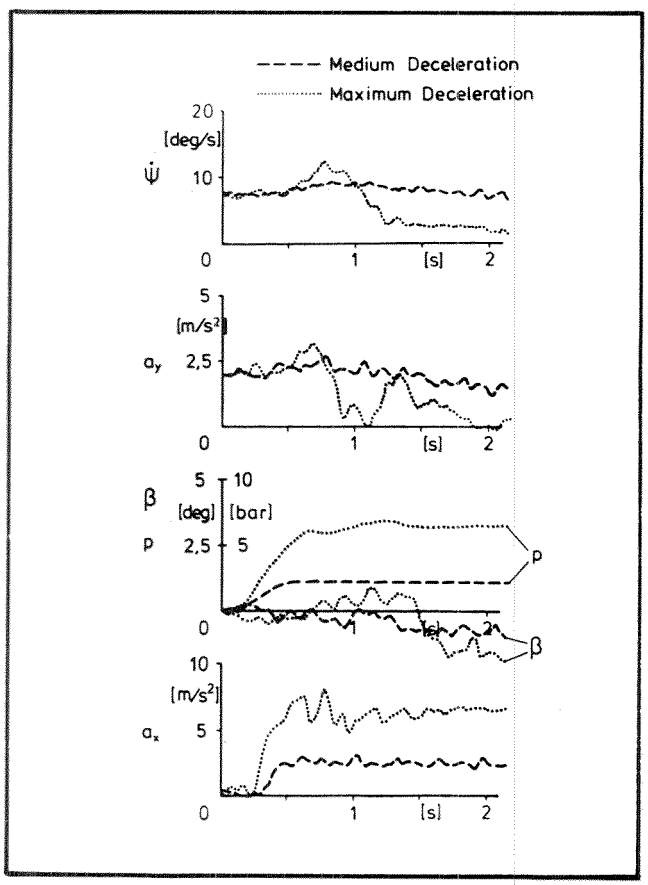

Figure 4. Time functions of characteristics measuring variables for braking during steady state turning ($a^{y,o}2m/s_2$, R = 105m, truck, drive road surface, maximum permissible weight)(10)

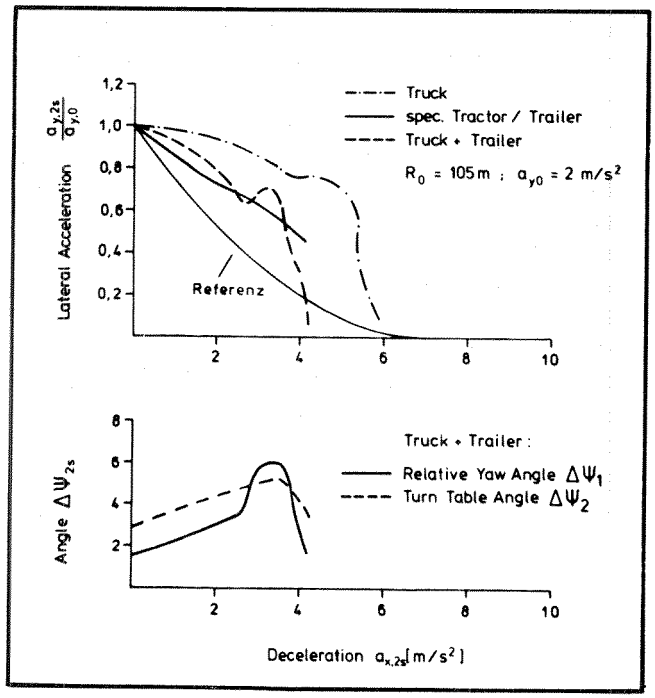

Figure 5. Comparison reference values for braking during steady state turning for a single truck, a truck-trailer combination (38t), and a special type semitrailer combination (40t) ($a^{y,o}$-2m/s_2, R = 105m, maximum permissible weight) (10,11)

great decelerations(11). Comparable trends of the evaluation function were established by (8) also. Although comparative tests have rarely been published so far, it can be assumed that Figure 5 is representing the likely range of evaluation criteria as valid for the vehicle category in question.

In view of the different response behavior of towing vehicles and trailers, it will be reasonable to incorporate in the analysis not only the evaluation functions but also the variation with time of the measuring variables 2s after initiation of braking.

Lane Change

This test procedure is applied to serve a dual purpose in the evaluation of handling characteristics of heavy commercial vehicles.

Evaluation of Transient Steering Behavior

The driving course chosen, e.g., by (4,16), is the dual ISO lane change(24), which is to be understood as a lane displacement of 3.5m over a distance of 30m. With this, the evaluation will cover the steering activity especially, i.e., the amount of required steering movements to be made by the driver to first keep to the lane and then to stabilize the vehicle.

Evaluation of the Damping Behavior of Combination Elements

In this test, which is based on a course similar to the ISO lane change, e.g., in the form of a single(9,11) or dual(2) lane change, the lane change will mainly serve to excite the combination's oscillation. The aim of the test procedure is to determine the damping of the yaw angles and the oscillation paths at the end of the trailer.

The measured values will therefore be recorded only after the lane has been changed and the vehicle is driven straight ahead again. A short steering angle impulse as applied for passenger car-trailer combinations will not suffice to generate an adequate oscillation energy in commercial vehicles(11).

Table 3 summarizes the maximum values obtained for different truck-trailer combinations, both loaded and unloaded, when driving on two road surfaces(9). The lane displacement was intended to be 3m over a distance of 40m. With no load or uniformly distributed load, the lateral movements of the trailer were established to be 1.5m on wet, antiskid asphalt pavement at a driving velocity of about 80km/h and on a less skidding blue basalt surface (moistened) at about 70km/h. When changing the lane at the highest possible velocity trailer oscillation, paths of 3m and over can be observed for both surface types. The vibration paths established for the unloaded truck-trailer combinations were on an average slightly shorter as compared with the loaded combinations. With the trailer unfavorably loaded, e.g., only in the back third, the driving conditions, in some cases, turned out to be much more critical.

To eliminate the driver influence on the measured results, it will be a meaningful approach to evaluate the results as a function of the actual vehicle excitation as represented by the yaw movement or the lateral acceleration in the coupling points(21).

Figure 6 shows the position of the elements of a special type 40t semitrailer combination after having passed the single lane displacement of 3m over a distance of 40m on a wet, hardly skidding surface at a 1s interval(11). This clearly proves the validity of the procedure for the application of new vehicle combinations also.

Transient Steering Behavior

The evaluation of the steering activity during lane change has proven to be a suitable tool to determine the handling characteristics during rapid steering motions, i.e., transient steering behavior.

Table 3. Maximum values reached during single lane change for driving velocity v_{max}, yaw angle in the coupling point ψ_{1max}, and at the turn table ψ_{2max} and for the lateral displacement at the trailer end s_{max}(9)

Truck-trailer combinations 32t and 38t		v_{max} (km/h)	ψ_{1max} (degree)	ψ_{2max} (degree)	s_{max} (m)
μ = 0.8	unloaded	85-75			0.6-1.0
	loaded	75-85		25-35	1.6-2.8
μ = 0.3	unloaded	70-75	28-45	24-35	1.0-2.8
	loaded	72-80		15-35	1.7-3.8

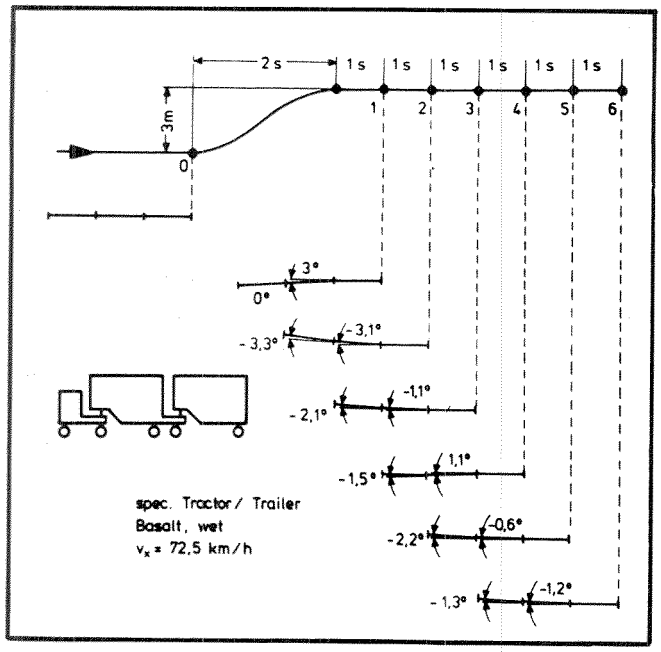

Figure 6. Positions after an extreme change of lane for a special type semmitrailer combination; (loading condition—maximum permissible weight; road surface—wet blue basalt)(11)

Step Steering Input

The step steering input as applied to commercial vehicles is comparable to that applied to passenger cars. A draft standard on this subject has been prepared(25). The driving velocities range from 50 to 80km/h with transient obtainable lateral accelerations of 2.5 to 5m/s^2. The steering wheel's rotational speed may reach from 300 to 500°/s. Because of the different, and in part not exactly stated, definitions of the delay periods between steering input and yaw velocity or lateral acceleration being used as an evaluation criterion, and because of the different starting conditions, the results obtained by different authors can hardly be compared. As a basic fact, the essentially higher inertia moments alone of the commercial vehicles will naturally cause essentially longer delay periods increasing with loading, as compared with passenger cars. For a 16t bus with permissible load, the deceleration is 0.05 to 0.10s as compared with an unloaded vehicle(3).

Figure 7 illustrates the basically different tendency in vehicle response between a bus(17) and a modern passenger car(27) exemplified by the yaw velocity. While the passenger cars reach a maximum value about 0.2 to 0.5s after steering input (50 percent rating), the motional variables referring to the bus change over into the steady state value aperiodically. In addition, the figure shows the distinctly decelerated response behavior of the bus compared with the passenger car. Measurements taken for semitrailer combinations(12,18) indicate a similar behavior with no reaching of the maximum yaw velocity or without excessive overswing.

Detailed comparisons on a literature basis cannot be made because there is no information available on series of measurements with different driving velocities and lateral accelerations. This will surely be due to the comparatively large space needed to conduct this test.

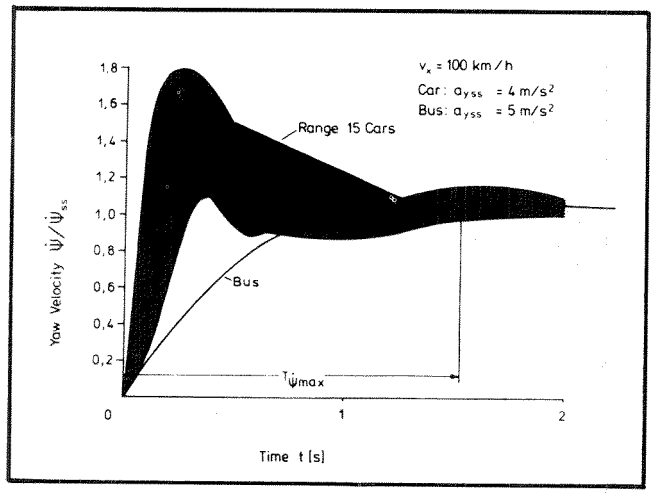

Figure 7. Comparison of vehicle response in the step steering input test for 1 bus(17) and 14 passenger cars(25)

Table 4. Test conditions and some results for the test procedure step steering input

Vehicle		v (km/h)	$a_{y,oo}$ (m/s^2)	$T_{\delta 50\% \psi 90\%}$ (s)	$T_{\delta 50\% a_y 90\%}$ (s)
Bus, Truck (17,20)		80	5	≈1	
Semitrailer comb. (12) 32t unloaded		68-72	3.5-3.8	0.4-0.5	0.7-0.75
Semitrailer comb. (10) 38t loaded	towing vehicle	54-59	3	0.2-0.3	
	trailer			0.7-1.0	

Frequency Response Characteristic

The determination of the frequency response characteristic of yaw velocity, lateral acceleration, and yaw angle with periodic steering input as described in the ISO/DIS(26) permits a more extensive evaluation of the transient steering behavior. The amplitude frequency characteristics of this variable related to the steering input are illustrated in Figure 8 for a loaded 38t container semitrailer combination at a driving velocity of 50km/h(15). The rapid decrease of the measuring variables with increasing steering frequency is indeed striking. Given a steering frequency of 0.5Hz, the obtainable lateral acceleration has dropped to about 50 percent of the value produced by the very same steering input under transient steering conditions.

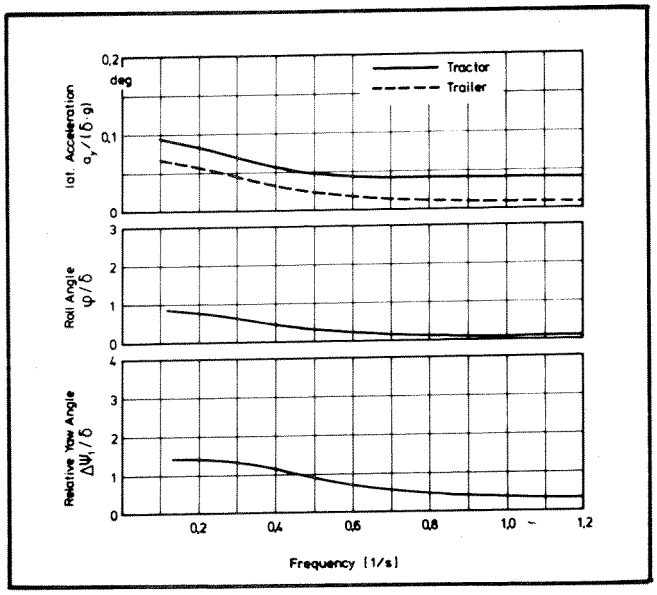

Figure 8. Frequency response characteristics of a fully loaded 38t container-carrying semitrailer combination at 50km/h(15)

Under comparable conditions, passenger cars are likely to reach this value only with frequencies above 1Hz. The large yaw inertia inherent in the commercial vehicles finds expression in this phenomenon. Unlike this, the yaw angle between the towing vehicle and the trailer decreases distinctly slower with the steering frequency but does not show a pronounced resonance point. Other measurements taken do, however, show such a resonance point in the range of 0.3Hz for a truck-trailer combination(18) and 0.3 through 0.6Hz for an articulated bus(19). The amplitude frequency characteristic of the yaw angle can be considered an index of the damping properties of the truck-trailer combination. Comparable findings on the oscillation behavior of a combination as derived from the lane change test can be derived equally for combinations with only one joint, i.e., semitrailer combinations, from the frequency response characteristics.

Measurements of amplitude frequency characteristics of the yaw velocity of a bus also show a rapid decline in yaw response without any distinct resonance point(17). To insure an all-inclusive evaluation, the phase angle characteristic, too, describing the promptness of a vehicle response has to be taken into account. Hardly anything is known about such measurements. To identify the phase angle characteristic of the yaw velocity, one can use the equivalent response time of the frequency at a -45° phase angle. According to (21), the result will be about 0.2s for an unloaded truck at v = 80km/h, and about 0.3s for an unloaded truck-trailer combination. The value obtained for passenger cars is ranging from 0.1 to 0.2s(28).

Summary and Conclusion

When analyzing the pertinent literature available on measurements taken on the handling characteristics of heavy commercial vehicles, one will easily find that results are on hand for buses, truck-trailer, and semitrailer combinations that were obtained from a good many test procedures. Since the authors working on this subject use different starting conditions, the findings cannot always be compared.

The test procedures applied to determine the handling characteristics of passenger cars are basically applicable to commercial vehicles and combinations as well. In doing so, one should bear in mind there is a need for adapting either the starting conditions or the criteria of description accordingly.

With regard to relevant test procedures such as steady state turning, braking during turning, and lane change, as well as transient steering behavior, it is possible, in some cases, to indicate measuring ranges or at least tendencies for the behavior of heavy commercial vehicles that will provide a sound capability, e.g., in comparing new vehicle combinations.

Tractor Semitrailer Unit for the Future

Pierre Soret
Renault Véhicules Industriels

Abstract

For the truck maker, safety is a major component of the general specifications. However important this component may be, it is only one item among others:

- The goods transport vehicle for 2000 induces a break in all fields of performance.
- Particularly for safety, we have deepened major locking areas as the rollover phenomena.
- We have elaborated, with other related industries, in a complete program named V.I.R.A.G.E.S., an experimental tractor-semitrailer unit, providing substantial improvements in all fields.
- We show here specific elements related to safety in all its aspects but under constraints of other heavy components of the general specifications.

It must be seen as the global approach and response of the makers.

Introduction—Safety and Truck

For the truck maker, safety is but an element of the general truck specifications, however important this element may be. The designer's choices come under a global compromise between a set of often conflicting obligations. The cost of the product compared to the market price is a major limit to the evolution of performance. Furthermore, different specific constraints (safety, environment, energy, etc.) often induced side evolution processes of vehicles that, to instantly meet a

requirement (either legal or regular), have hampered the development of other features of the transport vehicle.

For instance, the taking of an under-run structure or a retarder is surely an efficient factor of traffic safety, but it is an extra cost and extra weight that appreciably and directly affects the economy of transportation. In Europe, this step-by-step evolution of the transport vehicle has been the main feature of the past 20 years.

The margin answers then brought lead nowadays to a technical and economical compromise difficult to improve, especially when we want to use the new technologies for the most satisfactory economical conditions. Furthermore, the vehicle is not the responsibility of only one maker. Custom has separated two types of industry:

- The power vehicle
- The towed vehicle, trailer, or semitrailer

This distribution of activities has substantial consequences on safety since in this field, more than in others, the performance of the convoy has to be considered rather than that of the separate vehicles.

Also, we must notice that weight and dimension regulations do not take into account the capital elements of the transversal stability of the units. It is true that, on this point, different influences oppose each other and compromises are needed: for instance, motor vehicle/ railer vehicle mass ratio, and the ability to turn within the regulated swept circle.

To sum up, the analytic and margin approach that has prevailed in the evolution of safety of goods transport vehicles has reached its limits. It has to be replaced by a more synthetic approach that (1) associates truck and trailer makers, and (2) integrates the demand for safety into other strong demands related to the general evolution of road transport—energy, environment, driving and use conditions, and productivity.

Renault Véhicules Industriels undertook to answer this type of demand, along with related industries under the aegis of the authorities (Ministère de l'Urbanisme, du Logement et des Transports and Agence Française pour la Maîtrise de l'Energie) according to a program called V.I.R.A.G.E.S. (Experimental and Research Transport Vehicle Improving Energy and Safety Performances).

We present the outline of this program, especially as it relates to safety, but still keeping in mind we have integrated the need for a global approach to satisfy a compromise in appreciable evolution in all directions.

The project is backed by general specifications of the high-range road vehicle, 38/40 and 44t, a tractor-semitrailer unit. It does not systematically comply with existing regulations, and the choices made may allow valorization and quotation of certain trends in regulations and standards.

An experimental vehicle, the first step toward the aims of the general specification, is undergoing tests. Another, aiming at a substantial break in performance, is in the study phase and planned for testing in late 1987.

V.I.R.A.G.E.S.—General Specifications

General specifications of this vehicle aim substantially higher than the present industrial practice in the fields of energy, environment, comfort, and safety, but of reasonable access, at least from an experimental point of view, by means of new technologies.

As for safety, the aims were worked out with the help of the National Office for Road Safety (ONSER).

Primary Safety

Ride, Handling, and Rollover

The following prone factors were defined and numerically aimed:

- Driveability in evasive motion
- Road handling in curves
- Rollover resistance

To sum up, the main line is an improvement of the maximum transverse acceleration within the behavior of the vehicle is satisfying from $3.5ms^{-2}$ to $5ms^{-2}$.

Braking

The following accident-prone factors have been selected:

- Stability of the trajectory during braking
- Braking power
- Action delay
- Nonlocking of wheels
- Tightness of the circuits

Visibility and Lights

- Quantified improvement of forward, side, and back visibility field
- Modulation of lights according to luminosity
- Lowering splash and spray

Note: The detection of proximity of the vehicle running ahead or behind was not included in this study. It has been considered as relevant to auxiliary techniques, which are relatively easy to integrate, and having little influence on the architecture of the vehicle.

Secondary Safety

Three accident-prone factors were concerned:

- In priority, non-under-running on the front for passenger vehicle, in case of front-to-front shock
- Side guard against two-wheelers and, if possible, passenger cars
- Rear under-ride device as an improvement of regulations in force

Safety in Use

Nonquantified lines were defined for the driver's safety that related to work around the vehicle:

- Access to the cab
- Room for life aboard
- Coupling/uncoupling operations
- Loading/unloading operations

Last, considerations related to driving comfort but with positive return on safety are included in the program, such as control automatisms or driving aids.

Related Analytic Works

This project has led to increasing knowledge of physical phenomena for—

- Front-to-front shocks for passenger cars versus heavy vehicles
- Rollover of articulated units

The first are under development and will be presented with the second experimental vehicle. The second has been completed and the results have been communicated to the 1984 FISITA Congress in Vienna. They confirm the work of other researchers in the United States, Europe, and Australia.

The program has been carried out through four steps:

1. Test campaign on a standard tractor-semitrailer equipped for measuring the rollover limits in quasi-stationary conditions, circular, eight shaped trajectories, and in transient conditions (sharp bend and evasive motion).
2. Working out of mathematical models of transverse stability allowing the forecast of quasi-stationary and dynamic behaviors.
3. Making a more stable experimental convoy by modifying a standard tractor and designing a very torsion-resistant, three-axle semitrailer with axle-by-axle adjustable rolling stiffness.
4. Test campaign on this unit for measurements as in step 1.

The conclusions helpful to a designer can thus be resumed.

The sensitivity to rollover of articulated convoys is due mainly to the bad coherence of load transfers in rolling motion.

The rollover limit can be appreciably improved by making a stiffer chassis and by a rolling stiffness according to the suspended load per axle. It is thus possible to come closer to the theoretical rollover limit. This last depends on simple geometrical dimensions such as the gauge and altitude of the center of gravity. To improve it, the following will have to be considered: outlines that use for the best as much of the gauge as possible (regulations' limit); development of low, large tires; and suspension with trim correction to lower as much as possible the semitrailer floor and the center of gravity.

In transient motion, roll and yaw are dynamically stable. However, it is useful, in order to take the best advantage of good geometry and coherent stiffnesses, to adjust the other parameters of the vehicle so the transient response is correctly damped while keeping good driving comfort.

For the biggest limit values ($> 4ms^{-2}$), the fifth wheel backlash induces modifications in the mass transfers that it would be better to eliminate.

It still remains that, in limit conditions, the driver does not perceive the state of the vehicle and so cannot attempt corrective maneuvers. But the risk of this situation

decreases if the convoy is built according to the rules above-mentioned, and if, in consequence, limit transverse acceleration is appreciably increased.

Experimental Vehicle—V.I.R.A.G.E.S.

Let us not forget this is a multicriteria experimental vehicle that does not emphasize safety but improves it, along with other needs of the general and global specifications.

It is the maker's answer, necessarily related to compromises, not the safety specialist's.

To simplify, we present in the shape of a matrix the technical and technological choices made and their effects on safety criteria selected (see Tables 1 and 2).

These choices concern the first experimental vehicle. The second takes into account the same fundamental outline choices but covers the case of the 44t convoy and presents much improved technological devices, mainly in the field of the structure and chassis concept, having an important impact on secondary safety.

Conclusion

This global approach and the different related fundamental works bring new knowledge to the designers of truck and trailer industries.

The program V.I.R.A.G.E.S. allows evaluation of the capabilities of making other technical and economical compromises. It also permits a real break in all fields of the general specifications: fuel consumption, safety, environment, driving and service, reliability, and productivity. It is a difficult, new, and expansive experience, but it allows the goods transport vehicle to be developed in a satisfactory manner after 2000.

Protecting Car Occupants, Pedestrians, and Cyclists in Accidents Involving Heavy Goods Vehicles by Using Front Underrun Bumpers and Sideguards

S. Penoyre, and
H.J. Bates
Transport and Road Research Laboratory, Department of Transport, United Kingdom

Abstract

This paper starts with a review of accident situations requiring underrun bumpers and sideguards. Bumper design features discussed include height aboveground, strength, travel, and force-deflection characteristics. A joint programme between the Transport and Road Research Laboratory (TRRL) and TI Tube Products Ltd. is described for the design and development of a front underrun bumper using the plastic deformation of mild steel tubes to absorb energy, and results of car-to-truck front impact are summarised. The final design is able to protect seatbelted car occupants from intrusion from a frontal collision at a closing speed of 65km/h, for a total bumper weight of approximately 60kg. It is

recommended that any future legislation for front underrun guards require an energy-absorption capability, and a possible legislative test procedure is outlined.

Tests carried out on sideguards fitted to an articulated goods vehicle, using a simulated pedal cycle accident, are described. It was found that the incidence of running over of the cyclist could be reduced to 40 percent of the test runs by using a guard that just met the United Kingdom legal requirements. An improved guard with lower ground clearance reduced the incidence to near zero. Better performance in other respects was obtained by making the guard flush with the side of the semitrailer and by extending the sideguard longitudinally, nearer to the trailer wheels and closer to the tractor.

Introduction

Although the overall involvement rate of Heavy Goods Vehicles (HVG's) in injury accidents in Great Britain is about the same as that of cars, their rate of involvement in fatal accidents is about twice as great(1). The fatal casualties in these accidents are usually road users other than the HGV occupants. An analysis of all the fatal road accidents in Great Britain in 1976(1,2) involving HGV's found that, of the 844 fatalities, 391 were car occupants. About 250 of these were killed when their cars collided with the fronts of HGV's and about 50 in collisions into the rears of HGV's. There were also 47 pedal cyclists, 112 motorcyclists, and 159 pedestrians killed in these accidents. One of the most frequent causes of death for these unprotected road users was by being run over by the rear wheels of the HGV's. About 100 of the two-wheeler users and pedestrians suffered this fate, mostly after impact with the sides of the goods vehicles.

It was estimated in (2) that about 40 car occupant lives could be saved each year by directly preventing front underrun. There are probably as many again in these accidents into the fronts of HGV's who might also be saved where underrun is not the primary cause of injury but where a more controlled use of the existing energy absorption of the front of the car might save casualties. Energy absorption built into the HGV front underrun guard should increase the survivable speed of impact in these accidents and is more necessary in frontal than in rear impacts because of the higher closing speeds involved. This estimated saving of car occupant lives relies on seatbelts being worn.

It has also been estimated(2) that nearly 60 two-wheeler user and pedestrian lives could be saved annually by lightweight sideguards fitted to HGV's.

More recent figures obtained from the U.K. National Road Accident Statistics (Stats 19) suggest that the number of car occupants likely to be saved by front underrun guards is now nearer to 60 (compared with 80 in 1976), and the number of two-wheeler users and pedestrians likely to be saved by sideguards is about 50 (compared with 60 in 1976).

This paper presents first the results of impact tests carried out on one type of front underrun guard fitted to a rigid lorry, and then the results from testing a sideguard fitted to an articulated lorry.

Front Underrun Guards

Design Principles

There are three basic features of an HGV that combine to make it so aggressive to car occupants: mass, which can be from about 3 to 50 times that of a car; the great stiffness of its structure; and the height of this structure above the road.

The large ratio of truck mass to car mass and the principle of conservation of momentum insure that in a car-to-truck collision the velocity change of the car is much greater than that of the truck. For example, in a head-on collision between a 30,000kg truck and a 1,000kg car travelling in opposite directions with both vehicles initially moving at 30km/h, the velocity change of the car is about 58km/h and that of the truck is about 2km/h (that is, the car is finally being pushed backward at about 28km/h).

The strength and stiffness of the truck structure mean that very little of the kinetic energy dissipated in the collision is used in deforming the truck. Nearly all of the deformation occurs in the car's structure. The allowable limit is reached when the car structure collapses far enough for there to be severe intrusion of damage into the occupant compartment. This intrusion is made even more serious by the difference in height between the strong chassis members of the truck and the strong parts of the car front. The truck structure may be so high that it passes above the car engine and meets no resistance until it hits the windscreen pillars, and gives very severe intrusion into the car passenger compartment and its occupants.

It is not realistic to expect the design of car structures to be altered to reduce this height mismatch problem, since this would require either mounting car engines higher or providing strong structures high above the road at the level of the truck chassis. These changes would be unacceptable for many reasons. Therefore, the main contribution to protecting car occupants in car-to-truck collisions must be made by changing truck rather than car structure with respect to both bumper positioning and stiffness.

The truck underrun guard must clearly be low enough to meet the strong part of a car's front structure, so a ground clearance of not more than about 300mm is preferable. Truck front to car side impacts are also a

significant source of car occupant injuries, and to reduce these injuries the bumper should be low enough to hit the strong doorsill rather than the weak door. This will reduce intrusion and will also insure that the bulge into the car will be mainly below the occupant rather than level with his hips or ribs. If the bumper face is about 150mm deep, a maximum ground clearance of approximately 250mm would be desirable for this side impact case. The need to negotiate ramps may demand a slightly higher figure, but fortunately the bumper is usually close to the front wheels of the truck and little increase should be necessary.

A rigid underrun guard of suitable dimensions would overcome the structural misalignment problem and so would allow the car's strength and energy-absorbing capability to be used to help protect its occupants. Current cars are designed to provide protection for occupants wearing seatbelts in a head-on frontal impact into a rigid wall at up to 50km/h. It is therefore probable that a rigid truck underrun guard would prevent serious injuries in truck-to-car collisions up to this closing speed for a heavy truck, and this would protect to a slightly higher speed for a lighter truck.

However, in car front to truck front collisions, the vehicles are usually moving in opposite directions so the closing speeds in this type of accident are frequently well above 50km/h. To protect car occupants at these higher speeds, it is essential that the truck bumper is not a rigid structure but designed to yield in a controlled way to absorb part of the crash energy.

The energy absorbed by the bumper as it yields is, of course, given by the area of its force-deflection curve, and, for maximum absorption, as long a horizontal stroking distance as possible should be used. It is unlikely under current legislation controlling vehicle length that operators could accept a bumper that initially projects beyond the truck structure, while it must not move back so far when hit that the car windscreen pillars meet the truck chassis. Thus, the total crush of both the bonnet of the car and the bumper of the truck must not be greater than the original length of the car's bonnet. Small bonnets (e.g., Mini, Metro) frequently extend only about 900mm ahead of the base of the screen pillars and can crush approximately 500 to 600mm without giving serious intrusion into the passenger compartment. The maximum allowable stroke for the energy-absorbing truck bumper is, therefore, about 300 to 400mm. In practice, of course, lack of space below the truck front structure may require a shorter stroke than this for a front underrun bumper.

For a given allowable stroke, the maximum energy-absorption capability of the bumper would be obtained by designing it to deflect at a constant horizontal force chosen to be the greatest that can be applied to the car without producing serious intrusion or too violent a deceleration. In other words, the bumper force must match the force at which the car front collapses so that, at the end of a severe impact, both have crushed. The difficulty is that car frontal stiffnesses differ greatly between large and small cars, so a truck bumper optimised for collisions with small cars may be too soft for large ones. Since the proportion of small, light cars is increasing, and since these vehicles give less protection than bigger cars to their occupants in a collision at any particular speed, it is suggested that a small car (e.g., 750kg unladen) should be the most important design case chosen for the underrun guard. However, it is essential that the guard can also handle a collision with a heavy car without catastrophic failure.

Tests with a large number of recent European cars(3) show that on average a frontal force of about 230kN is developed when the crush reaches 300mm, while local peak forces of about twice this size are measured briefly as the engine is decelerated. These high forces suggest that the bumper should be designed to stroke at a force of approximately 200kN, which with a stroke of 300mm would give an energy absorption of 60kJ. This is equal to the kinetic energy of a lt-car moving at nearly 40km/h.

In reality, achieving this high constant force will be difficult in a bumper that must be both light and cheap. Its desirability is questionable, too, because it may not stroke at all when hit by a small, weak car at up to about 50km/h relative speed, and damage and intrusion may then be becoming critical for the occupants of such a car. Also, lower speed impacts occur more often than high-speed ones. It is likely, therefore, that a force-deflection characteristic that starts at a comparatively low level (possibly 100kN or rather less) and then increases as the bumper strokes is preferable to the constant force one, despite its lower energy-absorption capability.

Design Details

A cheap and light method of dissipating energy is to use plastic deformation of steel on the invertube principle. After discussion with several possible manufacturing partners, a joint programme of work between TRRL and TI Tube Products Ltd. was agreed to using this approach. The bumper bar, a rectangular hollow steel section 150mm × 75mm × 6mm wall thickness, was welded to two vertical drop arms about 260mm long, which were pivoted from brackets bolted below the end of the truck chassis member. Two invertube cartridges initially 450mm long and able to be compressed by 200mm joined the lower ends of the drop arms to additional brackets bolted below the chassis member 300 to 400mm from the other brackets (Figure 1).

These invertubes consisted of two steel tubes of different diameters (100 and 80mm), the smaller of which was turned back on itself at one end and was then peripherally welded to the open end of the larger tube.

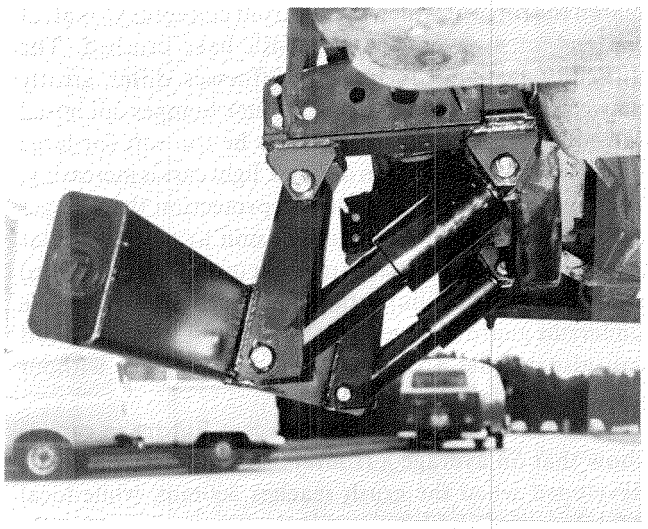

Figure 1. Invertube underrun guard

When a compression load is applied, the smaller tube progressively turns itself inside out as it is forced inside the larger tube ("like taking a sock off"). After an impact, the invertube units have to be replaced.

The invertube struts telescope at nearly a constant load over their 200mm stroke, but the geometry of the underrun guard means the horizontal force on the bumper approximately doubles as the bumper bar moves through its stroke of 220mm. This is advantageous as discussed above.

It is estimated that an underrun guard to this design would retail for approximately £150 plus VAT and fitting and that the invertube energy-absorbing cartridges would cost about £35 per pair to replace. The total weight of the guard is about 60kg.

Test and Development Programme

The original plan was to build an energy-absorbing front or rear underrun bumper that would pass the strength requirements of Construction and Use (C&U) Regulation 46B for rear underrun guards(4) before the invertubes started to stroke. For this, it should start to stroke at a load above the 100kN (approximately 10t) force required by that regulation.

Invertubes made from 14swg (2.03mm) steel tube were therefore used, with the two parts having diameters of 100 and 80mm. Dynamic tests carried out by TI Tube Products Ltd. using a falling weight rig at speeds up to 65km/h showed that these tubes each had a collapse load of 102kN, and, with a working stroke of 200mm, the bumper's total theoretical energy-absorbing capacity would be $2 \times 102 \times 0.2 = 40.8$kJ, equivalent to a lt mass falling through about 4m or moving at 32km/h. The geometrical design used would give a horizontal load on the bumper bar when stroking started of about 146kN, well below the figures measured for car frontal strengths described above but comfortably higher than the 100kN required by the C&U Regulation 46B.

However, tests in which BL Marina cars (1,000kg) were impacted centrally into the bumper mounted on a stationary Ford truck (5,100kg) showed that this bumper failed to stroke completely even in impacts severe enough to break the seatbelts of the dummy car occupants. In two tests with angled/offset and perpendicular/offset Marina impacts at 50 and 64km/h, the bumper did not stroke fully but still proved effective in preventing underrun and passenger compartment intrusion. A perpendicular central test with a 1,550kg Volvo car at 56km/h also failed to stroke the bumper fully but bent the truck chassis seriously behind the bumper rear mounting brackets.

It was therefore agreed that a major reduction in the strengths of the invertubes was required, and this was obtained by using 16swg (1.63mm) thickness tubes instead of 14swg (2.03mm). These have a load when stroking of approximately 47kN each instead of 102kN and require a total horizontal bumper force of about 68kN to start stroking. The maximum energy-absorbing capability of the invertubes is reduced proportionally to about 20kJ. It is no longer possible to withstand the 100kN loads of Regulation 46B before stroking, but the geometry of the bumper is such that this load is developed when it strokes about 175mm. Since the regulation requires that the distance of the bumper inside the rest of the vehicle's structure must not exceed 400mm, this regulation is passed by the modified energy-absorbing bumper, although most of its working stroke is used up during the test procedure.

The weaker bumper was tested in another Marina head-on central impact at 65km/h. It performed well, stroking fully and protecting the dummy occupants by leaving the passenger compartment almost undamaged (Figure 2) while developing only moderate seatbelt loads.

The latest test carried out so far in this development programme used the weaker (16swg) invertubes in a 65km/h head-on impact to assess the protection given to occupants of a small, light car with a short bonnet (Mini, 680kg loaded). This gave very satisfactory results as far as the behaviour of the bumper and the car structure were concerned, with the bumper stroking fully and only very minor damage intrusion into the passenger compartment. The present truck bumper design, therefore, appears to be reasonably satisfactory, although further tests are planned for offset and angled impacts with both the truck and the car moving. The feasibility of installing this bumper on modern trucks is also being studied.

Protection for car occupants at a closing speed of 65km/h does, of course, assume seatbelts are worn. If seatbelts are not worn, protection cannot be provided at relative speeds much above 40km/h.

The bumper developed in this programme is, of course, not the only way of producing an energy-absorbing truck

Figure 2. Damage to Marina car from impact at 65km/h into front underrun bumper

underrun guard, and it is to be hoped other design teams will be able to produce cheaper and lighter alternatives, possibly by using hydraulic systems. However, the programme has clearly demonstrated it is feasible to make such a device that need not be significantly heavier or more expensive than an adequately strong rigid (that is, non-energy-absorbing) bumper. The theoretical benefits in improved car occupant protection resulting from the use of an energy-absorbing design have been confirmed in practical car-to-truck impact tests.

A Possible Legislative Test Procedure for Energy-absorbing Front Underrun Guards

Widespread use of energy-absorbing underrun guards for trucks, in conjunction with compulsory seatbelt wearing for car occupants, would produce significant reductions in deaths and injuries, However, these benefits will be felt by the car occupants, while the cost of the bumpers will fall on the HGV owners. It therefore seems unlikely that many truck operators will voluntarily fit front underrun guards, and legislation will be needed. This should be drafted to require use of energy-absorbing bumpers rather than rigid ones for the fronts of trucks, as explained above. The test specification should probably use a rigid-faced impactor to hit the bumper, thus avoiding the cost and repeatability problems of deformable impactors. Since some designs of bumper may be very speed-sensitive (especially if they use hydraulic energy absorbers), an impact test rather than a quasi-static loading test is essential, and this should be carried out at a fairly high speed representative of the maximum survivable car-truck collisions, for example, 50 or 60km/h. The programme described above shows that the bumper can readily be designed to absorb 20kJ of energy, which would require an impactor mass about 200kg moving at 50km/h or 140kg at 60km/h. The moving mass could either be a trolley or a pendulum, which would have to fall through nearly 10m to reach 50km/h.

It is suggested that to pass this test would require (a) the maximum force acting on the impactor not to exceed 200kN (102g on a 200kg impactor) at any time, (b) the maximum force acting on the impactor not to exceed 100kN during the first 100mm of its movement after contact with the bumper, and (c) the maximum allowable horizontal movement of the impactor in the direction of impact not to exceed 400mm. The bumper would also have to meet the strength and dimensional requirements of C&U Regulation 46B.

The width of the impactor face used in the energy-absorption tests should represent a narrow car engine block of, say, 200mm. Its height should be approximately 200mm and its ground clearance also 200mm, so the height of the top edge of the impactor would be 400mm above ground level. The face edges should be curved to a radius of about 5mm.

The test impact would be carried out both at the centre of the bumper and offset to opposite the truck chassis members; new energy absorbers (or a new bumper) could be used for each impact. The truck would be butted up against a rigid heavy block during the test impacts to prevent its mass affecting the result and to insure that the impact energy is mostly absorbed by the bumper system.

The offset impact test should insure that the torsional strength of the bumper bar and its joints to the drop arms is high enough for the drop arms to remain parallel during stroking, so the bumper's total energy-absorbing capability will be utilised even in an offset collision.

Sideguards

An amendment to the United Kingdom C&U Regulations(4) came into operation on May 1, 1983. Two of the new regulations (46C and 46D) require the fitment from various dates of lightweight sideguards to new goods vehicles and trailers over certain weights and to some of the larger existing semitrailers.

The main purpose of the sideguards is to prevent pedal cyclists, motorcyclists, and pedestrians from being run over by the rear wheels of lorries. Because of their light weight, it was not intended, nor is it likely, that the sideguards will protect car occupants other than in accidents where the car strikes the side of the lorry at a shallow angle.

The programme of work described in this paper was initiated to determine how effective such sideguards would be, in preparation for European discussions to harmonise sideguard requirements. It was therefore decided to test what was considered to be a minimum legal sideguard and then to make changes to that guard to improve its performance.

The specification of the sideguard when fitted to a semitrailer tends to give it different characteristics compared with guards fitted to rigid vehicles and other types of trailer. The main difference is the distance from the bottom of the guard to the ground. Although, in common with other vehicles and trailers, the maximum ground clearance is 550mm, it is defined as such when the platform is horizontal. This means that when the semi-trailer is connected to a tractor unit, the actual ground clearance may be considerably greater than 550mm, particularly at the front of the guard.

It was mainly for the above reason that a maximum length, articulated HGV was chosen as the test vehicle. It was considered that a sideguard fitted to this type of vehicle, and just meeting the regulations, would represent the worst guard likely to be found in practice.

The accident situation chosen to test the effectiveness of the sideguard was a pedal cycle accident such as occurs in urban areas at low speed when a cyclist is overtaken by an HGV. As the lorry passes the cyclist, he or she may be nudged by the side of the vehicle or become unstable for some reason and topple toward the lorry, falling into the path of the rear wheels.

The accident data show that this is a relatively common cause of death for cyclists. Pedestrians are also run over by falling toward and under the side of HGV's.

It is hoped recommendations for sideguard design obtained from the cycle test will also help protect pedestrians.

Sideguards Used in the Tests

The Basic Sideguard

The sideguard used as the starting point in the tests is shown in Figure 3. It was of a tubular construction as illustrated in Figure 5a and was fitted to a 12.2m platform semitrailer, which was coupled to a Leyland 16-28 Roadtrain tractor unit. The guard was made so that it just met the specification described in paragraph 5 of C&U Regulation 46D(4).

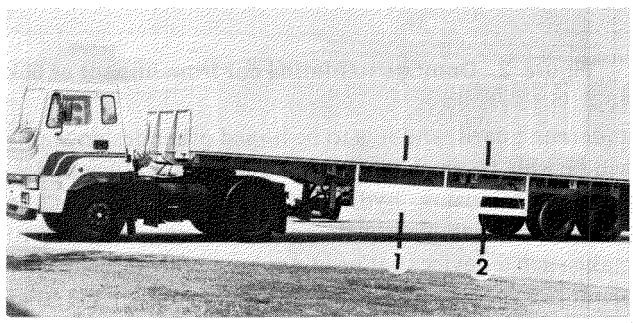

Figure 3. Basic sideguard showing dummy impact positions 1 and 2

The ground clearance was set to 550mm, the maximum allowed, with the platform horizontal. With the semitrailer coupled to the Roadtrain tractor unit, the actual ground clearance was 695 and 575mm at the front and rear of the sideguard, respectively.

The sideguard was set in from the face of the tyres by the maximum allowable 30mm, which for this particular semitrailer resulted in the face of the guard being 75mm inboard from the edge of the platform.

The overall length of the sideguard was the minimum allowed in that it was to the rear of the landing leg centreline by the maximum 250mm and forward of the front of the trailer tyres by the maximum 300mm.

The gaps between the rails of the guard were the maximum allowed consistent with the width of the rails themselves, which was the minimum allowable 100mm.

The number of uprights used to support the rails of the guard was the minimum needed to allow the sideguard to meet the strength requirement consistent with the

particular uprights and rails used. The sideguard in this form weighed approximately 45kg.

The Extended Sideguard

After analysing the results from tests on the basic guard, changes were made in an attempt to improve its performance, both to reduce the incidence of running over and to reduce the severity of injury due to other causes.

An overall view of the extended guard is illustrated in Figure 4, where it is shown with an actual ground clearance of 300mm. Other ground clearances of 400 and 450mm were also tested.

The guard was extended rearward to be as close as possible to the semitrailer tyres (Figure 5c) and forward as far as possible toward the tractor wheels.

The sideguard in its extended form weighed about 80kg, an increase of 35kg over the basic sideguard. It would be difficult to justify this extra weight and cost unless the extended guard proved to be much more effective.

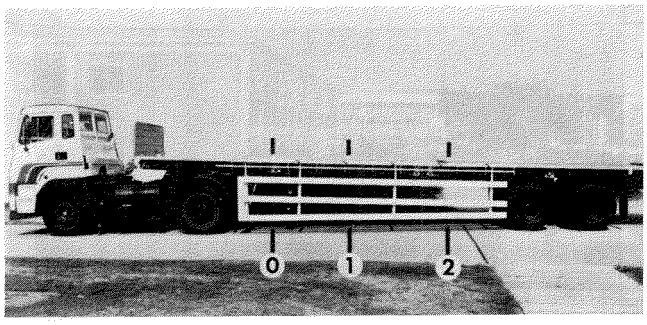

Figure 4. Extended sideguard showing dummy impact positions 0, 1, and 2

The Simulated Accident

The test consisted of driving the articulated lorry at low speed past a dummy mounted on a stationary bicycle. The dummy and cycle were released from their support and allowed to fall onto specific points along the sideguard.

The general arrangement is shown in Figure 6. The dummy was an RAE Mk5 and sat on the bicycle in the same way a normal rider would. The dummy and bicycle were prevented from falling over by a cable attached, via a magnetic release device, to a shoulder harness fixed to the dummy. The cable was, in turn, attached to a small mobile crane that enabled the dummy and bicycle to be placed leaning slightly toward the vehicle at an angle of about 5° and, for the majority of the tests, with the bottom of the bicycle wheels approximately 600mm from the vertical plane passing through the edge of the trailer platform. A couple of tests were also carried out at a distance of 1,000mm.

Most of the test runs were carried out with the vehicle being driven past the bicycle at 10km/h. Some runs were also carried out at 15 and 20km/h.

Tests were done with the dummy falling against the sideguard at two positions (1 and 2) along the basic sideguard and at three positions (0, 1, and 2) along the extended guard, as shown in Figures 3 and 4. This was achieved by driving the vehicle over a rubber tube laid across the test track. The tube was connected to an electrical air pressure switch, which released the magnetic device holding the dummy and bicycle.

The speed of the vehicle was controlled by using a fifth wheel measuring device attached to the tractor unit.

Ten runs were carried out for each condition because of the variability with which the dummy could fall. In this way, a more meaningful result was obtained in that a probability of effectiveness could be evaluated.

Each test run was recorded using two video cameras and recorders. One was so placed as to give a three-quarter view from the front of the dummy and bicycle, and the other, a narrow angle from the front.

Test Results

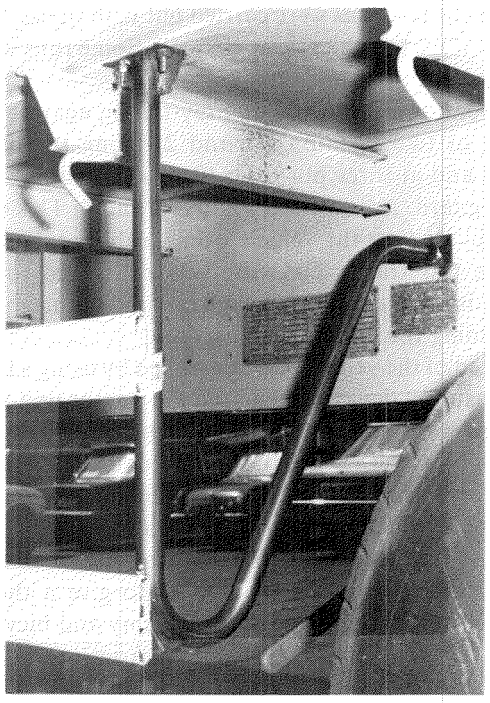
Tables 1 and 2 list the configurations of sideguard tested at the various conditions of overtaking speed, position of impact along the guard, and distance of the bicycle wheels from the semitrailer platform.

About 10 runs were carried out for each test condition. Information such as whether the dummy cyclist was run over or struck by the trailer tyres was in part obtained by observation at the time of the test, but it was confirmed, and more detailed information obtained, by analysis of the video recordings.

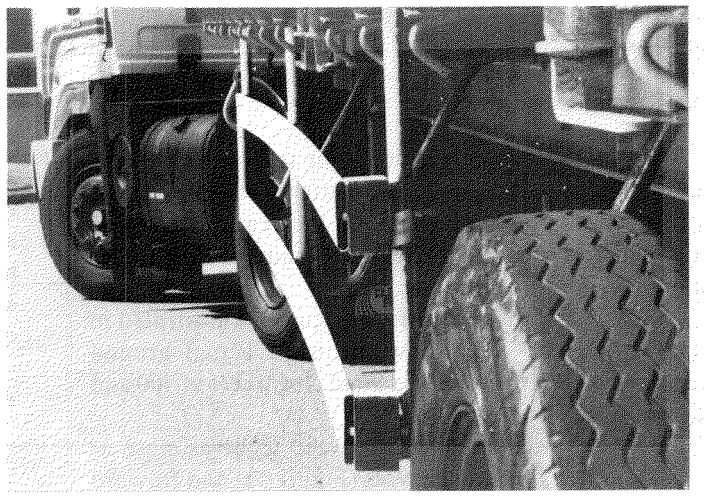
A typical test run is illustrated in Figure 7. The first photograph shows the dummy and bicycle just after the magnetic device had released the dummy (time t = .08s). The succeeding photographs are at about 0.57s intervals and show the dummy cyclist falling against the sideguard and then to the ground. It is important to note that the dummy is not attached to the bicycle in any way. The only differences between the test cycle and an ordinary bicycle are that the former has a specially shaped saddle to help keep the dummy and bicycle in a straight line and there are fittings that allow the dummy hands to rest on the handlebars without slipping off during the time between release and impact with the sideguard. The elbow joints of the dummy were tightened just enough to prevent the upper torso of the dummy slumping forward after release from the supporting cable. All other joints were loose.

Basic Sideguard Results

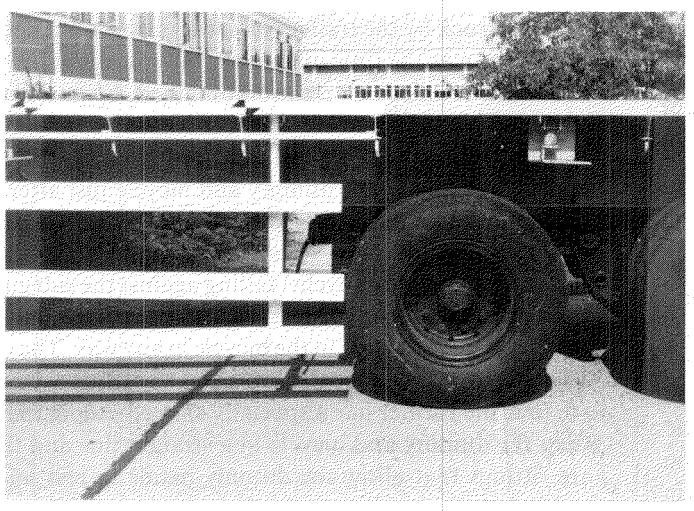
Before starting on the main tests, two runs were carried out without the sideguard in place. In both these runs, the



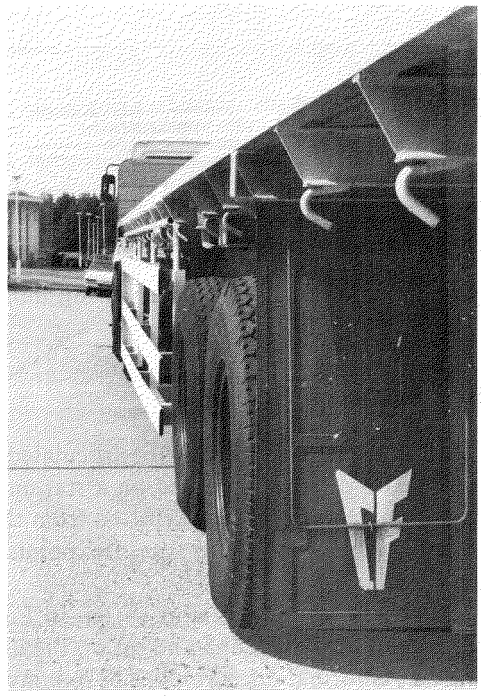
(a)



(b)



(c)



(d)

Figure 5. Details of sideguards

Figure 6. Dummy and bicycle before impact

dummy fell straight to the ground in the path of the semitrailer wheels and was run over.

The first six tests with the basic sideguard fitted, as listed in Table 1, were carried out with the sideguard set in from the edge of the trailer platform by the maximum allowable distance.

Four of the tests were at 10km/h and the other two at 15km/h. Two tests were carried out with the bicycle wheels 1,000mm from the platform edge and the rest at 600mm.

It was found that when the dummy impacted at position 1, at the lower speed, there was time for the dummy to slide down the guard and, having reached the bottom of the guard, there was sufficient ground clearance for the dummy to roll under the sideguard. It was largely a matter of chance whether it rolled far enough toward the trailer wheels to be run over. Table 3 shows that in Test 1, the dummy was run over in four of the nine runs, giving about a 40 percent probability of being run over.

When the dummy impacted at position 2, at either speed, it had less time to slide down the guard and fall

Table 1. Basic sideguard test conditions

Test	Sideguard configuration						Test conditions		
	Whole guard inset by maximum allowed	Rear of guard flared out from half way point, level with edge of platform	Rear of guard flared out from three quarter point level with edge of platform	Protective tube at junction of load hooks and I-sections	Uprights inset from guard rails	Guard rails flush with edge of platform	Impact position	Overtaking speed (km/h)	Distance of bicycle wheels from platform edge (mm)

Table 3. Comparable tests to show the effects of ground clearance on running over

Ground clearance (mm)	Test	Number of runs	Numbers run over	Numbers probably fatal	Comments
"550"	1	9	4	3	Dummy able to roll under guard into path of wheels after falling
"550"	12	11	3	3	Dummy fell off guard later than Test 1.
300	18	10	0	0	Dummy held away from path of wheels by bottom rail.
300	19	6	0	0	Similar to Test 18 but earlier impact point on guard.
400	23	10	4	0	Dummy body restrained by bottom rail but limbs run over occasionally.
450	24	10	2	2	Dummy able to roll under guard as Test 1, but had less time to do so.

For all these tests the guard was inset by 75mm, test speed was 10km/h and bicycle wheels were 600mm from edge of platform.

below it. The tendency instead was for the dummy to slide off the end of the guard and be struck by the edge of the leading tyre. The impact was made more severe by the fact that the dummy could fall into the 300mm gap between the end of the guard and the front of the tyre. In Test 2, at 600mm, 10km/h, and position 2, the dummy was struck by the leading edge of the tyre in about 40 percent of the cases.

The overall effect of speed was such that at the higher speed of 15km/h, there was less time for the dummy to slide down to the ground and be run over, even when impact was at position 1. However, the impact with projections such as load restraint hooks and lateral I-sections beneath the platform and the tyres was considerably more severe at the higher speed. A few runs were made at 20km/h, but the dummy was damaged too frequently and it was considered impracticable to continue testing at this speed.

At this stage of the testing, some modifications were made to the basic sideguard to help decide which features should be incorporated in the extended guard.

Throughout all the test runs, the shoulder had tended to go between the top rail of the sideguard and the platform, the head striking the platform edge itself. In about a third of the cases, the shoulder was then struck by either the load restraint hooks or the lateral I-sections to which they are attached. To try and reduce the incidence of striking these projections, a steel tube was positioned longitudinally at the junctions of the hooks and I-sections (Figure 5d). The tests (12 and 13) showed that this worked well and prevented the shoulder striking the projections. This also resulted in the dummy not being brought to the ground quite so quickly with a consequently slightly reduced incidence of running over as shown in Table 3, Test 12.

In an attempt to reduce the incidence and severity of impact with the tyre, as found when testing at position 2, three modifications were tested.

The first modification was to curve the sideguard so that a smooth flare was produced bringing the rear edge of the guard level with the edge of the platform, as shown in Figure 5b. The second was a more abrupt flaring of the guard, from about a metre from the rear edge of the guard, again so that it was level with the platform edge. Neither of these changes, when tested at impact position 2 (Tests 8, 9, 10, and 11) reduced the incidence of hitting the protecting edge of the tyre. It was hoped that the flaring out of the guard would give an outward push to the dummy to prevent impact with the tyre, but, because of the 300mm gap between the end of the guard and the tyre, it still tended to fall back onto the tyre.

The third modification was to bring the whole guard out level with the edge of the platform (Tests 14 and 15). The incidence of hitting the edge of the tyre was reduced from the original 40 percent to about 10 percent when tested at position 2, but it was not clear why this modification was more effective than just bringing out the rear end of the guard.

It was obvious from all the tests of the three modifications that further improvements would be obtained by reducing the gap of 300mm between the rear of the sideguard and the front edge of the semitrailer tyre.

It was noted that in Tests 14 and 15 with the whole guard flush with the platform edge, the impact of the head with the platform edge was not as severe as with the inset guard, as well as reducing the incidence of the dummy hitting the tyre. This was because the shoulder did not travel as far under the trailer platform.

Wooden blocks were used to make the sideguard flush with the platform edge (Figure 5d), resulting in the

uprights supporting the sideguard being inset by 95mm from the face of the guard. This prevented the dummy from being struck by the uprights. The earlier tests had shown that the dummy's hip was struck occasionally by the uprights, which led to the dummy being thrown off the guard soon after the initial impact.

Tests 14 and 15 with the inset uprights and rails flush with the platform edge showed that the dummy remained in contact with the guard for a longer period, which lessened the probability of it being run over.

From the results of the tests on the basic sideguard and its modifications, an extended guard was constructed with the following features.

Distance of the Sideguard From the Ground.

One extra rail was added to the guard, parallel to the ground with the semitrailer coupled to the tractor unit. The ground clearance was adjustable to 300, 400, or 450mm. The lowest of these was roughly equivalent to the minimum allowed on coaches. The other two distances were just less and just greater than the dummy shoulder width. It was hoped that if the ground clearance was less than the shoulder width, it might prevent the dummy from rolling under the sideguard once it had fallen to the ground.

Length of the Sideguard

The guard was extended forward as near as possible to the rear of the tractor unit. This was done not only to fill in the obvious gap through which cyclists or pedestrians might fall but also to give a point of impact that was further forward than those used in the tests with the basic sideguard. The earlier tests had shown that when the dummy impacted at the more forward position on the guard, it was more likely to be run over. Thus, an even more forward position of impact would be a better test of the effectiveness of the sideguard. The forward extension should also help prevent impact with the hard front edge of the guard, which is otherwise difficult to make less injurious.

The rear of the sideguard was extended to be as close as possible to the trailer tyre to test whether it would prevent the dummy striking the forward edge of the tyre.

Distance of the Sideguard From the Edge of the Platform

Three of the nine tests on the extended guard were carried out with the guard flush with the platform edge as this was shown to be beneficial in the earlier tests. The remaining tests were done with the guard inset at various distances from the edge.

Sideguard Uprights Inset From the Rails.

The extended guard was constructed so that the uprights would be inset by 95mm from the face of the rails when the guard was flush with the edge of the platform.

Extended Sideguard Results

Test conditions 16 to 22, as shown in Table 2, were carried out with the sideguard ground clearance at 300mm.

In the tests where the sideguard was flush with the edge of the platform, the dummy tended to remain upright and came off the end of the guard onto the tyre sidewall, even at impact position 0. It had been noted in the earlier tests with the basic sideguard that the dummy was knocked more easily to the ground when the guard was inset. Therefore, some tests (18, 19, 21, and 22) were carried out with the sideguard inset from the platform edge. In these runs, which were directly comparable with the tests carried out on the basic sideguard, as detailed in Table 3, the incidence of running over was reduced to zero.

When the dummy fell to the ground and rolled toward the vehicle, it was prevented from rolling into the path of the wheels by the bottom rail.

When the sideguard was flush with the platform edge (Tests 16, 17, and 20), the results confirmed the earlier findings from the basic sideguard tests in that the incidence of the dummy striking the trailer tyre was negligible. In addition, impact with the load restraint hooks and lateral I-sections was less severe, as was impact of the dummy head with the platform edge. In these three tests, running over occurred in only three instances. In each case, the dummy was run over by the rear trailer tyre after coming off the rear end of the sideguard and onto the sidewall of the front trailer tyre.

Test 20, in particular, with the guard flush and the uprights not inset, confirmed the earlier findings of Tests 14 and 15 with regard to the dummy being knocked to the ground by the uprights.

In Test 23, with the ground clearance at 400mm, the dummy was run over in 4 of the 10 runs, as shown in Table 3, but 3 of these cases were relatively less serious in nature, involving either an arm or a leg.

With the ground clearance at 450mm (Table 3, Test 24), running over occurred twice, and these cases involved either the dummy head or trunk.

Acceptable Ground Clearances for Sideguards

The results shown in this paper indicate that if the ground clearance of the sideguard could be reduced to about 300mm, the incidence of running over would be negligible. It no doubt will be argued that such a low clearance is not acceptable to operators of HGV's even

though an equivalent ground clearance does appear to be acceptable to coach operators. Increasing the clearance to 400mm gives nearly as good results, and it is interesting to note that, since 1980, goods vehicles in Japan(5) have required sideguards with a maximum ground clearance of 450mm. From observation of the vehicles in Japan, even the largest articulated vehicles often have clearances of 380 to 400mm without obvious operating difficulties.

Severity of Injury to Two-Wheeler Users and Pedestrians

No attempt has been made in this paper to estimate severity of injury except to distinguish between obviously fatal injuries when the head or trunk of the dummy was run over by the trailer wheels and the relatively less serious injuries caused by running over limbs.

Qualitatively, some of the impacts of the dummy with the leading trailer tyre and the head with the platform edge appeared to be very severe. This was particularly true with the inset guard. It is hoped in the near future to carry out some tests with an instrumented OPAT dummy to estimate the severity of likely injury caused by such impacts.

Alternative Sideguards

The present paper deals only with sideguards made up of uprights supporting longitudinal rails. Where access beneath or to the side of the vehicle or trailer is necessary, this may be a sensible choice of construction. However, on trailers or semitrailers where this access is less important, other types of construction could be used. An obvious alternative is a skinned sideguard using a lightweight frame covered with aluminum or a glass-reinforced plastic sheet. On platform-type trailers, some ingenuity could be required to overcome the problem of access to restraint hooks, but this form of construction would present a smoother surface for the cyclist or pedestrian to fall against.

From work done on HGV aerodynamics, it has been shown this type of sideguard would also give reduced aerodynamic drag, a definite bonus for the vehicle operator. It might also reduce spray and should make the side of the trailer more conspicuous, especially if treated with bright paint and reflective strips.

Conclusion

Front Underrun Guards

1. An energy-absorbing underrun bumper for trucks has been developed that should protect the occupants of a car hitting it from death or serious injuries at closing speeds up to about 65km/h provided they are wearing seatbelts to the latest specifications and the car interior is sufficiently spacious forward of the front occupants.
2. The bumper absorbs approximately 20kJ of impact energy by deforming steel tubes using the invertube principle. The bumper weighs about 60kg and would probably cost about £150 retail. This is only slightly more than the estimated cost of an adequate rigid (that is, non-energy-absorbing) guard.
3. In view of the benefits in reduced car occupant deaths and injuries that would result from the use of energy-absorbing front underrun bumpers on trucks, it is suggested that any future legislation for these guards be based on requiring an agreed capability to absorb energy rather than specifying a minimum strength. A possible legislative test procedure for energy-absorbing bumpers has been outlined using an impactor with a rigid face perhaps 200mm square, weighing 200kg, and hitting the bumper at 50km/h. The maximum allowable deformation of the bumper and the maximum force experienced by it would be limited, provisionally to 400mm and 200kN, respectively.
4. The almost universal wearing of seatbelts in the United Kingdom makes it worthwhile to fit underrun bumpers giving this performance. In countries where seatbelts are rarely worn, there may be little justification for underrun bumpers to prevent intrusion into occupants at relative speeds much above 40km/h.
5. Further tests are planned with both the truck and car moving to confirm that the underrun guard is effective in these conditions.
6. Work is in hand to investigate the feasibility of fitting guards to modern HGV's.

Sideguards

Tests have been carried out on sideguards fitted to the semitrailer of an articulated HGV by simulating an accident where the lorry overtook a pedal cyclist at low speed. From these tests, it was found that—

1. With a sideguard fitted that just meets the UK C&U regulation, the pedal cyclist was run over by the wheels of the semitrailer in about 40 percent of the test runs. This compares with the near certainty of being run over every time without a sideguard fitted.

   Because the whole sideguard was inset from the face of the tyres and also because of the 300mm gap between the rear end of the guard

and the leading trailer tyre, the pedal cyclist could be struck severely by the leading edge of the front trailer tyre.

Due also to the guard being inset, the head of the cyclist could severely strike the platform edge.

The pedal cyclist was more likely to be run over by the trailer wheels at the lowest test speed used of 10km/h than at higher speeds.

2. With a sideguard extended rearward to be closer to the trailer tyre and brought out flush with the platform edge and having a reduced ground clearance, the performance of the guard was improved as follows.

   With a uniform ground clearance of 300mm, the incidence of running over was reduced to zero. At ground clearances of 400 and 450mm, the incidence of running over increased slightly.

   The incidence of the pedal cyclist being struck by the edge of the leading trailer tyre was considerably reduced.

   The severity with which the dummy head struck the platform edge appeared also to be reduced.

   Insetting the uprights from the rails of the guard prevented the dummy from being knocked to the ground by the uprights.

   The forward extension of the sideguard would reduce the possibility of falling in front of the guard or onto the hard front edge.

3. The procedure described in this paper could form the basis for the development of a standard test to evaluate the effectiveness of future sideguards.

Load Restraint for the Protection of Occupants in Light Vans Including Car Derivatives

D.G.C. Bacon and
I. Gazeley
The Motor Industry Research Association

Abstract

The problems of restraining miscellaneous loads in light vans and passenger cars derivates were quantified with a view to developing specifications for strong anchorage points, bulkheads, racking, and restraint systems. The project brought together the main organisations involved: the fleet operators, vehicle manufacturers, restraint manufacturers, and racking manufacturers.

In an information gathering phase, the type of accidents were defined against which the restraint system would be required to provide protection. The specified accidents were simulated using barrier crash tests and dynamic sled tests. The test vehicles were equipped with bulkheads and storage bin systems. Various schemes of loads were held down with webbing restraints attached to anchorage points. This test work, as well as providing the loading information for the restraint specification, also indicated the performance given by existing systems. Specifications for cargo restraint systems were drawn up and prototype designs engineered to this standard for evaluation. Performance tests were carried out on the overall systems

to cover the different conditions and types of load experienced in service.

The final stage of the project involved preparation of the detailed specifications for the anchorage points, bulkheads, racking systems, and restraints that would form part of a Recommended Practice.

Introduction

The light van is one of the most widespread vehicles on the roads today. Passenger car derivatives and the forward control vans, which form the two main groups, are used by the thousands for carrying light loads.

It is, of course, often necessary to restrain the load within the van. This is needed for the protection of the front-seat occupants and sometimes for the prevention of damage to the load itself. Indeed, sometimes it is necessary just to prevent the load from becoming mixed by the motion of the vehicle. For all these reasons, a variety of load restraint systems has been developed. The main ones are—

- Bulkheads, intended to provide occupant protection by holding back the load
- Racks, used with containers into which loose tools and other small items can be gathered
- Webbing restraints, used to anchor heavy loads of a variable nature
- Clamps, used to hold down heavy items of a predetermined kind, such as trolley jacks

The need for such systems is felt particularly by the major national organisations who operate large fleets. Such organisations operate in a more systematic way than the small operator and place a greater emphasis on safe operation.

In fitting out their vans for various purposes, the major national fleets found they faced a common problem. There were no established fixing points within the back of the van to which the fleet engineers could attach their systems. All sorts of methods were improvised for overcoming this difficulty, and pickup points were devised on an ad hoc basis. It was considerably more difficult to add strong anchorage points after the vehicle was completed than it would have been in the course of manufacture. Furthermore, the engineers of the vehicle manufacturer would have been far better placed to decide suitable locations and designs. Finally, there was no control over the strength of these anchorages. If they were designed into the vehicle, instead of being added on an ad hoc basis, they could have had a specified strength.

The project described in this paper brought together the main organisations involved, that is, the fleet operators, vehicle manufacturers, restraint manufacturers, and racking manufacturers. They steered a programme of test work, analysis, and assessment to provide a consensus specification for light van restraint systems.

Survey of Fleet Operators' Accident Reports

A search was made through the records of four fleet operators to determine the number of accidents involving frontal impacts and the range of impact speeds. The combined number of vehicles operated by the organisations amounted to approximately 15,000, and the search covered a 5-year period. Side and rear impacts were not considered since it was felt these types of impacts would not propel unrestrained loads toward the occupant compartment. The accident reports studied did not refer to displacement of cargo. The investigations looked at a total of 303 vehicles that were in motion when the accidents occurred.

The obstacles that the vehicles collided with were categorised and are shown in Table 1.

Table 1. Obstacles encountered by vans from a survey of fleet accidents

Cars	:	218
Roadside furniture	:	33
Heavy commercials	:	23
Motorcycles and cyclists	:	11
Farm machinery	:	8
Buildings	:	4
Others	:	6

The distribution of the number of vehicles relative to impact speed is shown in Figure 1. Taking into account that the majority of impacts involved another car and 95 percent of the accidents were at speeds less than 64km/h (40mph), then this information provided the guidance for the speed to be used in the crash tests with a rigid nondeformable barrier carried out in this project. In vehicle-to-vehicle impacts, the equivalent barrier impact speed can be considered to be approximately half the vehicle speed. Therefore, in this work an impact speed of 32km/h (20mph) was employed to cover the majority of accident circumstances in frontal impacts.

Test Procedures

Crash Simulation Testing on the HYGE

To carry out a typical test series, a van floorpan or bodyshell was secured to the HYGE sled through its suspension mounting points by a purpose-built rigid frame. Particular attention was paid to making certain that it was well secured in view of the number of dynamic tests to which it would be subjected. The van would then be kitted out with the appropriate load of equipment for a test. Cameras required for filming movement of objects

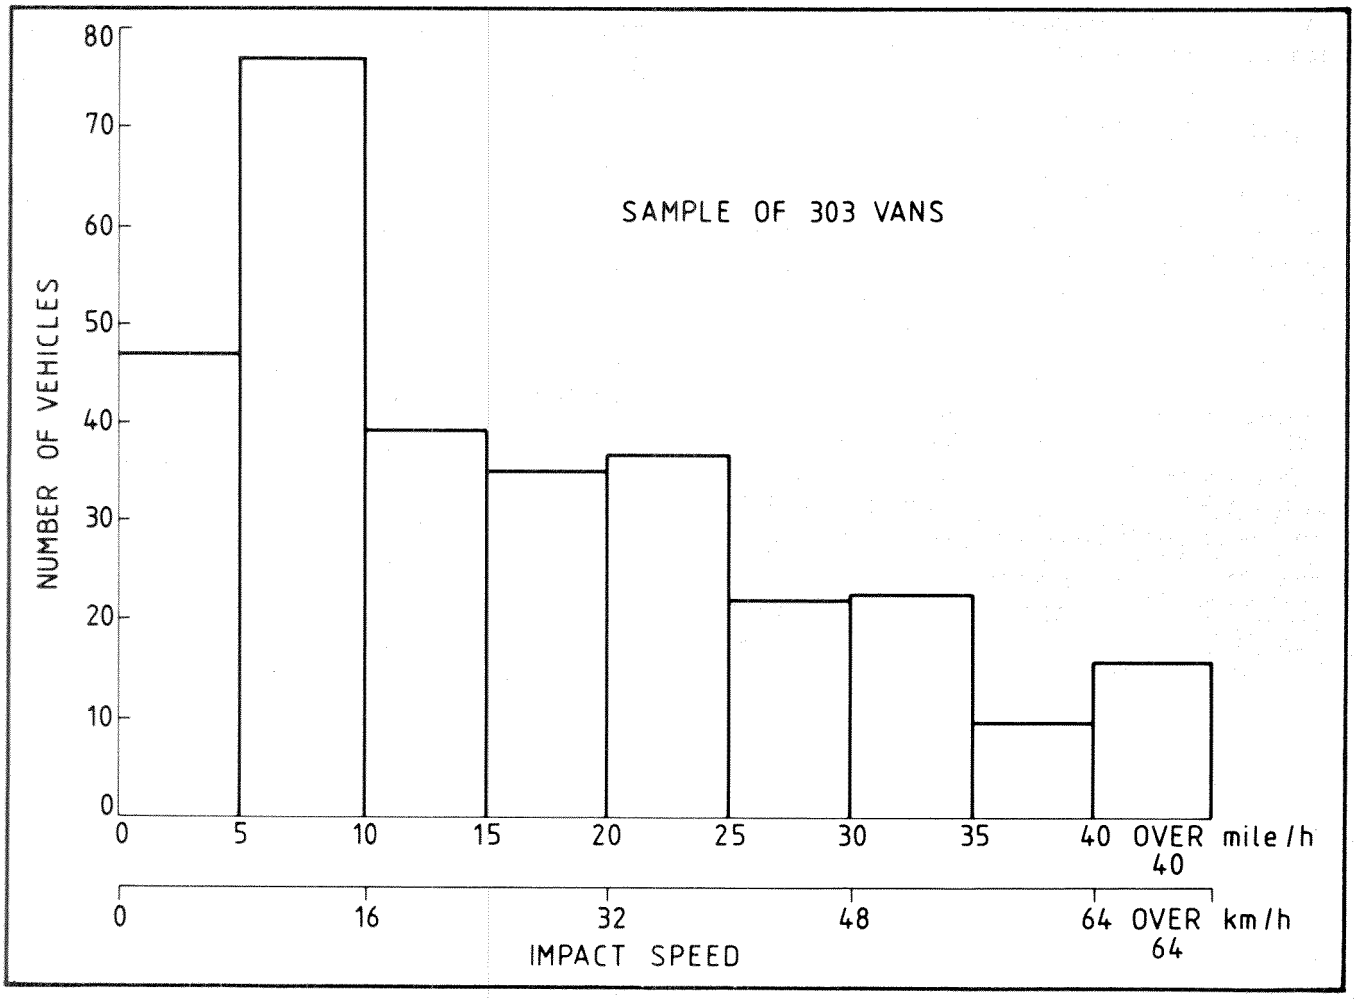

Figure 1. Number of vehicles involved in accidents in specified speed ranges

during the test were positioned on the sled and instrumentation transducers attached to record forces and accelerations. The sled with the bodyshell mounted on it was then accelerated backward by firing the HYGE, thus simulating a forward deceleration impact. Instrumentation and film analysis were then carried out to assess the results of the test.

Figures 2 and 3 show views of typical floorpan and bodyshell installations before a test.

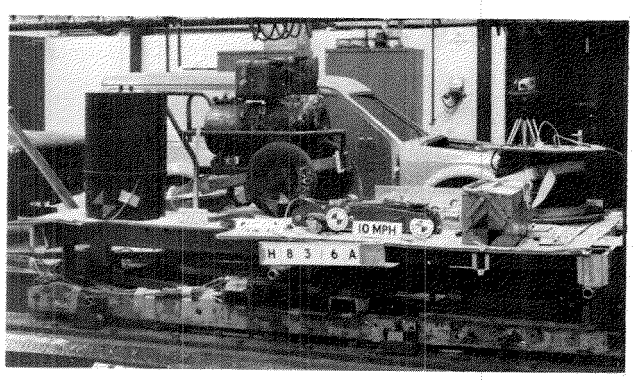

Figure 2. Van floorplan test on the HYGE, showing equipment carried and webbing restraints

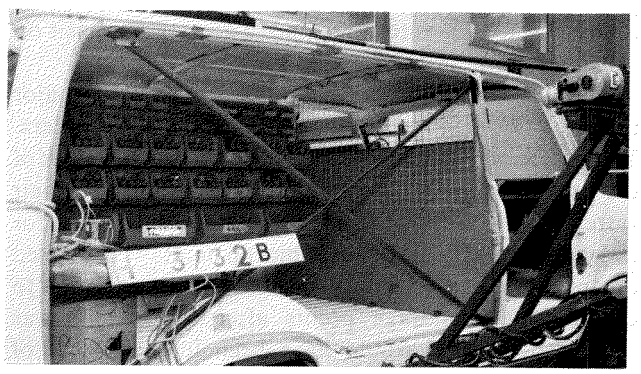

Figure 3. Van bodyshell test on the HYGE, showing equipment carried and storage bin system on vehicle side

Barrier Crash Testing

In preparation of a van for a typical load restraint test, large apertures were cut in the van side to give good photographic coverage of the movement of the cargo inside. Usually some light cross-bracing was welded across the apertures to maintain the stiffness of the body.

Any racking or storage bin system would be fitted to the opposite side that had not been cut.

Static Load Testing

Tests were carried out with a floorplan of the vehicle bolted to a channel section subframe. Shackles were installed into the floor anchorage, and then a load was applied at a specific angle by means of a hydraulic ram and a chain. A view after one of the tests can be seen in Figure 4.

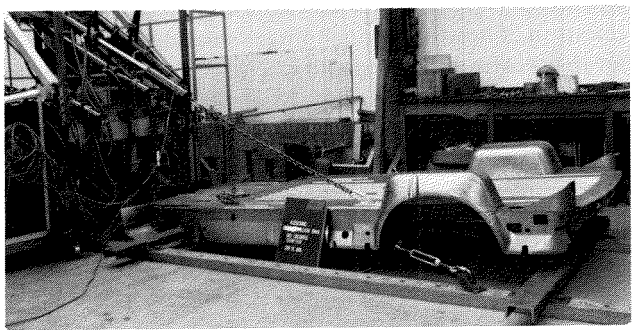

Figure 4. Static load anchorage test using van floorplan

Road Manoeuvre Testing

A series of braking tests were performed to evaluate the retention of storage bin systems. This work was followed by cornering tests that involved driving the van at various speeds around a constant radius to induce lateral accelerations.

Test Programme

An outline description of the test programme is given in Table 2. Full details of the tests and their results have been published in a MIRA report(1).

Bulkheads

Bulkheads provide a division between the load-carrying area of the van and the occupant compartment. Their main function is to prevent loose objects sliding or flying forward to cause damage or injury. Existing bulkheads are constructed from various sheet or mesh materials and are attached to the van sides, roof, and floor by a variety of means. Figure 3 shows a typical ad hoc timber and mesh bulkhead.

The existing Swedish regulation for bulkheads, SS2562, provided an immediately available specification, which was assessed to see if it matched the requirements of these investigations.

Bulkhead Test Programme

The majority of bulkhead tests were carried out in vehicle bodyshells in the "body in white" condition on the HYGE. Various items of cargo were left loose in the back, which then moved forward to strike the bulkhead. Small items of high mass, such as a trolley jack, were used to give a concentrated load that could cause problems with some designs of bulkhead.

In addition, bulkheads were assessed in the programme of full-scale crash tests that involved impact from similar items of cargo.

Bulkheads—Summary of Findings

It was not practicable to view the bulkhead as a restraint device capable of stopping all loads carried up to the maximum capacity of the van and at all possible impact speeds. A maximum load would have to be specified that could be allowed to come loose in an impact and also a maximum velocity at which the bulkhead was capable of stopping such a load. This load and velocity would be relatively small compared with the maximum payload and the maximum speed the van could reach. This meant the remaining cargo of the van should be adequately restrained to floor anchorage points. Information from other parts of the project were brought in to provide guidelines for the loose load and impact velocity.

In a survey of typical storage bin contents of vans, load values of about 110kg were found for a 900kg payload vehicle. The accident survey showed that an equivalent

Table 2. Load restraint test programme

Type of Test	No. of Tests	Speed km/h	Vehicle State	Evaluating			
				Bulk-heads	Anchor-ages	Storage Bins	Restraint
Barrier Impact	4	32	Whole van	*	*	*	*
Hyge Sled	23	16-40	Bodyshell	*		*	
Hyge Sled	8	16-40	Floorpan		*		*
Static Pull	14	—	Floorpan		*		*
Braking	6	20-60	Whole van			*	
Cornering	9	20-90	Whole van			*	

barrier impact speed of about 32km/h (20mph) covered most of the crashes seen on the roads.

These figures of 110kg at 32km/h seemed a reasonable target for the performance of a bulkhead for that size van, and the sled and crash tests indicated some current designs of bulkheads were capable of withstanding that type of impact. It also seemed reasonable that vans with higher payloads should have stronger bulkheads and smaller vans less strong bulkheads.

This philosophy was part of the Swedish regulation on bulkheads which specified a range of impact energy for bulkheads to withstand, based on vehicle maximum payload. This energy specification has been interpreted in terms of loose payload and impact velocity in Table 3. It can be seen that for the 900kg van, the unrestrained payload is 90kg at 32km/h.

Table 3. Permissible unrestrained payloads impacting bulkheads at different velocities in accordance with Swedish standard SS2562 for various size vehicles

Size of Vehicle Payload	Unrestrained Payload Permissible Energy Level (Joules)	Unrestrained Payloads Impact at 16km/h 10mph	Impact at 24km/h 15mph	Impact at 32km/h 20mph	Impact at 40km/h 25mph	Impact at 48km/h 30mph
250kg	1000	100kg	45kg	25kg	16kg	11kg
400kg	1600	160kg	71kg	40kg	26kg	18kg
900kg	3600	360kg	160kg	90kg	58kg	40kg
2,000kg	8000	800kg	356kg	200kg	128kg	88kg

The main requirements of the Swedish regulation in relation to bulkheads were adopted as the specification or Recommended Practice resulting from this project. This had the considerable benefit of a common requirement for vehicle manufacturers to meet.

However, attention was drawn to a desirable addition to the standard relating to the prevention of small objects passing through mesh-type bulkheads in the vicinity of the driver's head.

Load Anchorages

A load anchorage is a strong point on the van floor or sides to which items of cargo can be attached. The load anchorage will have a defined capacity under certain loading conditions, which will mean the item of cargo can be restrained up to a specified level of impact severity.

The problem for the fleet operators had been that until recently most vans did not have established anchorage points. To attach restraints or racking systems required the improvisation of drilled holes and attachment of reinforcing plates. The strength of these arrangements was often in doubt, and in most cases it was not known how strong they should be anyway.

It was considered more difficult to add anchorage points after the vehicle had been manufactured, and it was more appropriate for them to be incorporated during vehicle build. Also the manufacturers' designers would have more information to engineer the required strengths. However, the positions and number of these anchorages would be very much influenced by the experience of the fleet operators in their day-to-day usage of the vans.

The main task was to decide what was expected of a load anchorage, in terms of where they would be located within the van, and what would be attached to them. The question of how many anchorages should be provided in a van was also addressed and whether this number varied with the size of the van.

Load Anchorages—Purposes and Locations

The fleet operators' experience showed there was a dual function requirement for floor anchorages and there was also a need for anchorages at a high level in the van.

The floor anchorages had to be sufficiently numerous to allow convenient lashing of cargo at most positions on the load-carrying area, though it was considered more probable that this lashing would take place at the rear end of the vehicle because it was more accessible to the operator. Therefore, in defining an arrangement of anchorage points for the larger vans, more points have been put at the vehicle rear. It was also evident that a large proportion of these fleet vehicles have installed side-mounted racking systems with storage bins. These systems require attachment for the feet of the louvred panels to the vehicle floor. To keep the number of anchorages down, it was decided that those along the sides of the floor should have a dual function of lashing point and rack-mounting point.

The side-mounted racks require an upper fixing point, which is usually the vehicle cant rail (or similar structure) to attach the top of the rack. As the racking system is

vertical (or nearly vertical), this upper fixing point defines the lateral location of the floor anchorages along the side of the floor.

In summary, the anchorage locations in the floor were planned as a row on each side at a lateral spacing dictated by the upper fixing points and a row on the vehicle centreline biassed toward the vehicle rear. The upper anchorage points consisted of a row on each side in the cant rail.

Types of Load Anchorage

Various designs for a single-load anchorage or attachment point were examined. Some of these were simple but difficult to use, and others were complex in design with useful features but quite costly to incorporate. The intention was to find a suitable design that was acceptable to both the fleet operator and van manufacturer while still meeting a specified load condition.

The variants based on the 7/16in UNF-threaded hole were more attractive for several reasons. The concept of an anchorage being a reinforced 7/16in UNF-threaded hole is widely accepted in the field of vehicle safety belts. Also this design allows the addition of, say, the attachment of a bracket for racking systems as well as the link for the load restraint. The 7/16in UNF-threaded hole as an anchorage was adopted for floor anchorages.

The van manufacturers found this type of anchorage could be incorporated in the vehicle build without extensive tooling changes. Consequently, these anchorages were fairly inexpensive and had a high probability of actually being offered as an option (or as standard equipment).

It was decided that the upper fixing points could be a simple hole or any other connection detail at the discretion of the manufacturer as long as it met the strength criterion. However, to avoid any element of doubt about reinforcement details, it was preferred that this upper fixing point should again be a threaded hole but of a smaller diameter than the floor anchorages (and seatbelt anchorages). In this case, a metric thread of 8mm was chosen as the standard.

Floor Load Anchorages—Test Programme

Dynamic Tests

The aim of this programme was to establish the dynamic loading of floor anchorages under typical conditions of payload and impact severity. These data would provide the guidelines for the specification of anchorage strength in terms of a static pull test.

A series of sled tests were performed using van floorpans on the HYGE sled. A range of items of cargo to be restrained in these simulated impacts was provided by the fleet operators. Electronic force transducers were attached to the webbing restraints to record the tensile loads in each run of webbing. Figure 5 shows typical loads measured. From these records, it was possible to establish the load variation on each anchorage during the test and also the maximum value that occurred.

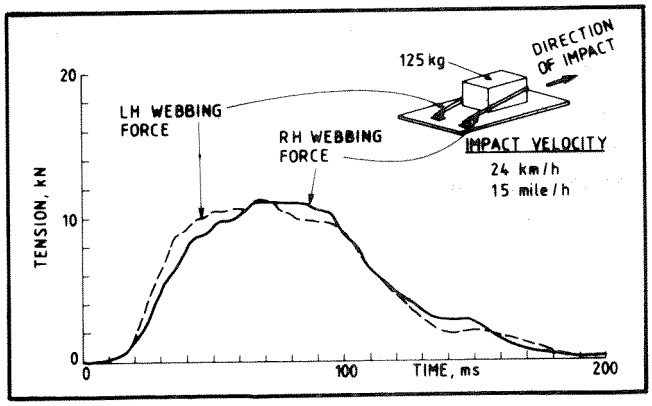

Figure 5. Loads measured in webbing restraint

Static Tests

The aims of the programme were to achieve similar anchorage deformations in the static pull test and the equivalent dynamic test to discover the static force that would destroy the anchorages and to establish a standard static test of force against a time period for testing anchorages without having to rely on dynamic testing.

Dynamic/Static Comparison

The greatest loads of about 20kN were measured in restraining a 125kg generator in simulated 40km/h (25mph) crashes. This payload was considered to be typical of some of the heavier items used by the fleet operators in their vans, and, if it could be restrained successfully by the anchorage system, it would represent a suitable standard to achieve.

The floor distortion caused by dynamic loads of 20kN was reproduced in static tests by loads of about 15kN that were of much longer duration. This observation follows other experiences in impact studies on steel structures, which show a dynamic amplification factor with higher velocities.

The outcome of this exercise was the establishment of the strength requirement of floor anchorages at 15kN. The angle of load application was specified to be 30°, which was consistent with typical lashing angles for cargo. A minimum load application time of 0.2s was also specified to be consistent with similar tests on seatbelt anchorages (Figure 6).

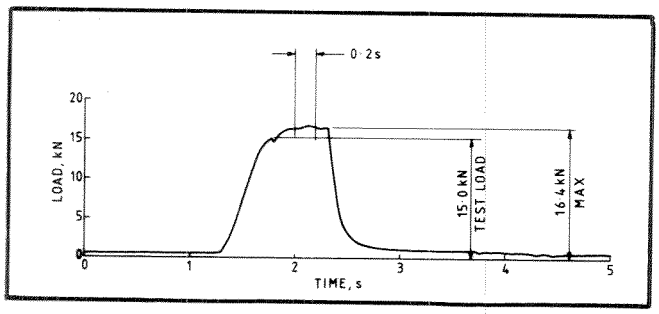

Figure 6. Typical static loads applied to floor anchorages meeting strength requirement

Upper Fixing Points—Test Evaluation and Results

The attachment of storage bin systems was usually straight onto the upper fixing points, and the measurement of forces acting at these points could not be measured directly. The method used was to take a value for the deceleration of the van in an impact, which, with knowledge of the mass of the storage bin system, would give a value to the force acting.

This information led to consideration of the strength of the upper anchorage fixing points as a function of the van maximum payload. Rounded values of upper fixing point load for both sides of the van were calculated as follows:

250 to 400kg payload	4.0kN
900kg payload	9.0kN
2t payload	20.0kN

A formulation based on payload was put forward for the strength of the upper fixing points.

Floor Anchorage Locations

The anchorage point layout for a light van (short wheelbase) was designed to suit fleet operators' needs and is shown in Figure 7. For longer vehicles, it could be seen that an additional anchorage would be required on each side and in the middle. This aspect is covered by the Recommended Practice as a function of loading area length.

The anchorage point layout for car derivative vans followed similar principles.

Storage Bin Systems

Racking systems in vans provide storage bins of various capacities (usually 5, 10, and 15kg) that are

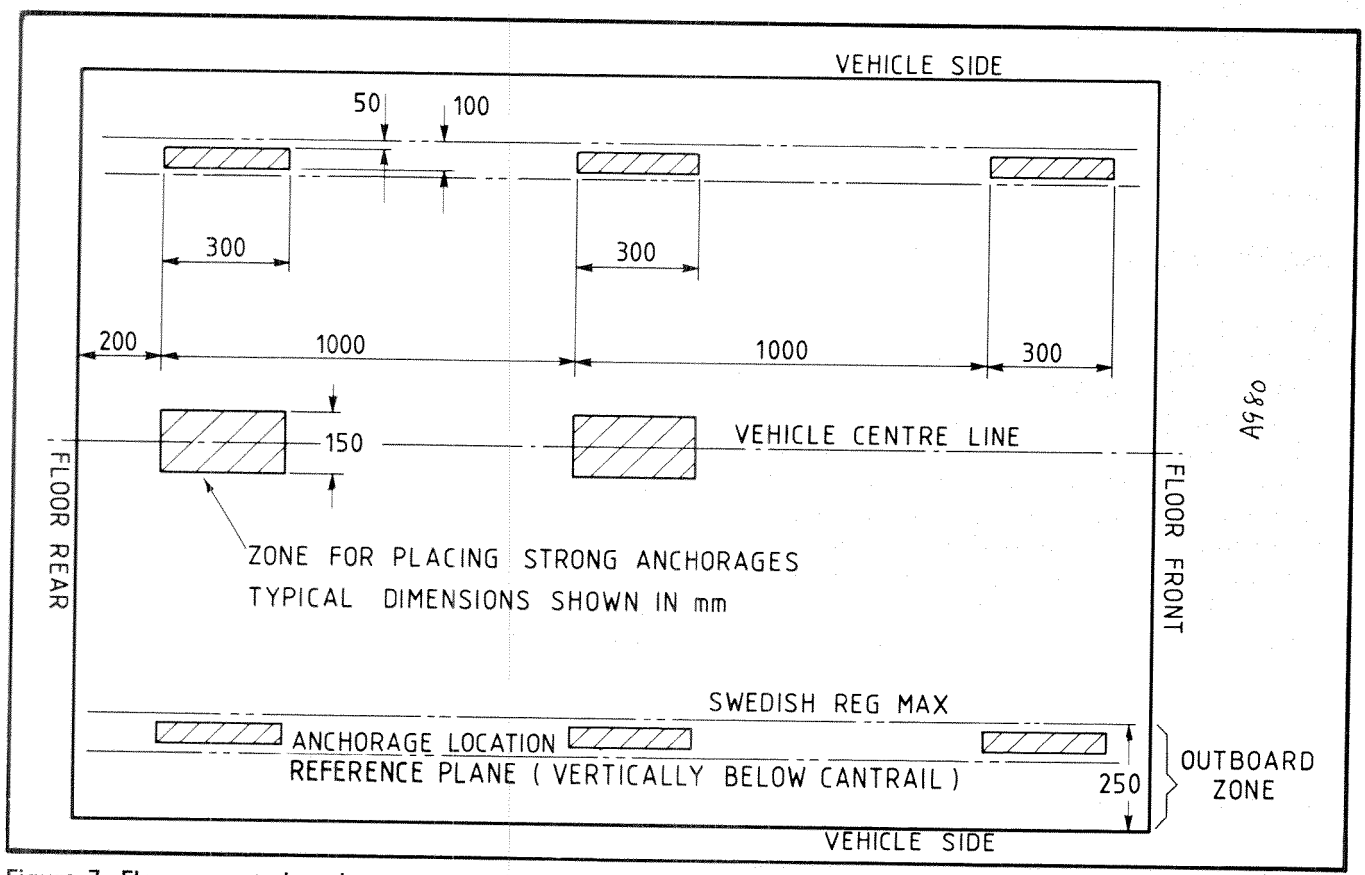

Figure 7. Floor-mounted anchorage zones for 1t payload vans

hooked onto pressed steel-louvred panels. Two systems made by different manufacturers were assessed in this project. Both were based on wall-mounted assemblies that were used mainly in workshops for storage of small items such as nuts and bolts. The louvred panels offered flexibility in the position that a bin could be attached, and it was common practice to unhook a bin of necessary components and take it to where a job was being done. Figure 3 shows a typical storage bin system.

Although this project concentrated mainly on the storage bin/louvred panel system, racking and shelving constructed from slotted angle is also widely used by fleet operators. The main requirement for this type of racking is strong attachment points, and it would be the intention that the anchorages specified in this work would be employed for these fittings as well.

Storage Bin Systems—Test Programme

Impact Tests

The majority of sled tests employing van bodyshells and all full-scale van crash tests carried storage bin systems fitted out with a variety of bins and bin-loading schemes.

It was apparent from the very first test carried out with fully loaded bins at 16km/h that they become detached from the louvred panels. A repeat test with partially loaded bins (about 50 percent) still showed bin separation from the panels.

Once it was realised that in almost every impact circumstance the bins would leave the panels, most of the tests assessing the strength of bulkheads also included some loaded bins.

Road Manoeuvre Tests

A small test programme was initiated with a van fitted out with a storage bin system and involved standard hard braking and cornering tests.

Under braking, it could be concluded that despite some small forward movement, all bins remained on the panels and retained their contents. Average accelerations during these tests did not exceed 1.0g. The value, 1.0g, was used in specifying the longitudinal load test for bins.

During cornering, the tests showed that all bins were retained by the louvred panels up to the maximum lateral acceleration of 0.7g. Only small items were displaced from a small bin at accelerations of 0.54g and above. In this work, the value of 1.0g was adopted for the lateral load test specification for bins.

Storage Bin Systems—Summary of Findings

In almost every impact test of racking systems fitted with bins, loaded to a variety of schemes, the bins became detached from the louvred panels and flew forward to strike the van bulkhead.

A major concern was that even if a method was devised to retain the bins, the bin contents may come out and still become a hazard.

It was concluded that if bins and contents would come loose in an impact, the bulkhead would have to be the prime protective device. However, bulkheads will only withstand a specified range of impact energy based on vehicle maximum payload. This meant the maximum unrestrained payloads for different impact speeds would be as given in Table 3. Therefore, the maximum weight of unrestrained bins and contents that could be carried in a van would be given by the 32km/h column, e.g., 90kg for a 900kg payload vehicle. This became the basis for the maximum permissible loading of a storage bin system.

Restraint Systems

This section relates to the various fittings such as shackles and D-links, together with webbing harnesses, ropes, or chains that connect the cargo to the anchorages in the load floor.

Every test carried out in this project with a restrained item of cargo employed some type of restraint system. Therefore, many restraint components were proved in the assessment of other systems.

Having decided on a strength specification of 15kN for the load anchorage, this automatically set the minimum standard for all other components in the load path. However, in line with working practices for these systems, a percentage overload was desirable—this was set at 33 percent giving a restraint test load of 20kN.

This criteria can be met by chains, wire ropes, rope, or synthetic webbing. The latter was the material used in the tests and proved very suitable. It is easy to use, absorbs much of the dynamic force, and does not cause secondary damage to the cargo.

Exercises were also carried out in lashing items of cargo to the anchorage layout specified for a variety of van floors. In an early vehicle test, it was most noticeable that, in a forward collision or severe braking condition, the cargo attempts to move vertically and, if insufficient vertical restraint is applied, it is possible for the cargo to rise and roll over the horizontal restraint.

Conclusion

This project brought together the main organisations involved in the problems of the transportation of cargo in vans.

Information was gathered from the fleet operators to provide background data for the performance of the bulkheads, load anchorages, and storage bin systems. This not only established the range of items carried in

vans but also involved the definition of the type of incident against which the systems must hold the fitted equipment.

Simulation of the incidents, which included vehicle collision, emergency braking, and cornering, formed a major part of the test programme that provided the data to quantify the problems of restraining miscellaneous loads. This enabled specifications to be drawn up and assessed against a background of realistic information.

Some of the more important conclusions of the work are as follows:

- Injury from loose objects may be prevented by fitting an impact-resistant bulkhead between the load-carrying area of the van and the occupant compartment. Typically, such a bulkhead fitted in a 900kg payload van will stop unrestrained objects of 90kg moving at 32km/h (20mph).
- Fleet operators require strong anchorage points to be installed in the floor of the van so cargo can be restrained. A static load criterion has been specified for these anchorages as a result of the tests in this work. The strength required is a load of 15kN at an angle of 30°. Anchorages should consist of 7/16 UNF-threaded holes in an arrangement that is a function of load floor length.
- Strong anchorages are also required at a higher level in the van for the attachment of the top of racking systems. The preferred form of these anchorages is an 8mm threaded hole.
- The performance of side-mounted storage bins was assessed and, as a result, it was recommended they not be used without a bulkhead being fitted to the van. The capacity of the storage bin system should be limited to what the bulkhead can contain in an accident.
- Restraint systems such as chains, ropes, or synthetic webbing can be used to connect the cargo to the strong anchorages in the load floor. It is a requirement that all components in the load path should withstand a load of 20kN.

As a conclusion to the project, the various specifications developed in the course of the work were brought together in a Recommended Practice(2).

Abstract

Data about severe coach accidents are still limited. More knowledge in this field is required to define safety priorities that designers and manufacturers need to consider in future vehicles. Despite the good safety level of coaches, some spectacular accidents nevertheless occur causing serious injuries and death to the users, and these are often brought to the public's attention by the media.

This survey is based on all the fatal coach accidents that occurred in France between 1978 and 1984. The paper describes the causes and accident configurations and analyzes the injury mechanisms. Countermeasures are discussed, and possible ways of minimizing occupant injuries, related to strength of front end structures, seat back improvements, window retention, and fire protection, are suggested.

Introduction

During each of the past 10 years in France, 32 people were killed and 162 seriously injured on average in

coaches and buses. Coach accident victims represent only 0.2 percent of the total of road accident victims.

Table 1 shows for 1984 the number of deaths and serious injuries among motorized road users, together with an estimate of user kilometers and the fatality rate for each mode.

Table 1. Road transport casualties in France in 1984

	Killed	Seriously Injured	Deaths Per Thousand Million User kms
Bus and coach	18	452	0.5
Truck	165	712	6
Car	7,111	39,930	16
Moped and motorcycle	1,684	15,238	100

It is clear that the fatality rate of coach and bus users is very much lower than that of any other means of traveling by road.

However, action to minimize future similar occurrences, where possible, is in the hands either of designers and manufacturers or legislators. Real-life accident data overviews are needed to help them rationalize new improvements for coach safety. Few studies have been published on this matter.

Baxter(1) discussed some of the problems associated with coaches involved in rollover-type accidents and proposed a minimum standard for the strength of coach structures.

Stansifer and Romberg(2) conducted a cost-benefit analysis of safety belts based on 66 intercity bus accidents. They concluded that a requirement to fit safety belts at all seats in coaches should not be recommended. This conclusion is also supported by frontal impact test findings(3) that demonstrated lapbelts could do more harm than good due to harder head impacts against seat backs.

Davies(4) analyzed 11 school bus crashes in Ontario. The author mentioned that padded seat backs designed to yield under impact loading would be better than voluntary seatbelt usage. It was recommended that emergency exit windows be required as well as an emergency exit door.

Due to the small number of severe cases recorded in each country, efforts to analyze coach accidents must be intensified, and the comparison of independent studies must be encouraged.

The Sample

Characteristics

The study concerns 48 accidents in which at least one coach occupant was killed. They include all fatal coach accidents occurring on the road network where the Gendarmerie Nationale operate (the entire French network except major conurbations and suburban motorways) during a 7-year period (January 1, 1978, to December 31, 1984).

All vehicles were large buses (empty weight: >8,000kg and 40 passengers or more) except six were busettes (empty weight: >4,000kg and 30 to 39 passengers). Cases involving small buses or city buses were eliminated from the sample.

The accident reports were collated and studied at the Paris Headquarters of the Gendarmerie by two accident analysts. These documents, in particular, provide information concerning the general circumstances of the accident, the site plan, interviews with those involved, the seriousness of victims' injuries, as well as photographs of vehicles involved.

In the case of 14 accidents, a much deeper analysis performed by our laboratory enabled the police-based information to be complemented.

Active Safety Aspects

According to the police data(5), the extent of coach driver blameworthiness in all personal injury accidents is fortunately very low (only 30 percent). But, in the fatal accident sample, this rate is 2.5 times higher (73 percent) than the former. This highlights the importance of the coach driver in accidents where there is at least one occupant death. This high degree of presumed blameworthiness should be related to the fact that, in 18 cases out of 48 (38 percent), the coach is the only vehicle involved.

Accidents often have many causes. The distribution of main apparent causes of the 35 accidents in which the blameworthiness of the driver seems clear-cut is shown below:

Loss of control on a bend	—	6
Loss of control on black ice	—	5
Slowing down	—	5
Other cases of loss of control	—	4
Driver's drowsiness	—	4
Dangerous overtaking	—	3
Alcohol	—	2
Driver feeling unwell	—	2
Mechanical failure	—	2
Inattention	—	1
Unknown	—	1

Moreover, in 13 out of 35 cases, the drivers were exceeding the speed limit for the type of road.

Main Impact Types and Distribution of Victims

In two-thirds of the cases, coaches sustained more than one impact during the accident. This should be related to

the fact that glancing blows are frequent. It is noticeable that the stopping distance of the coach after the first impact is less than 10m in only two cases but above 40m in half the cases. Thus, for multiple impacts, the main one is taken to be that producing the fatal injury.

Three types can be distinguished:

- Frontal impacts: 42 percent (20/48)
- Rollover or tipping-over accidents: 33 percent (16/48)
- Other cases: 25 percent (12/48) (including fire, falling into water or a ravine, side impacts)

In accidents in which at least one coach occupant is killed, the distribution of injury severity among victims (Table 2) in frontal impacts and in rollover and tipping-over accidents is somewhat comparable.

The high proportion of those killed in the impact type classified as "Others" is due to the inclusion of the 48 persons burned to death in a single fire accident, as well as accidents in which the coach fell into a ravine or into water (32 killed out of 73 involved).

It will be observed that even in a sample of accidents in which a coach occupant was killed, approximately three-quarters of those involved were uninjured or only slightly injured.

Table 2. Distribution of victims by impact type

		Impact Types							
		Frontal	Overturning Accidents	Others					Total
				Fire	Falls into a ravine	Side impacts	Falls into water	Miscel-laneous	
(number of case)		(20)	(16)	(1)	(2)	(4)	(2)	(3)	(48)
Injury Severity	Killed	46	30	48	25	11	7	3	170
	Severely Injured	135	104	0	12	25	1	0	277
	Slightly Injured	290	262	0	13	30	12	35	642
	Uninjured	253	161	16	0	38	3	88	559
Total		724	557	64	50	104	23	126	1,648

Frontal Impacts

The 20 frontal collisions resulted in 46 fatalities (about one-quarter of the total) and 135 seriously injured (half of the total of seriously injured) out of 724 passengers involved.

Front End Damage Area and Severity of Victims

Frontal impacts have been broken down according to the degree of overlap of the coach front with the struck obstacle (which in 15 out of 20 cases is a truck, and in the others a high, stiff, fixed object). The degree of severity of injuries according to the extent of overlap is given in Figure 1.

Less Than 1/3 Overlap Impacts

They represent half of all fatal frontal impacts. Respectively, 44 percent and 48 percent are killed and severely injured in this collision type. Seven out of the 10 cases are offset to the left (Figure 2).

1/3 to 3/4 Overlap Impacts

These represent 41 percent of killed and 22 percent of severely injured. They occur mainly in slowing-down situations. Due to the driver's reaction, the right front is concerned in 3 out of the 5 cases.

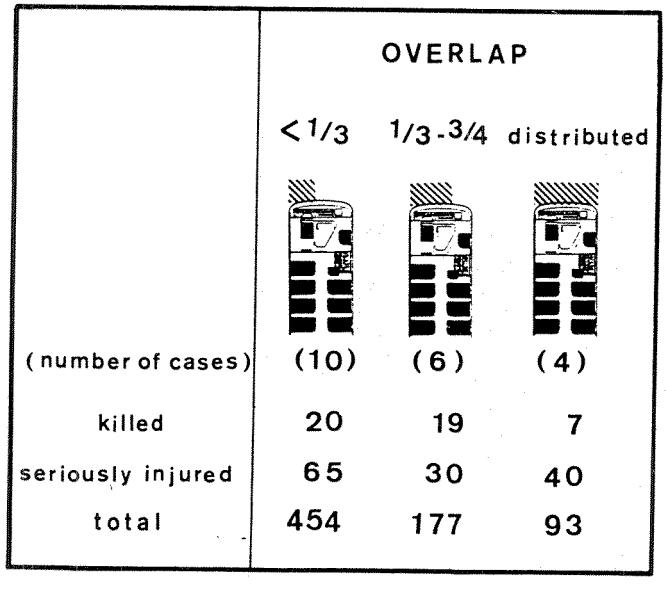

Figure 1. Distribution of injury severity of victims by overlap in frontal impacts

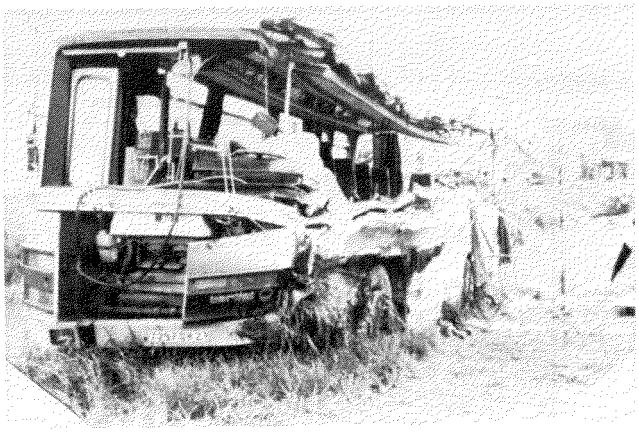

Figure 2. 1/4 offset impact against a truck—8 killed, 2 seriously injured for 27 involved

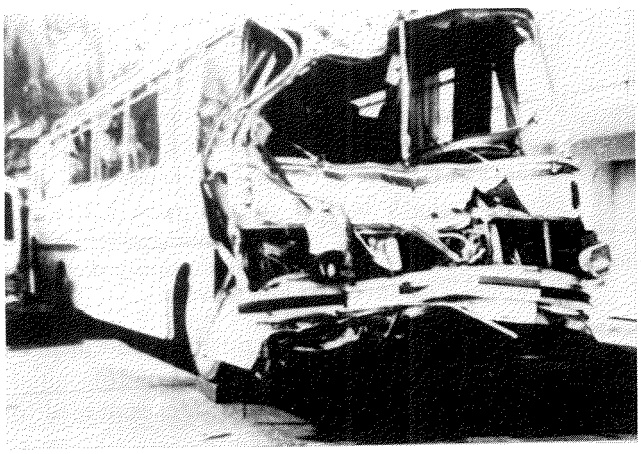

Figure 3. 1/2 offset impact against the rear of a truck—1 killed, 10 seriously injured for 28 involved

Distributed Frontal Impacts

Only 4 out of 20 fatal frontal impacts show deformations spread across the whole of the front of the coaches involved. They result in few killed (15 percent), but the seriously injured are relatively numerous (30 percent).

All in all, in fatal frontal impacts, offset cases cause 82 percent of all deaths and 59 percent of serious injuries.

Intrusion and projection are, respectively, the main mechanisms of injuries for those killed (91 percent) and for the seriously injured (61 percent). The two fatalities by projection took place in particular circumstances (one child standing up in the gangway and an elderly person involved in a multiple frontal impact accident).

Among frontal projection victims, the body areas of face and knee/leg are injured in 36 and 30 percent of the cases, respectively.

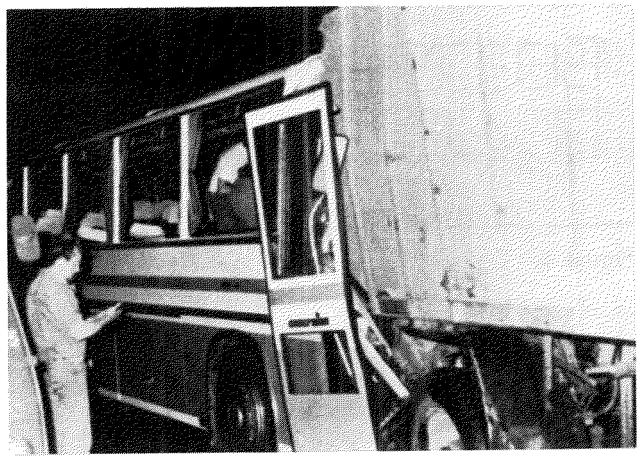

Figure 4. Distributed front impact against a truck—1 killed, 24 seriously injured for 51 involved

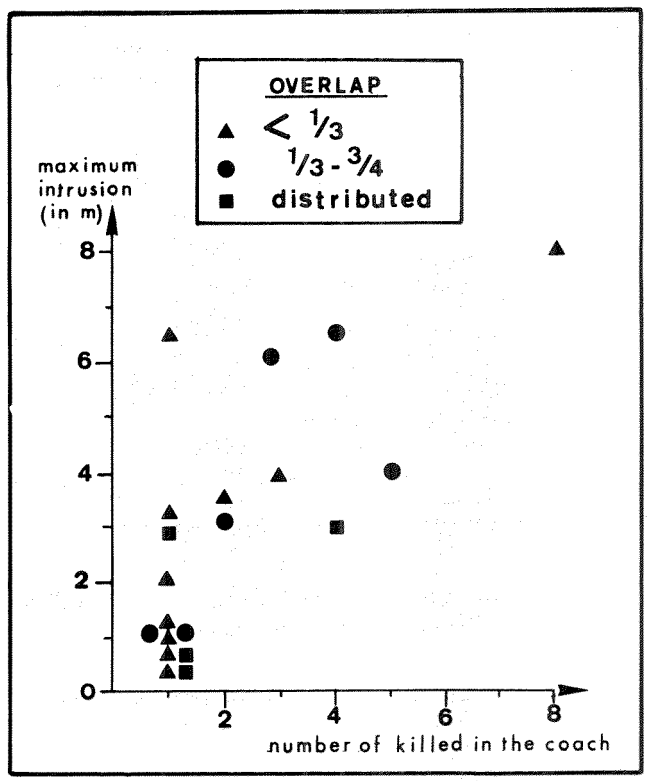

Figure 5. Number of killed in the coach

Rollover and Tipping-Over Accidents

In 14 out of 16 cases, rollovers occurred after the coach had left the road beside which was a shallow embankment of at least 1m in depth. An initial impact against a heavy vehicle and loss of control on a motorway without the vehicle leaving the road were the two remaining events precipitating rollovers. Estimation of the vehicle speed at the first moment of loss of control is given in 10 cases by the tachygraph and 6 by the driver or witnesses (Figure 8).

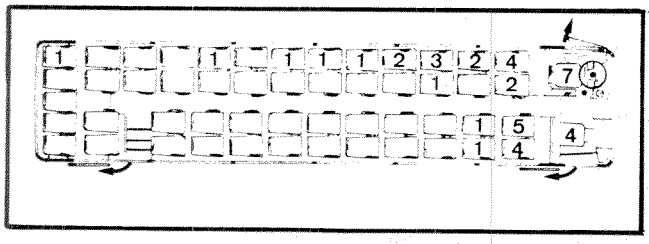

Figure 6.

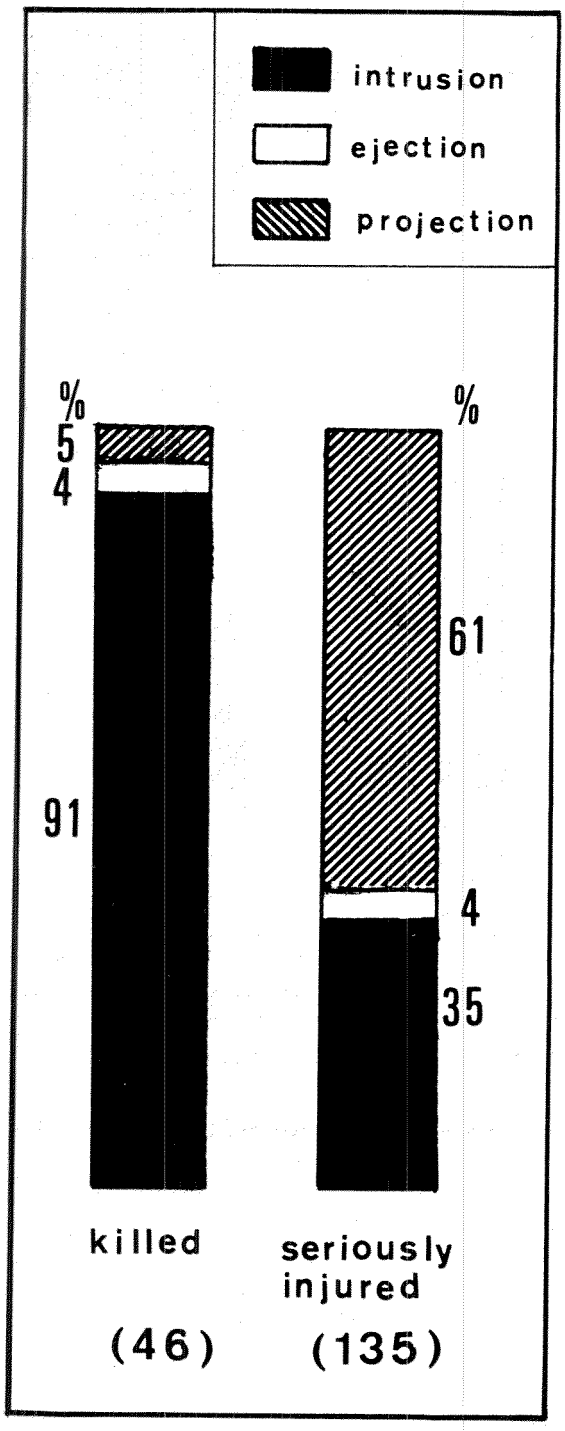

Figure 7. Injury mechanisms in frontal impacts

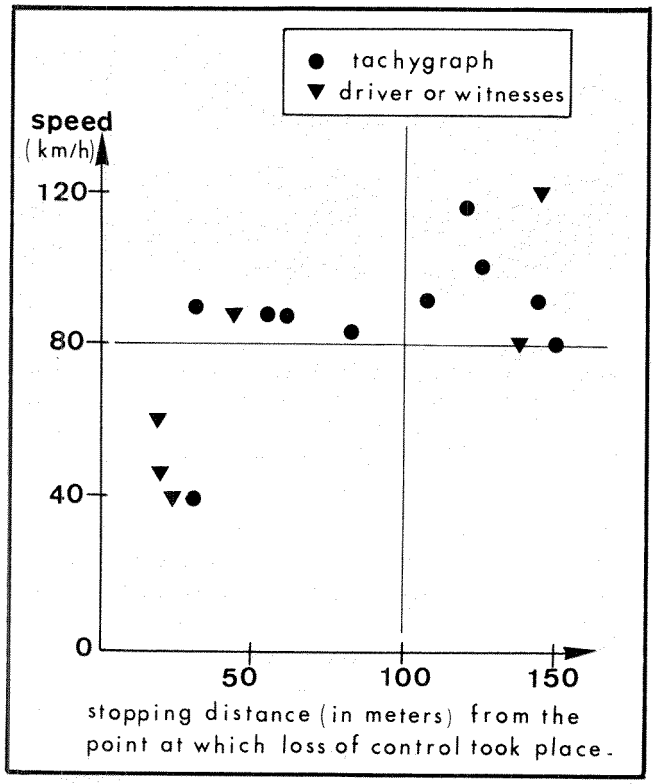

Figure 8. Estimated initial speed and stopping distance of coaches involved in rollovers

The forward motion of coaches during the accident is obvious. In about half the cases (7 out of 16), initial speeds were 80km/h or more with distances needed to stop not less than 100m.

Rolls (180° or more) with at least one contact "roof-ground" occurred in 10 cases, making 18 killed and 66 severely injured among the 329 involved. Tipping-over accidents (90° only) were observed in 6 cases—12 killed and 38 seriously injured were recorded among the 228 involved in such configurations. Thus, the importance of tipping-over accidents must not be underestimated. While there is no collapse of the body in tipping-over accidents, it must be mentioned that, in fatal coach accidents, distributions of the severity of injuries are rather similar between those involved in rollover and tipping-over accidents.

Coach Body Deformation and Severity for Occupants

The collapse of coach body was nil in 9 cases, partial in 3 cases (the crush did not exceed the upper quarter of the side window), and substantial in 4 cases (the cant rail reached the top of the seats).

The 7 cases with collapse of the body superstructure have been divided according to whether the tipping over or the rollover occurred on a flat surface or against an aggressive localized obstacle (an embankment or a highway guardrail—Figure 9).

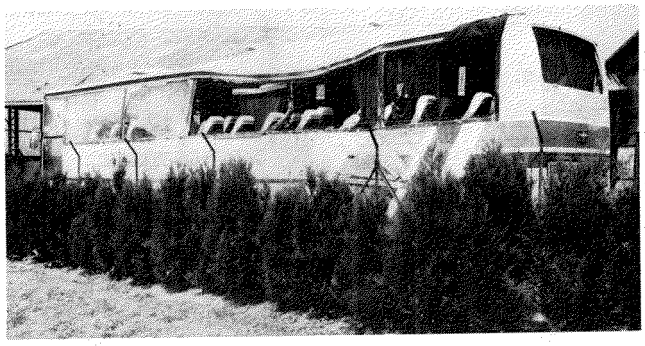

Figure 9. Localised coach body deformation after tipping over on a motorway against a median highway guardrail—5 killed, 14 seriously injured among 46 involved

It will be observed in Table 3 that the side collapse after a rollover on a flat surface occurred in only 3 out of the 16 overturned fatal coach accidents, representing 19 percent of all seriously injured persons. While coach deformations are spectacular in such cases, this configuration is not representative of the majority of seriously injured persons in coach-overturning accidents.

It is noticeable that 22 out of the 26 killed (exact place unknown for 3, and 1 standing up in the gangway) were sitting alongside the side windows (Figure 11).

Partial ejection occurred in rollovers inducing a collapse of one side of the coach body structure. On the impact side, the cant rail and also the luggage racks are crushed toward the gangway area (Figure 12).

It is noticeable that none killed and only a few seriously injured were observed in the rows offside the impact in spite of the reduction, there also, of the passenger space. In this configuration, all killed and most of the seriously injured were sitting alongside the windows on the impact side. In the collapse, people are partially ejected through broken tempered window glass and crushed between the ground and the exterior of the coach.

These victims represent 45 percent of those killed and 30 percent of seriously injured persons.

Last, the nonejected occupants have sustained serious injuries due to their projection against upper interior fittings or the side part of seat frames.

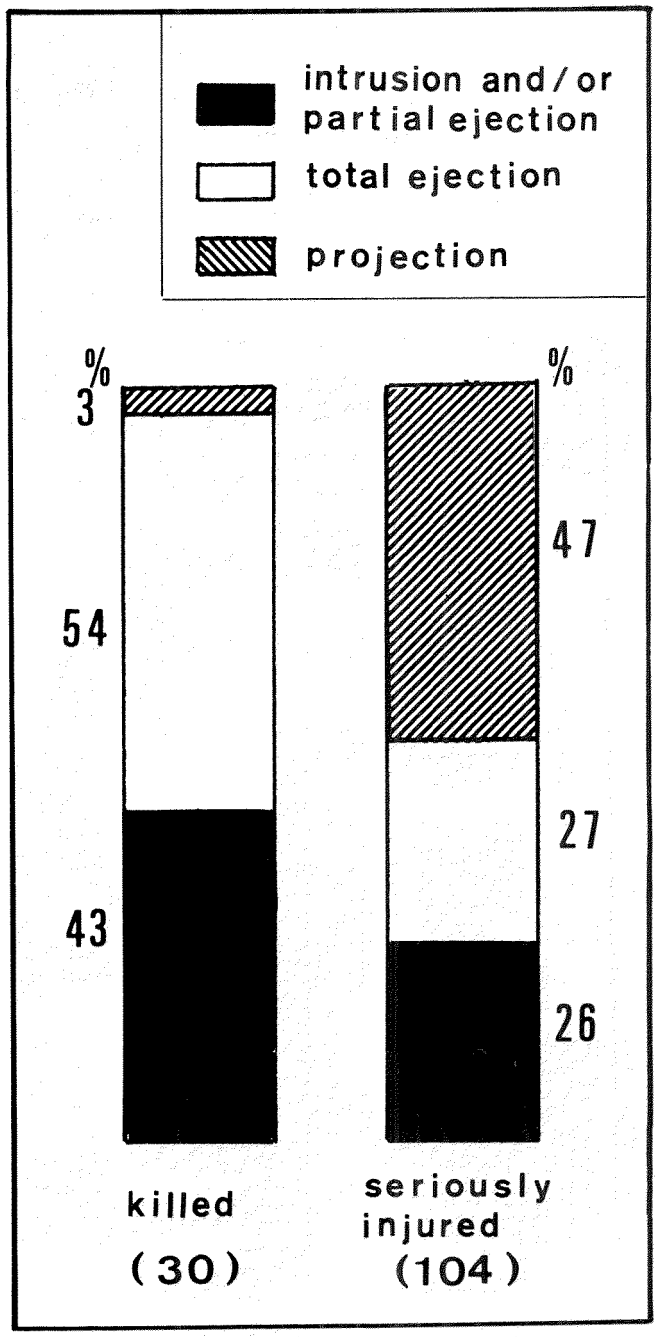

Figure 10.

Table 3. Distribution of victims by type of body deformation in coach-overturning accidents

Body Deformation	Obstacle Surface	Rollover (R) or Tipping-over (T) Accidents	Killed	Seriously Injured	All Involved
Nil or slight	Flat	4(R) + 5(T)	11	47	288
Side collapse	Flat	3(R)	9	16	121
Local collapse	Narrow and Stiff	3(R) + 1(T)	10	41	148
	Total	10(R)+ 6(T)	30	104	557

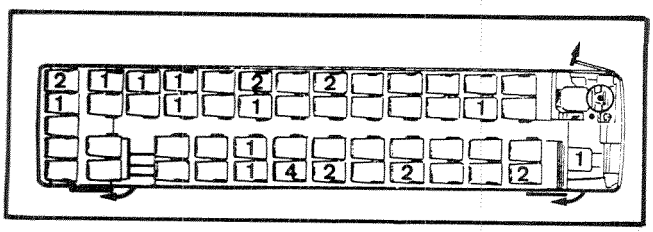

Figure 11. Distribution of 26 killed involved in overturning accidents by seat location

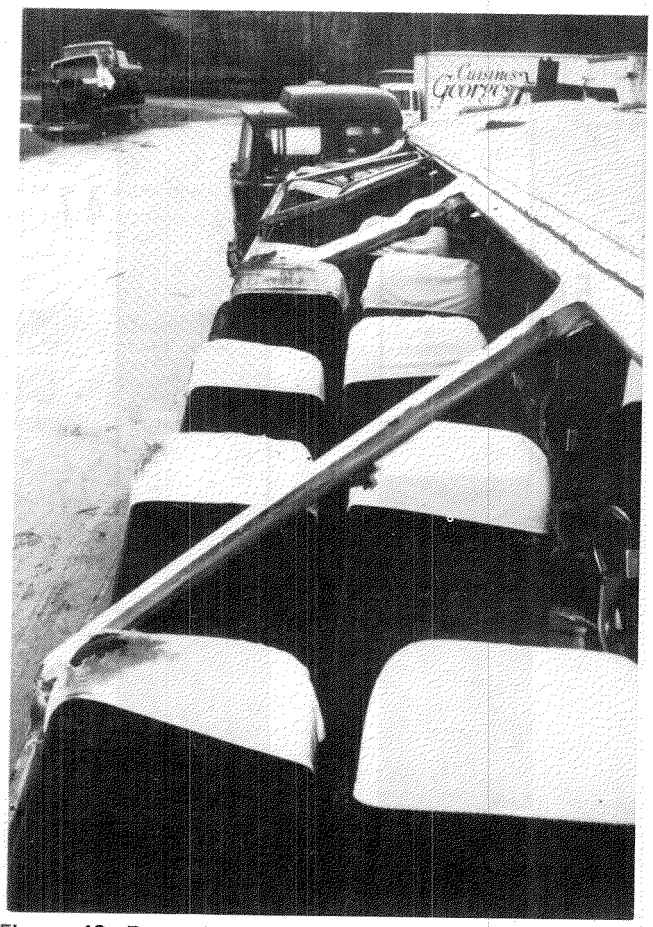

Figure 12. Example of side roof collapse—3 killed, 11 seriously injured for 42 involved

Other Accident Types

The 12 remaining accidents generated 55 percent (94 out of 170) of all killed but only 14 percent (38 out of 277) of all seriously injured studied in the sample.

The wide scatter of accident types (fire, falls into a ravine, side impacts, falls into water) and their respective severity has been previously given (see Table 2).

The coach fire problem was dramatically highlighted by the motorway accident that occurred at night in July 1982 in Beaune (Figure 13).

The coach was running at about 100km/h and, due to the slowing down of the preceding vehicles and despite braking by the coach, it hit the rear of four cars causing

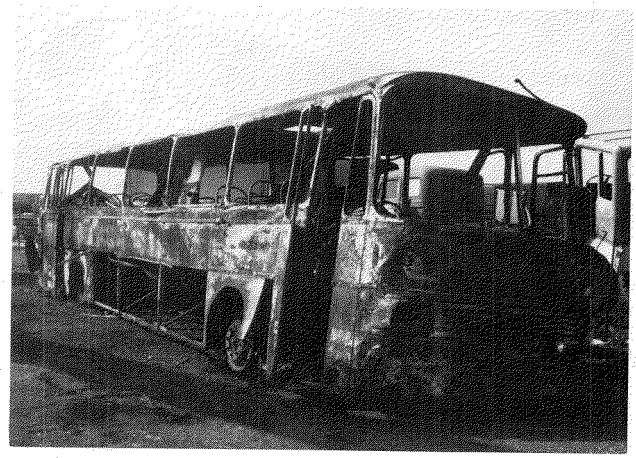

Figure 13. Fire accident—48 killed out of 64 involved

fuel tank damage with leakage for three of them. A fire immediately broke out, especially involving the front of the coach, which was only slightly damaged by actual impact.

Only 15 out of the 59 children and 1 of the 5 adults were able to escape by the rear door during a period not exceeding 2min. All of them were uninjured. The investigation showed that the victims were probably asphyxiated before being burned.

Falls into water were observed in 2 cases, generating 7 fatalities by drowning out of the 23 involved in the 2 slightly damaged coaches.

It appears from the survivors' statements that the main difficulty is to find and reach coach exits quickly. As far as fire accidents are concerned, it must be pointed out that the problem of emergency exits must not be underestimated since one-third of all fatalities (55/170) in the studied sample were related to this important point.

Only falls into ravines more than 30m deep are considered. As excepted, the severity is high since half of the involved (25 out of 50) were killed in the 2 recorded cases. The analysis pointed out that 16 fatalities have been crushed by the important collapse of the front end and roof structures. For the remaining 9 deaths, the absence of damage in their seat compartment areas indicated that projections of occupants were too severe and exceeded the human tolerance limits.

As far as side impacts are concerned, the obstacle was a truck in 3 cases and a tree in another. Passive safety in such collisions is not currently feasible. For example, in one truck-to-coach accident, the truck driver lost control on a bend and impacted the middle side of a coach coming from the other way. Despite the small degree of residual crush ($\leq$140mm), the 6 persons sitting alongside the windows in the impact area were killed.

The remaining 3 fatal accidents classified as "Others" were due to the death of the driver (driver feeling unwell two times, and hit by an external projectile lost by a truck in another).

Injury Mechanisms

Many different kinds of injury mechanisms leading to death were observed (Figure 14).

The importance of fire/asphyxia, intrusion, and projection against the occupant compartment walls will be especially noted. These three mechanisms together account here for virtually all the cases of death and serious injury.

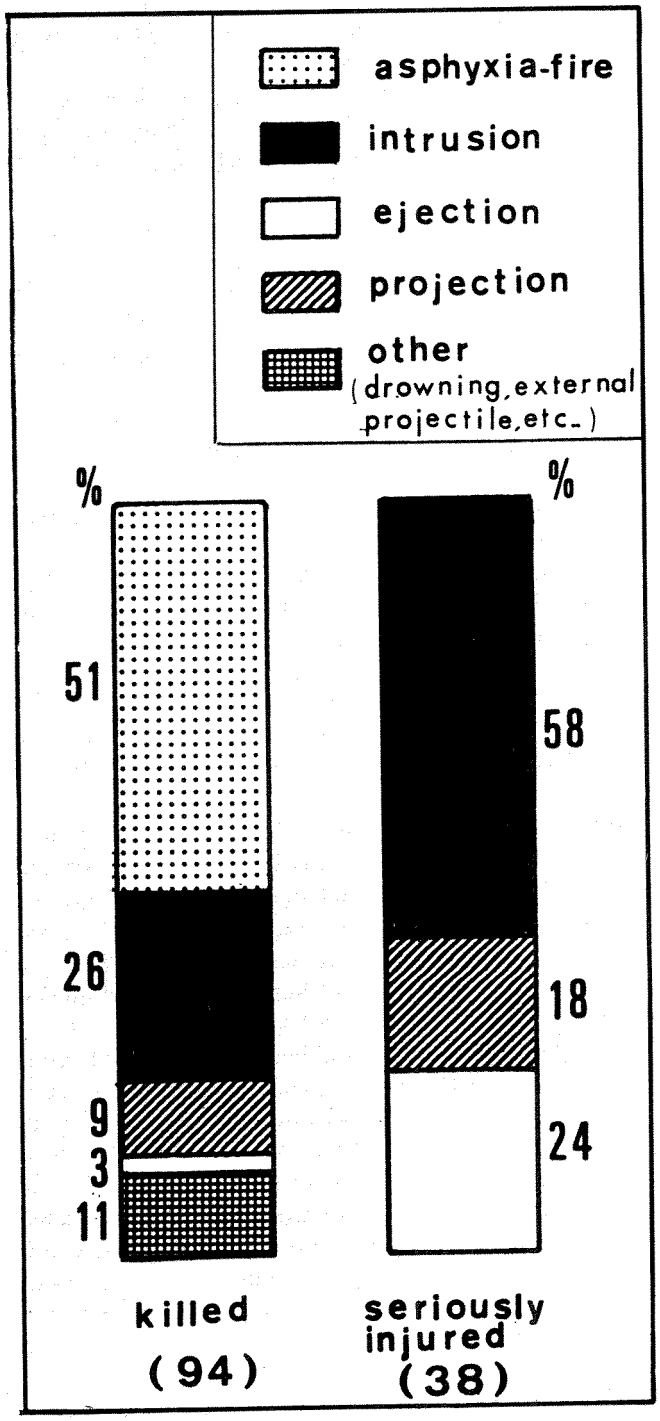

Figure 14. Injury mechanisms in accidents classified as "others"

Discussion

How can the safety of passenger coaches be improved?

One answer could be by action on active safety, primarily on braking, and by action in the field of passive safety—body strength, seat design, and better protection against the consequences of fire.

Braking Improvements

The kinetic energy reduction at the instant of impact can be determinant on the accident's seriousness. It is thus necessary to use to the maximum the potential possibilities of improvements in braking performance. These improvements should include—

- Improvements of speed reduction performance without brake overheating, especially in long descents
- Reduction of minimum stopping distances when the normal brakes are used
- Maintenance of directional stability during braking

It must be remembered that in 12 out of the 48 cases studied it was considered that better braking performance would have avoided the collision, or, at least, reduced the collision severity.

Mandatory retarders are recommended as a countermeasure in one case, but, as it is well known, most coaches today are not equipped with such a device.

Stopping distance reduction is concerned in 7 cases. A shorter stopping distance cannot always avoid the collision, but it permits a reduction in its seriousness, provided, of course, that the driver is not tempted to drive at constant risk.

Thus, the minimum stopping distance using normal brakes could be reduced by 12 to 15 percent and should not tend to increase the risk of wheel-locking.

The fitting of an antilock braking system would have been favorable in 4 out of the 48 cases in our study (loss of control during braking on slippery surfaces). The advantage is increased for vehicles with powerful brakes reaching wheel-locking limits even on dry asphalt.

Thus, these two measures—minimum stopping distance of braking and fitting of an antilock braking device—should be applied simultaneously.

Passive Safety

How can the passive safety of coaches be improved?

To answer this question, the injury mechanisms leading to death and serious injury must be borne in mind (Table 4).

Intrusion is the leading cause of fatalities in coaches. In frontal impacts, it would be desirable to increase front

Table 4. Summary of injury mechanisms

	Killed (n = 170)	Seriously injured (n = 277)
Intrusion	47%	35%
Asphyxia-Fire	28%	0%
Total ejection	12%	15%
Projection	7%	50%
Other	6%	0%
	100%	100%

structure resistance, especially in highly offset impacts, but the feasibility of this is doubtful. Reinforced coach stiffness aimed at avoiding intrusion from the front row of seats could be an objective. The problem of protecting the driver and the occupant of the hostess seat remains. In tipping-over and rollover accidents, proposed standards(1) aimed at avoiding crushing of the superstructure concern only a maximum of 6 to 15 percent of all severely injured victims in the sample. In the light of our analysis, it may be feared that, even if one managed to eliminate superstructure collapse sufficiently, the number of seriously injured victims would not be reduced significantly because of the high risk of ejection.

Ejection is the cause of 12 of 15 percent of serious injuries and occurs mainly in overturning accidents. Ejection occurs via side windows (71 percent), the windscreen (22 percent), and the rear window (7 percent). A simple lapbelt would provide effective protection against the risks related to total ejection. A 100 percent wearing rate would eliminate 12 percent of all deaths and many serious injuries also. To combat ejection, the other alternative is that of restraining uncontrolled kinematics by the windows themselves (acting as a net). This could be achieved by adding glued laminated glass. This totally passive safety characteristic could in addition improve coach structural resistance. Such an approach, however, has the disadvantage of militating against rapid passenger evacuation (except, if satisfactory solutions in terms of emergency exits—whatever the coach's final position after impact—can be developed).

Last, it seems that lowering the height of the bottom of the side windows increases ejection risk. In the absence of either making the window act as a net or of restraint system use, the bottom of the side window should not be lower than the shoulder of an average adult passenger.

Projection of a passenger against internal panels of the coach compartment was the cause of half the serious injuries, but only of 7 percent of deaths. It is only really possible to envisage two countermeasures, that is wearing a restraint system or modifications to seat backs:

- Restraint System—Case-by-case analysis shows that wearing a seatbelt, even a 3-point type, would not have avoided with certainty any of the few cases of deaths due to projection that occurred mainly in falls into a ravine

  The countermeasure of universal wearing of 3-point belts among all the seriously injured in our sample would, according to our estimate, have lessened the injuries of 43 percent (120/277) of such nonfatally injured people, taking all impact types together. This percentage contains a wide range of conditions of very different presumed effectiveness and type of protection achieved (Table 5).

  The countermeasure of universal wearing of a lapbelt among those seriously injured in our sample would have forestalled 25 percent (70/277) of such injuries, taking all impact types together. The difference in the preceding estimates is due to the fact the wearing of a lapbelt would not provide a cranio-cervical protection in frontal impacts. This evaluation does not take into account the possible adverse effect mentioned by recent reports(3) in frontal cases.

  However, these are estimates of maximum benefits, and it is believed such devices would be less than universally used in coaches. Thus, the only efficient action, without compulsion for coach users, consists of improving the restraint effect of seat backs.
- Seat-back Improvements—These modifications would aim at achieving the following objectives, especially in frontal impacts:
  - Limiting the forward movement of the occupant to the back seat without overloading to the occupant seated in front of him.
  - Reducing the seriousness of lower limb impacts (for example, by knee bolsters) and of cranio-facial injuries (for example, by appropriate padding). Such modifications should take into account the simultaneous need to protect both children and adults, especially the elderly.

  Compared to 3-point belt-wearing, the effectiveness of this purely passive protective device is less pronounced because it only concerns occupants seated behind a seat back; and such a device cannot, in case of very oblique frontal impacts, prevent all risks for occupants seated near the central gangway.

  All in all, this countermeasure could, in our view, eliminate 20 percent of all those seriously injured.

The last point related to passive safety is the consequences of fire. Fire as a cause of death is rare. Nevertheless, we should mention that the fire case studied highlights the problem of being able to get occupants clear of coaches quickly. The same would be true for

Table 5. Presumed effectiveness of 3-point belts for all seriously, but not fatally, injured occupants

Impact types	Number of seriously injured avoided by prevention of		Presumed 3-point belt effectiveness
	...projection	... ejection	
Frontal	50	5	41% (55/135)
Overturning	36	24	57% (60/104)
Others	1	4	13% (5/38)

coaches falling into water. Apart from such cases, the problem does not arise.

One may note that the means of achieving the two aims of reducing ejection and facilitating evacuation are currently contradictory. Can the frequency of ejection be reduced by increasing the number of emergency exits, especially through the side windows?

In this context, doors seem to be the emergency exits that are the most rational and involve the fewest problems. In case of tipping-over accidents, the possibilities of transforming the rear window and roof windows into emergency exits cannot be neglected. In all cases, the rapidity of evacuation must be a priority, and everything must be done to maintain clear and free gangways, door approaches, and emergency exits.

The effort to obtain better flammability characteristics of vehicle interior materials must be pursued, but it is also necessary to consider the effects of smoke emission and toxic gas, which may accompany such fires. The fact that smoke is opaque is an important cause of panic, and carbon monoxide induces paralysis, particularly of the lower limbs. Measures aimed at improving smoke emission evacuation will reduce the risk of asphyxia and facilitate the rapid escape of coach users.

Conclusion

Travel by coach is by far the safest means of road travel, but seeking ways to prevent coach accidents or to lessen their effects is still necessary.

This survey, based on 48 fatal coach accidents, shows it is clearly preferable that accidents be avoided by greater care being taken by coach drivers, since 73 percent of these were blameworthy in the studied sample. But because an exceptionally large number of people are at risk in such accidents, improvements in the construction of coaches must also be developed if some of the causes of death and serious injuries are to be minimized.

Shortening stopping distances by increasing braking performances could avoid or reduce in severity about 15 percent of the cases studied.

Intrusion in frontal impacts is the main cause of death in coaches. Increasing coach front structure resistance, especially for highly offset impacts, would be desirable, but the feasibility of this is questionable.

In the sample analyzed, death by being thrown forward against a seat back has not been observed, but this accounted for half of those accidents involving serious injuries. Particular attention should be given to improving seat backs to insure adequate passive restraint for head and lower limbs in frontal impacts.

Total and partial ejection are frequent and severe in rollover and tipping-over accidents. Window retention using glass plastic products mounted so as to act as a net could prevent ejection without any restraint usage. But such a device is in conflict with the need to be able to use all glass-covered apertures as potential emergency exits, particularly in cases of falling into water or the outbreak of fire. Improvements in escape routes for the last two cases must be considered.

In case of fire, measures aimed at evacuating smoke emission will reduce risk of asphyxia and increase the time available to leave the vehicle.

To provide a chance of assessing more precisely the effect of feasible and necessary safety measures, doing so on the basis of very severe coach accident data, the comparison of independent studies has to be intensified through the auspices of international organizations.

Acknowledgments

Optimisation of a Bus Superstructure from the Rollover Safety Point of View

D. Kecman
Faculty of Mechanical Engineering, Belgrade
Consultant to Cranfield Impact Centre

G.H. Tidbury
Cranfield Impact Centre, Cranfield, United Kingdom

Abstract

Bus superstructures may soon be subject to new rollover safety requirements. Increased rollover safety must be achieved with minimum weight or cost penalty; hence, optimisation has a significant practical relevance.

This paper demonstrates the possibility of predicting the collapse performance of a bus superstructure by a completely theoretical model. The work described also created a basis for the option offered by the new regulations that allows type approval by calculation combined with some component tests. It also shows how a safety structure can be optimised from the weight or cost point of view by means of a special computer program.

Introduction

The importance of adequate bus rollover safety has been recognised for many years. Bus superstructures may soon be subject to new rollover safety requirements, which are currently being discussed by Working Party 29 of the ECE.

The regulations are likely to offer the following choice of methods for obtaining type approval:

- A standard full-scale rollover test
- Pendulum tests on individual structural segments (bays)
- A calculation method, combined with some component testing

The standard full-scale test implies rolling a complete vehicle from a tilting platform onto a horizontal plane 800mm below. The superstructure must not intrude into a residual (survival) space defined with reference to the H-point and centreline of the seats. Such a test is very expensive and unsuitable for development purposes.

The pendulum test on structural bays is carried out by an oblique impact at the cant rail level. The speed of impact is 3 to 8ms, while the impact energy represents a fraction of the total energy for the complete bus. The energy is proportional to the mass of the vehicle and the vertical fall of the centre of gravity between the maximum level of the fitting platform and the position corresponding to the first contact of the body with the ground. The energy declared for each pillar of the bay must meet five constraints specified by regulation.

The introduction of the calculation method was based mainly on the work carried out at the Cranfield Impact Centre(1-6), although such an option was in the original Hungarian submission to the Working Party. It will almost certainly be a requirement that the calculation must include effects arising when the structure undergoes large plastic deformations. Separate component tests may be required to verify the assumptions for the collapse behaviour of components.

A calculation method offers not only the chance to obtain type approval without large-scale testing, but it is also suitable for bus body development and optimisation in terms of both safety and economy.

Theoretical Prediction of the Collapse Behaviour of a Complete Bus

Bus bodies under impact develop localised bending failures—hinges, which absorb most of the impact energy. Investigation of almost 30 bus rollover accidents(5) identified a variety of collapse modes (Figure 1). Mode A with hinges at the waist and cant rail levels was most common. Hinges at the floor level (B,C) occurred mainly near door apertures, while roof members also collapsed (D,E) in some cases. Control of the overall collapse mode is very important because it affects the amount of deformation prior to the intrusion into the survival space. Mode A usually provides the greatest angles of hinge rotation.

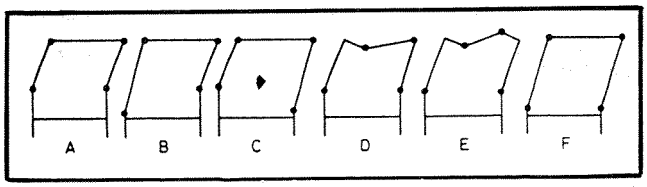

Figure 1. Collapse modes of bus rings

Isolated rings collapse in mode F, which demonstrates the effect of the surrounding structure (cladding, longitudinal beams, seats, floor) in altering the collapse mode of any ring in a bus body. These effects were studied within the elastic range(6), and it was demonstrated they can be modelled successfully by springs C and C, attached as shown in Figure 2. The impact load P is applied obliquely to one of the cant rails.

Spring C has an axial and bending stiffness selected in such a way that the bending moments of the floor, waist, and cant rail levels of the simplified model correspond to those obtained by a much more detailed elastic analysis of a segment of the body.

It was also demonstrated that rings with an incomplete floor member (i.e., without the dotted line in Figure 2) are much more flexible than the complete ones. However, the typical restraining effect of the surrounding structure in the vertical direction (simulated by spring C) is sufficient to eliminate the effect of the central gap on the collapse mode.

A collapse analysis of a complete, all-metal body of a coach was carried out(3,4,6). The skeleton was made of rectangular and square section tubes clad with aluminium sheets. A quasi-static analysis of a standard rollover test situation is possible because of a relatively low impact speed (less than 10ms) and because the mass of the deforming structure is much less than the mass that is being retarded.

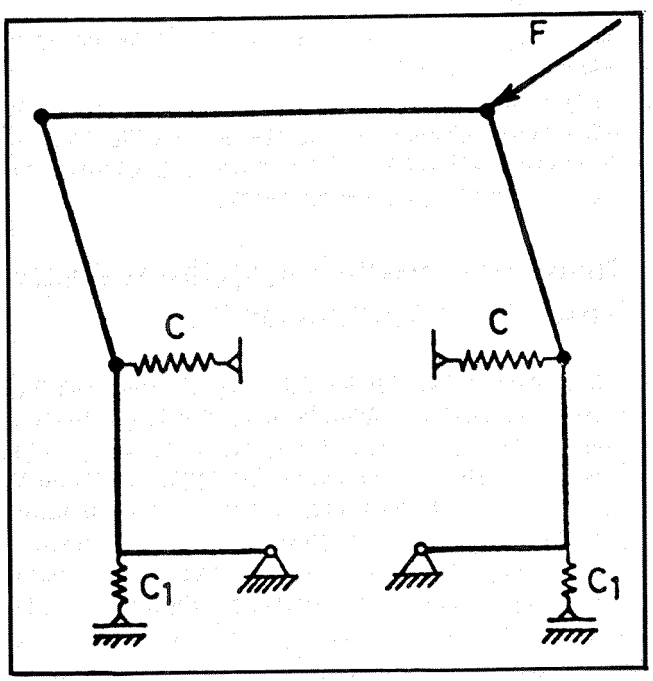

Figure 2. Collapse mode of bus ring with springs simulating the connecting structure

Collapse analyses were performed using the Cranfield Structural High Deformation program CRASH-D, which allows for the highly nonlinear effects of large deformations, hinge occurrence, and variable hinge moment-rotation curves.

The analysis started with the elastic finite element model in Figure 3a, which included all the main beam and plate elements. Loads were applied obliquely along the cant rail and the main load paths determined. It was shown theoretically(3) that the collapse mode can be controlled by careful selection of the side components below the waist rail. The model for collapse analysis was much simpler (Figure 3b) and included only those main elements that would form the main collapse mechanism. Fictitious beams were attached laterally to the pillars at

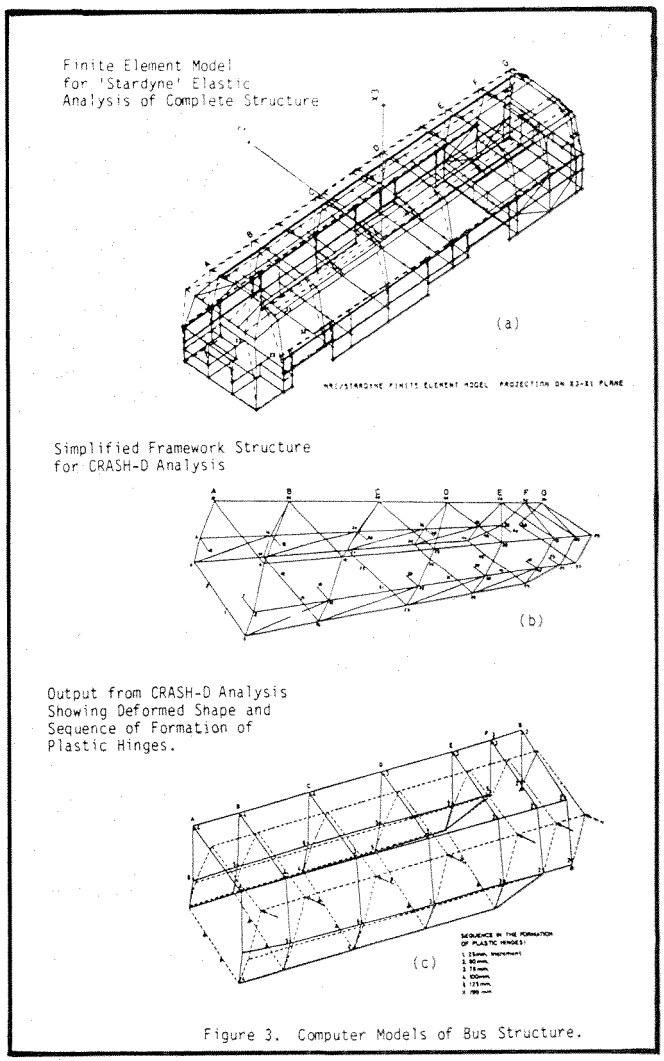

Figure 3. Computer models of bus structure

the waist rail level to simulate the effect of those elements in the side structure that were eliminated from the first model.

The theoretical collapse mode (Figure 3c) predicted hinges at the cant rail and waist rail level in all rings except the front door, where the hinge occurred below the waist rail. Secondary hinges, which did not take part in the main collapse mechanism, were also predicted at the floor level of all rings. The full-scale test of the vehicle (performed after the analysis) gave an excellent agreement with the predicted location and character (primary or secondary) of all hinges.

To predict the final deformations of the structure, it was necessary to determine the energies absorbed by each ring and compare the sum with the total energy input. At the time of analysis, variable hinge moment-rotation curves could be modelled in two-dimensional structures only. The theoretical load-deflection curves of all rings were, therefore, produced by separate analyses. Rings A and G (Figure 3c) included two normal rings, but they collapsed differently. The elastic stiffness of all rings was obtained from the model in Figure 3a, and the theoretical collapse phase was common to all normal rings. Theoretical moment-rotation curves, including the calculated strain-rate effect, were used in the model.

The energy input per ring was equated to the area under the load-deflection diagram, and hence the maximum ring deflections were calculated. Comparative results are summarised in Table 1, where δ_m represents the maximum deflection of the cant rail when it is impacted along a line at 30° to the floor cross-member. The difference is less than 15 percent except in ring F (21 percent), to which displacements could not be applied directly. The agreement is, in fact, better than is shown in Table 1 because experimental displacements were measured after the test when some springback from the maximum deflections had already taken place.

Section Optimisation From the Safety Point of View

The bending moment that can be carried by a thin-walled rectangular section tube drops off rapidly after the onset of collapse. Repeatability of collapse modes produced by uniaxial bending enabled a definition of the theoretical hinge collapse mechanism to be made(6,7). The bending and rolling deformation along the concentrated yield lines (Figure 4) was related to the hinge rotation angle θ, as was the energy absorbed by plastic

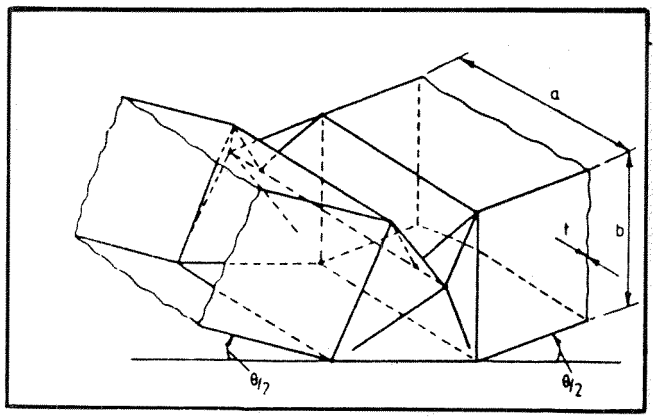

Figure 4. Theoretical model of hinge collapse mechanism

deformation. In such a way, it was also possible to derive the theoretical M-θ curves (Figure 5c) in terms of the section dimensions a, b, t (Figure 5a) and the yield stress o and maximum nominal flow stress of the material (Figure 5b). The theory was verified by very extensive experimental work on tubes with a/t ratios between 9 and 128 and a/b ratios between 0.33 and 3. The agreement with experimental data was excellent (examples are shown in Figure 6).

The theory provided a basis for the development of a section optimisation program WEST(8) for the selection of the lightest or cheapest standard or nonstandard section tubes meeting the following safety criteria: maximum bending strength, energy absorbed, and remaining strength after a given hinge rotation angle. It

Ring	A	B	C	D	E	F	G
δ_m(theoretical)(mm)	536	555	505	491	488	488	430
δ_m(experimental)(mm)	577	550	508	466	424	402	385

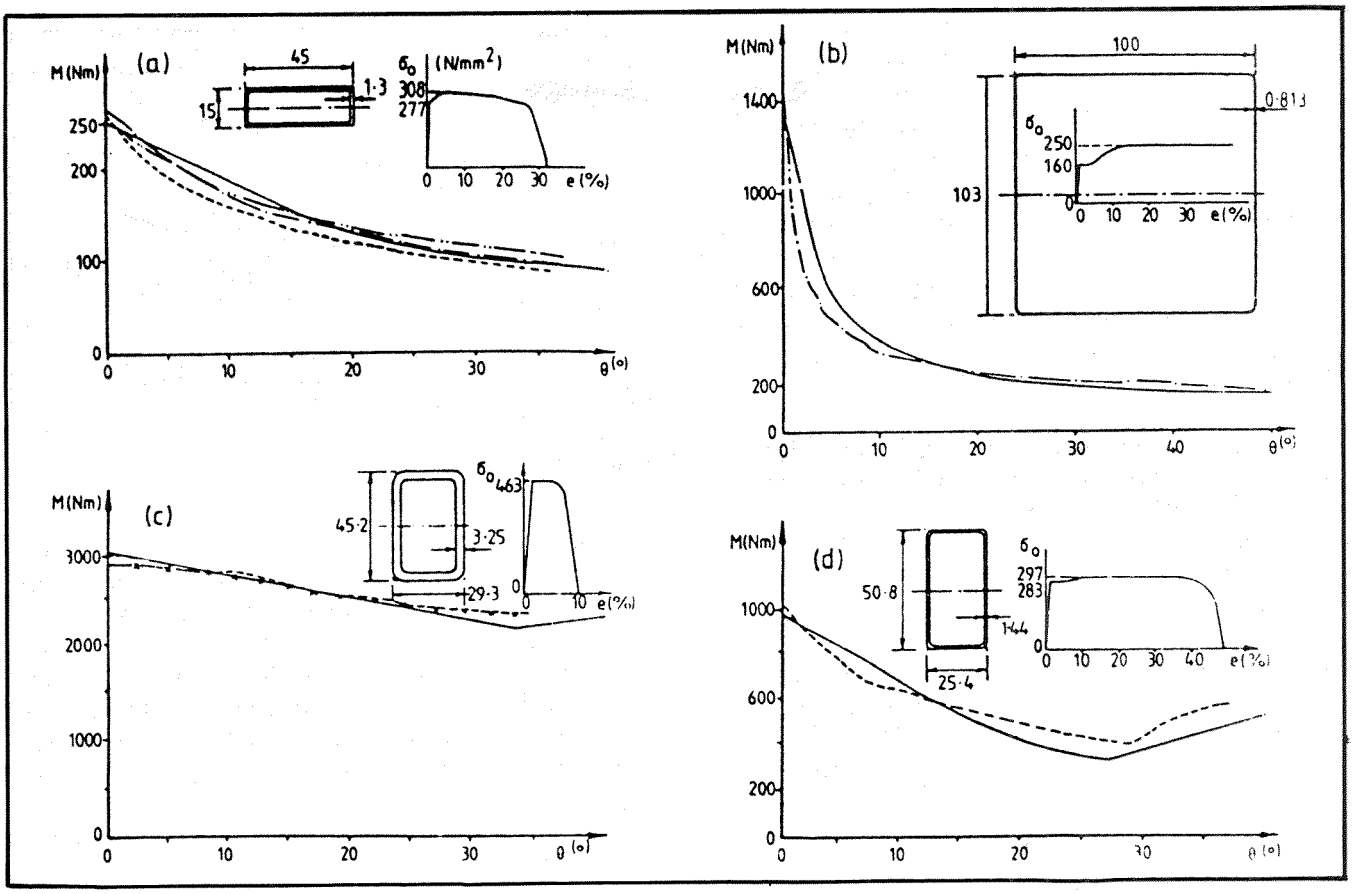

Figure 6. Theoretical (solid) and experimental (dotted) curves for a range of tube dimensions

also enables selection of minimum material properties if section dimensions and the target safety performance are specified. The program can also produce the bending collapse properties of given sections, which may be used further, either directly in design or as input data to finite element programs for collapse analysis.

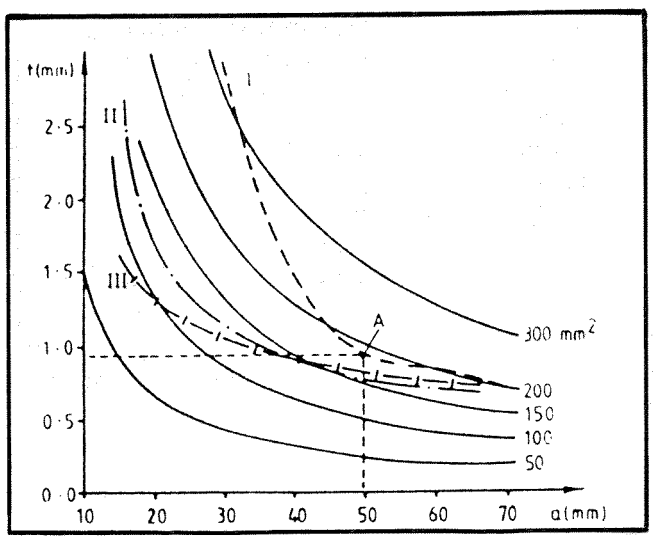

Figure 7. Diagram illustrating operation of optimisation program WEST

The most general case corresponds to the selection of a minimum weight theoretical section made of a given material and meeting one, two, or all three of the safety constraints. By specifying the ratio of the properties about the two principal axes, it is possible to determine the aspect ratio a/b of the section and reduce the number of variables to two, say a and t (Figure 5). Each of the constraints can then be solved for the wall thickness t starting from a range of values of the width a. Three curves are thus obtained (I, II, and III in Figure 7). The section with minimum area, i.e., weight, corresponds to the point A that is lowest on the complex surface defined by constant area curves (shown solid in Figure 7) but that does not fall below any of the three curves I, II, and III.

Procedure for Optimisation of a Bus Structure From the Rollover Safety Point of View

Optimisation of a bus structure from the rollover safety point of view is performed in the following stages:

(a) Choice of the general concept (e.g., two safety rings at the front and back, or no special rings). Subsequent steps allow a parallel estimate of both options.

(b) Assume starting section dimensions and perform an elastic analysis of the complete body or the segment as if it were going to be subject to a pendulum test (main load paths are determined and information on the effects of noncollapsing members is estimated).
(c) Perform collapse analysis of a simplified model, using collapse properties calculated by the program WEST and allowing for the full range of deformations required to absorb the energy required.
(d) Analyse the results of step c and determine the hinge rotation angles and energies required. Use these as input data to the program WEST to determine new section dimensions or material properties, depending on which of the four program options is considered most significant (lightest standard or nonstandard tube, cheapest standard section, or material for given dimensions).
(e) Repeat steps (c) and (d) until the best solution is found.
(f) Repeat steps (b) to (d) to check that the alterations do not introduce important new effects on load redistribution, elastic stiffness, etc.
(g) Design and produce components (beams and joints) based on the theoretical analysis and test them to collapse statically and dynamically (by a small pendulum). This exercise should prove that the assumptions concerning beam and joint stiffness, strength, and energy-absorbing properties are correct.
(h) Accept the solution, or repeat the same procedure with appropriate corrections if results of step (g) require it.

Conclusion

A design procedure has been outlined that involves the use of three computer codes:

- A standard structural finite element code working in the elastic range, e.g., Stardyne
- A special large deflection framework code that includes collapse hinges—CRASH-D
- An optimisation program for the choice of tubular framework members—WEST

The time involved in carrying out the procedure is short enough to become part of the early design process for a new vehicle. It provides the most rational and cost-effective method for the design of structures to comply with the new strength of superstructure regulation.

Acknowledgments

While the optimisation code is solely the work of the first author, the general method of analysing the whole structure was developed at the Cranfield Impact Centre under the sponsorship of the Department of Transport.

Improvements for Bus Safety

Klaus Rompe and
Hans Joachim Krüger
Institute for Traffic Safety, TÜV Rheinland e.V., Cologne

Abstract

Today about 14 percent of passenger transport on the roads is accounted for by buses. For bus occupants, the risk of being killed as a result of a bus collision is about 40 times lower than in passenger car accidents. Therefore, buses can be classified as road vehicles with the most upgraded safety. Nonetheless there are some aspects of safety still to be developed in the future:

- There is still a lack of objective criteria designed to assess the driving behavior of the new type generation of high-capacity buses.
- Underfloor cockpits restrict the driver's field of vision and expose the driver and, hence, the occupants to additional risk of injury in accidents. Bus driver cockpits could be adequately improved at low cost.
- The anchorage of seats and the capacity of deformation energy of backrests can be exploited to incorporate an advanced passenger restraint system.
- There is need for specifying criteria of effectiveness applicable to emergency exit systems.

Safety of Buses

Today approximately 14 percent of the total passenger transport on the roads of the Federal Republic of Germany is accounted for by buses(1). It is obvious the safety of these vehicles is a reason for their attractiveness. The risk of being injured in an accident by bus is 10 times lower than in a passenger car accident. Referring to the number of kilometers per person, the risk of being killed is even 40 times lower. There are, however, three essential arguments for a further increase of bus safety in the future:

1. Along with the technical development of safety components in buses, e.g., antiskid devices, retarders, headlight range adjustment, and passenger protection devices, there has also been a change in the construction concept of buses. In modern bus construction, the permissible limiting values for the outer dimensions—18m long, 4m high, 2.5m wide, and weight 28t—today are fully exploited (Figure 1). For long-distance travel, high- and double-decker buses—even in an articulated form—have become more popular, and, as a result of their increasing number, they also play a role in the overall accident occurrence. There is, however, especially for these vehicle types, very little knowledge concerning the driving properties, particularly in critical driving situations(2).
   Recently, for reasons of cost, more and more lorry chassis parts are used for bus construction. This raises the question as to whether this will change the design strength of the bodywork in a collision and the structural aggressivity of the vehicle toward other vehicles.
2. Due to the heightened seating position of bus occupants, the consequences of collisions with other traffic participants are generally not severe. The construction of high- and double-decker buses, however, could favor the frequency of the accident type "running off the road." The danger arises of overturning and, at the same time, up to 150 passengers are subjected to a hazardous

Figure 1. Modern high-capacity coach dimensions (above—18 x 2.5 x 4m, seats100-144; below—18 x 2.5 x 3.2m, seats 68-80)

situation, e.g., individual survival space is not granted by the structural strength.

3. Children and elderly persons figure significantly in the number of injured bus passengers(3). Since these persons are more or less dependent on bus transport, their protection should be particularly considered.

By order of the Federal Ministry of Transport, the Institute for Traffic Safety of TÜV Rheinland has conducted several investigations to find new possibilities to improve bus safety.

Safety is based on the ergonomic design of the bus driver's workplace. The driver obtains essential information for driving by his vision. Therefore, the sight from the vehicle to the front, to the side, and via the mirrors to the rear is of particular importance (Figure 2).

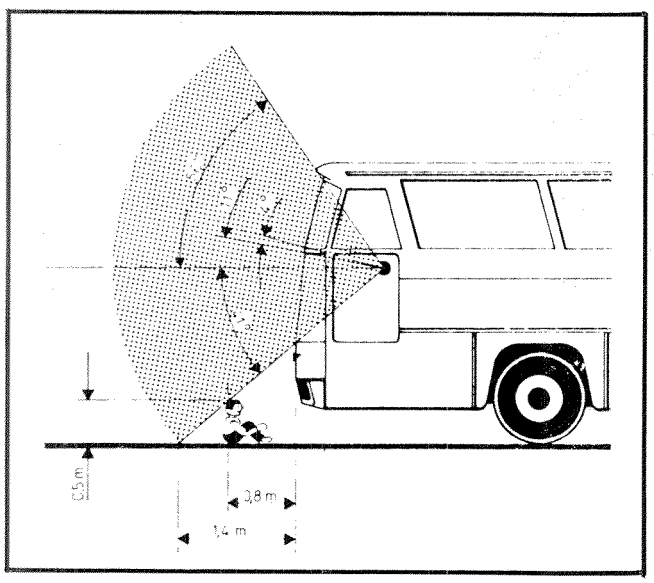

Figure 2. E-point level and frontal direct field of vision

For high-decker buses, an average height of the driver's eyes of 2.2m above the road was calculated. Together with the extremely large surface of the windscreen, this means perfect vision to the front. For underfloor cockpits, coming more and more into use, the eye level 0.5m lower than usual causes problems concerning safety. The all-round vision of the driver is limited, and the danger of the driver being injured in an accident with a passenger car (the most frequent participant in a collision) is increased (Figure 3).

If the sight conditions to the right and to the rear are taken into consideration, problems are caused by the conflict between structural strength and the required unhindered all-round vision (Figure 4)(4). Nonmisting, heated side windows, additional mirrors, and a television system at the rear of the vehicle could be technical solutions. A comparative assessment of the different possible systems is being effected at present.

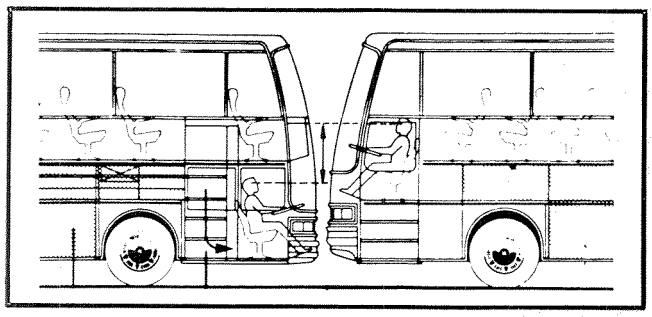

Figure 3. Eye level in underfloor cockpits

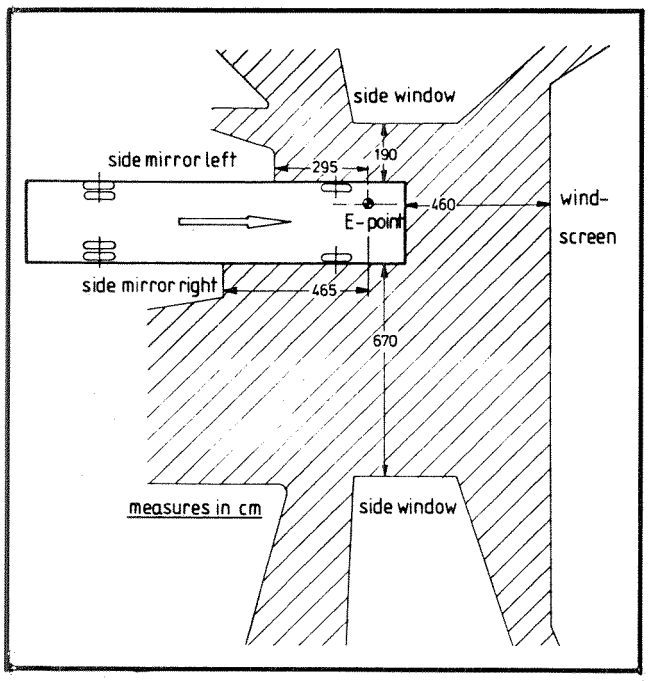

Figure 4. All-round field of vision

Also, control switches and monitoring instruments must be arranged favorably within the driver's field of vision. It is, however, questionable whether he is able to observe up to 84 displays besides his actual task of driving (Figure 5).

Based on our measurements and driver interviews, further improvements are required, especially for the ergonomic design of control devices at the driver's workplace(5). One example is a suitable resting place for the left foot in a rest position. The slope of the accelerator frequently does not meet comfort requirements. To reduce the time of change from the accelerator to the brake pedal, the half-loaded accelerator should be positioned approximately to the same height as the unoperated brake pedal.

Within the driver's reach, all control devices should be arranged within a radius of approximately 700mm around the shoulder joints. This requirement is not yet fulfilled in all cases. The movements of the gear level,

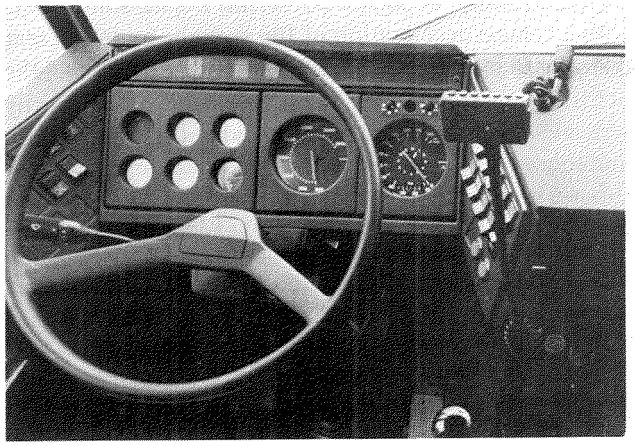

Figure 5. Instrument panel with 84 controls and displays

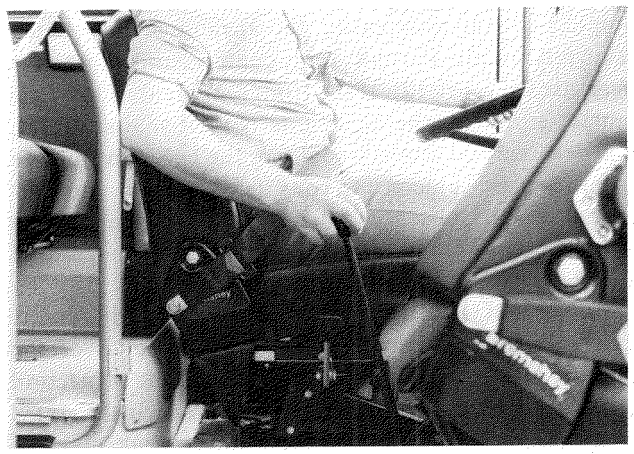
which are still necessary, exceed this range by far (Figure 6).

The example given in Figure 7 shows that one hand must leave the steering wheel to activate the windscreen wiper. To maintain continuous two-handed steering, all controls operated frequently should be located within finger reach around the steering wheel.



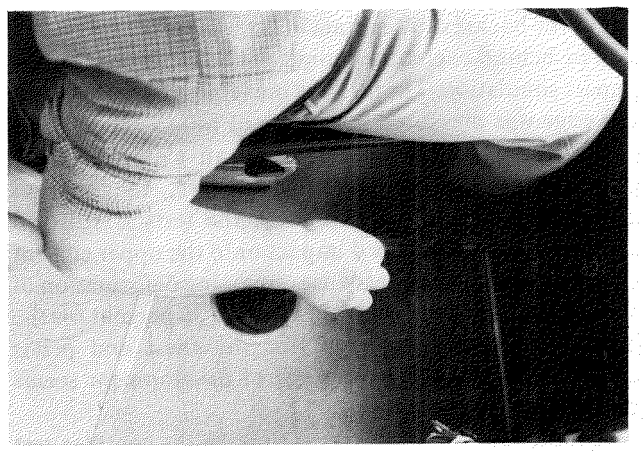


Figure 6. Nonergonomic gear level position

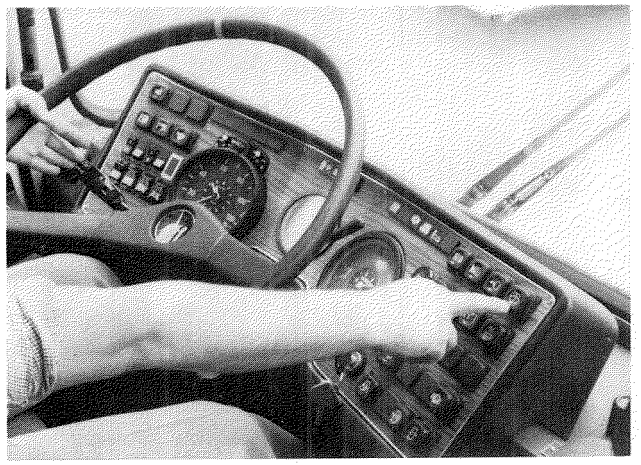

Figure 7. Interruption of two-handed steering for switching on the wiper/washer system

Although the driver's workplace conditions in buses are sufficient in general, these examples show that further improvements are possible without great effort.

Fifty to 60 percent of all bus accidents are head-on collisions, more than half of which are collisions with passenger cars. Because the passenger seats are located about 1.2m above the road, the risk of bus occupants being injured is relatively low. However, the risk is considerably higher in overturning vehicles. The risk of the occupants being injured or killed occurs particularly when the vehicle deformation does not maintain necessary survival room for the passenger seats. If the passengers are thrown out of the vehicle, the risk of being killed is about six times higher than in similar accidents with passenger cars(6,7). In about 50 percent of all overturning accidents, passengers are thrown out. Therefore, the accident type "overturning of vehicle" must be given more attention in the future.

In the Federal Republic of Germany, long-distance buses with a permissible travelling speed of 100km/h for motorways must be equipped with lapbelts for those seating positions that do not have a similar seat in front of them—the so-called risk seats. However, the systems available at present with uncomfortable locks, long belt straps, and even with automatic locking retractors are not accepted voluntarily by the passengers (Figure 8). Moreover, automatically locking lapbelts, such as those currently in use, restrict the occupants and it has proven difficult to have them fasten their belts. It has, therefore, been investigated in comprehensive studies how to improve the restraining effect of seat systems to add to occupants' safety(8,9).

During the first stage of the investigation, we varied the distance between the seat rows from 700 to 1,000mm. In simulated head-on collisions with vehicle decelerations of 5g, we measured the strain of different size dummies in sled tests. Figure 9 illustrates the movement paths of an adult dummy for head, chest, and pelvis. On the left part

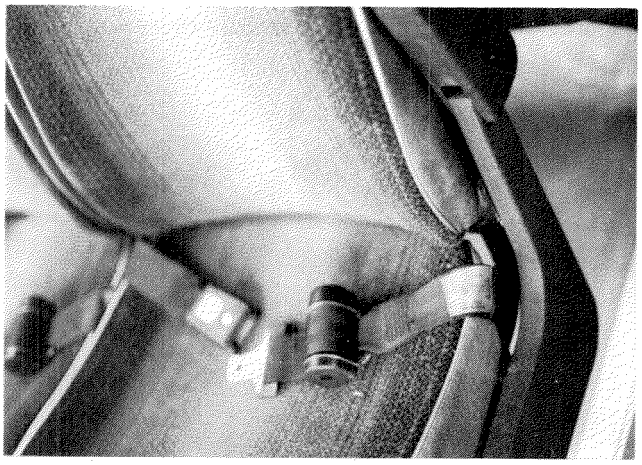

Figure 8. Lapbelts on exposed seating positions in 100km/h limit coaches

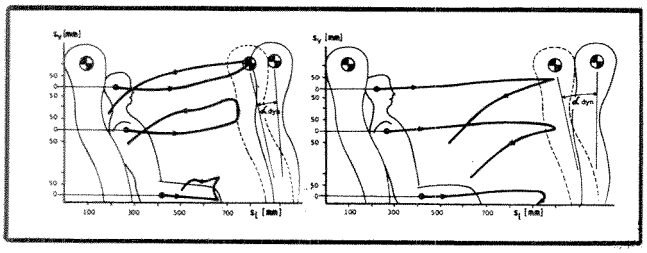

Figure 9. Trajectories of child-dummy movements at 5g deceleration in different distances between two forward-faced double seats (left—70mm; right 900mm)

of the figure, the distance between the seats is 700mm; on the right, it is 900mm. The test results showed that, for child as well as adult dummies, a minimum of injuries may occur with a distance between the seats of 800 and 850mm (Figure 10). This figure illustrates the resulting head acceleration in a head-on collision for an adult dummy as a function of the distance between seats. Due to different impact conditions of the head onto the backrest of the front seat, the strain of the occupants is increased for small and long distances between the seats.

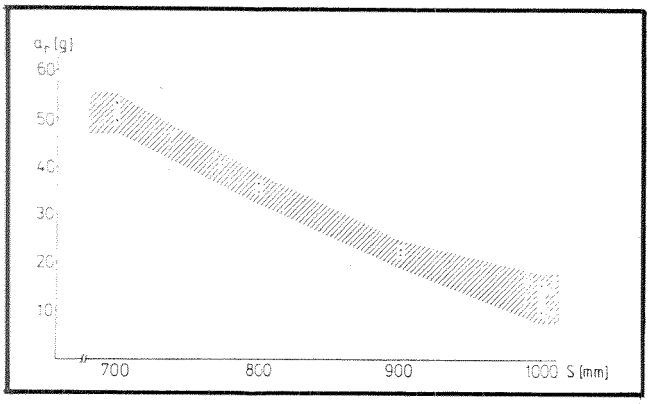

Figure 10. Resultant head deceleration of child-dummy as a function of distance S to the next impact

Subsequently, we carried out further impact simulations with a vehicle deceleration of 10g with the optimum seat distance to investigate the strain on the dummies and the deformation behavior of the front backrests. Primarily we stated that the seat anchorage did not stand the strain and loosened. Figure 11 shows a construction drawing of this anchorage on the left outer wall of the vehicle and on the bottom of the right side of the vehicle. To change the

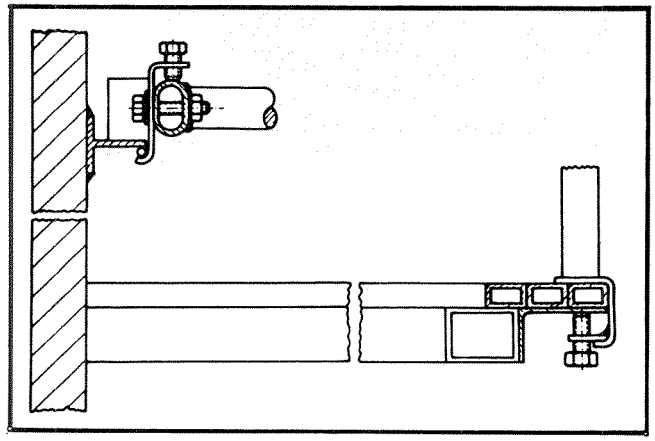

Figure 11. Lateral and inside elements of seat anchorage

number of seat rows easily, the anchorage is executed relatively simply. Partially, only compression joints have been used (Figure 12). If the front seat breaks loose, the impact strain on the occupants is relatively small. If, however, several seat rows loosen, the occupants on the front rows are subjected to considerable strain. Furthermore, partially loosened or displaced seats will hinder the work of emergency helpers considerably in case of accidents.

For further tests, the seat rows were fixed additionally. The measured strain on the chest and pelvis of the dummy was relatively low compared to the protection criteria to be considered concerning the survival chances of the passengers. For the head, however, peak values of 150g were measured, caused by impact of the head on the top of the backrest. A contact of occupants sitting side by side or behind each other could not be observed for this impact simulation. The forward movement of the backrest top edge was measured in a range of 140 to 180mm.

If the seat is considered to be an element of the occupant-restraining system in buses, the energy-absorption capacity measured in the tests is still too small. Especially the head impact onto the upper edge of the backrest does not yet cause remaining deformation of the seat. A reduction of strain of about 30 percent for the head and about 15 percent for the chest and pelvis compared with the actual stage of development seems possible.

Another aim of the tests was to leave the complex test procedure using dummies with complete instrumentation

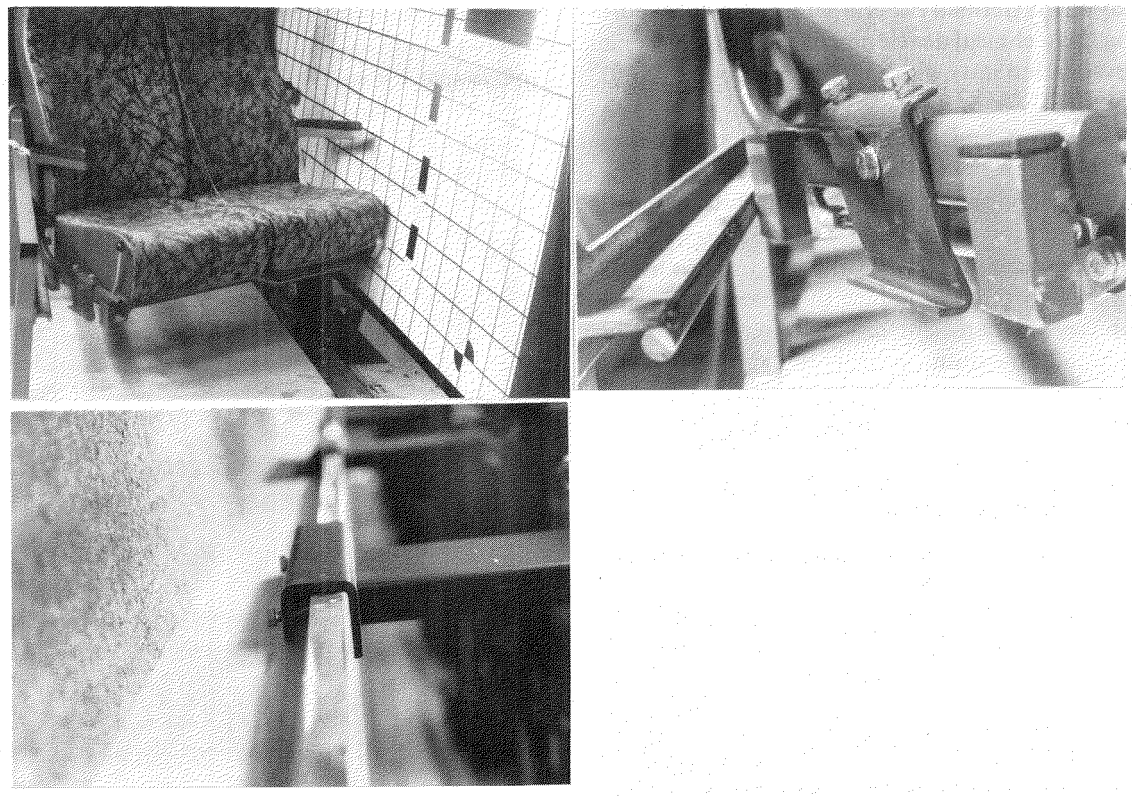

Figure 12. Failure of anchorage elements in a simulated 10g frontal impact

and develop a simplified test procedure. In several stages, the required masses were reduced accordingly without considerably changing at the same time the kinetical and kinematical ratios during the impact (Figure 13). Such a test procedure will give much help to the manufacturers of bus seats concerning increased safety for passenger room. If the resistance of the seat anchorage on the vehicle bottom is guaranteed, it will define individual survival room for each passenger, considering also the required backrest deformation (Figure 14).

At least for two accident types, the severity of the accident results is considerably dependent on the bus emergency evacuation system. After a collision, single exits may be blocked within the collision range. In general, there are sufficient evacuation possibilities in the residual compartment.

In case of the vehicle overturning, however, more than half the exits may be blocked. Escaping from the compartment to the top requires enormous physical strength. Compared to the normal escape direction to the back or through the roof, this way seems to be a detour. The most important requirement for an emergency evacuation system is caused by a burning vehicle in a lateral position.

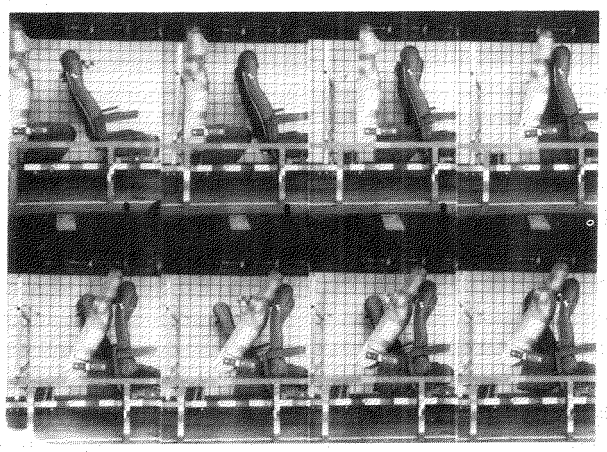

Figure 13. Simplified test with reduced dummy masses

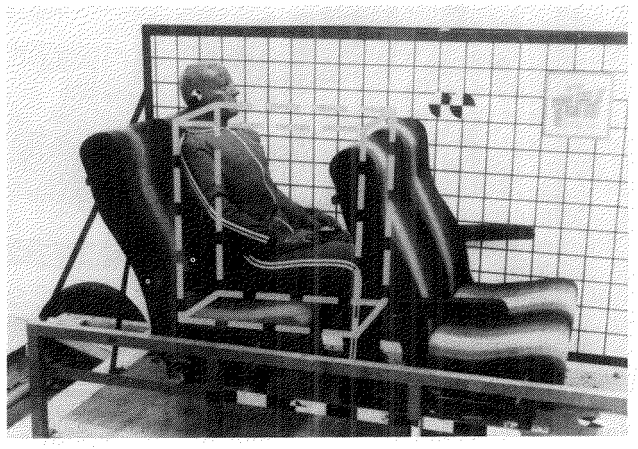

Figure 14. Individual survival room for each passenger

In a study by the German Federal Ministry of Transport concerning the technical development of emergency exit systems, evacuation tests with a children's group (8 to 10 years) and an adult group were carried out in a long-distance travel bus and a short-distance bus. During several test runs, the following main escape directions were prescribed: doors (Figures 15 and 16), as well as two emergency windows on the left side (Figure 17). A platform was erected in front of the windows to avoid injuries caused by jumping. Since the emergency scene shown for the compartment discourages hesitation in front of a free evacuation opening, the platform was a protection measure(10).

The evacuation tests showed the following results:

- .Escape route: doors

  For each vehicle type, the evacuation was finished after about half a minute (children, long-distance travel bus: 40s). Two-thirds of the passengers escaped through the rear door.
- Escape route: two emergency windows, left side (2 and 4 side window)

Figure 15 Evacuation test through the doors with an adult group and a short-distance bus

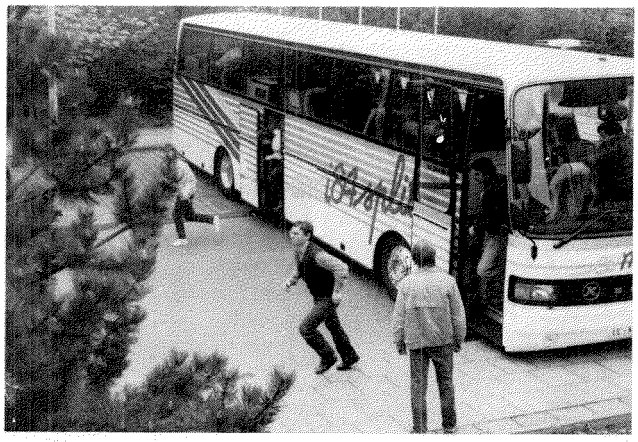

Figure 16. Evacuation test through the doors with an adult group and a long-distance travel bus

Figure 17. Evacuation through an emergency window

Destroying the window glass and removing approximately 90 percent of the window surface required 15s, equally for single- or double-glassed windows. Half the adult group left the vehicle by each window within less than 1min (52s).

It seems important that, in case of alternative escape routes, the doors—especially the rear door—are preferred. As a result, a stoppage is caused in front of the rear door, whereas the capacity of the other exits is not fully exploited. Improvements will be possible for the ergonomic design of the exit aids, for children in the door area and for adults with access to emergency windows. As the most effective measure, the internal door access areas should be kept free (ticket barriers, folding seats, etc.).

For a normal position of the vehicle and an escape route to one side, the evacuation time is less than 1min. The relative requirement for airplanes is 90s. This is based on the toxic effect of fumes, which determines the escape time of possibly injured passengers. Up to now, accident analysis has not yet brought secured time values for vehicle evacuation.

A comparison of international construction regulations concerning bus emergency exit systems shows that, besides the minimum requirements for vehicle construction, there exist alternatives for a great number of other

technical solutions. The position of the individual emergency exits and the necessary opening by folding out, removing, and destroying (tool!) require detailed knowledge and ability of the bus passengers, which, in general, is not given. In contrast to construction regulations for airplanes, there is need of an effectiveness requirement for the bus emergency exit system, based on the required evacuation time.

From the frequent use of doors, these must range equally as an element of the emergency exit system. The mounting position of the emergency door-activating device must be determined on a standard basis within a limited area for vision and handling by the standing bus occupant. This device must be secured against unauthorized use (threshold of shrinking from an impulse for action). An emergency door at the vehicle's rear could be an additional main escape route.

The rigid side windows consist of single security glass and guarantee also the structural rigidity of the vehicle compartment. As a result, opening each of these windows by destroying it is given as a technical solution and could mean a most important capacity increase for the emergency exit system. The necessary emergency hammer—available only within vision and handling range—raises a reasonable expectancy of effectiveness, also for nonspecialists.

Emergency holes in the roof could be an efficient escape route with a minimum climbing height, especially from vehicles in a lateral position.

The improvement of passenger safety must be proved with an efficiency test of the emergency exit system. Subject to test methods still to be determined, a limiting value of 45s seems possible for evacuating a completely occupied, upright-standing vehicle.

It is required also for developed bus emergency exit systems that the passengers have good knowledge of the details. Therefore, it seems important to instruct bus passengers regarding the emergency equipment of each vehicle, its use, and passenger behavior.

This study has made it clear that improvements of bus safety are necessary and possible.

Heavy Truck Safety—What We Know

Henry E. Seiff
Motor Vehicle Manufacturers Association

Abstract

The overall highway fatality rate has dropped almost continuously since 1925, from 20 to 2.5 per 100 million miles of travel in 1984. Still, the almost 44,000 fatalities in 1984 can and will be decreased. In 1983, 5,475 of the 42,584 highway fatalities were in accidents involving medium or heavy trucks. Only 18 percent of these were occupants of the trucks themselves; 82 percent were pedestrians or occupants of the other vehicle. The greatest number of combination truck accidents takes place on two-lane rural roads. Single-vehicle accidents are responsible for 70 percent of heavy truck occupant fatalities. Doubles and heavier trucks appear to be as safe as other heavy trucks. Rollover and ejection are responsible for the greatest number of truck occupant fatalities.

When asked about her top priority as the new Secretary of Transportation, Mrs. Dole replied, "There's no higher mandate for the Department than to promote safety. . . ."

The Secretary is particularly concerned with heavy truck safety.

Several years ago, the Motor Vehicle Manufacturers Association (MVMA) summarized the state of heavy truck safety research in its presentation, "Heavy Truck Safety—The Need to Know." It emphasized the urgent need for adequate safety research as a foundation for improving heavy truck safety. It is appropriate now to follow up with a summary of the things we have learned since that time and to place the heavy truck safety problems in perspective.

In reviewing highway fatalities and fatality rates for all motor vehicles, we see the extraordinary safety gains that have been made over the past 60 years (Figure 1). The fatality rate (persons killed per 100 million vehicle-miles of travel) has dropped almost continuously from 1925 to the present—from nearly 20 to 2.5 in 1984. Although vehicle-miles traveled have constantly increased, with the exception of World War II and a short time after the 1973 and 1978 oil shortages, the total number of highway deaths peaked in the late 1960's and early 1970's. The year 1984 marked a 22 percent decrease in deaths from the high year of 1972, despite a 36 percent increase in vehicle-miles traveled(1).

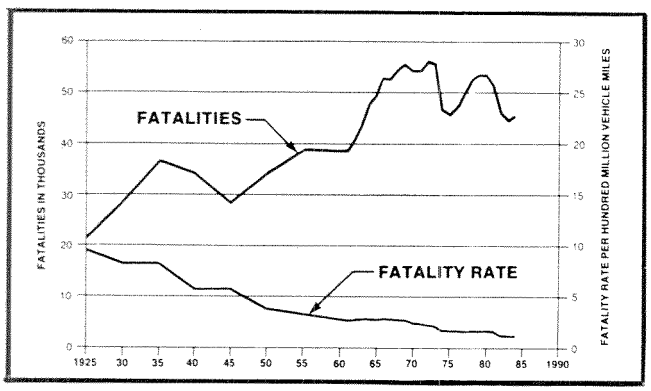

Figure 1. U.S. motor vehicle accident fatalities, 1925-1984

Although we can be justly proud of these figures, we still had almost 44,000 fatalities on our highways in 1984. We believe we can and will lower this number in future years.

The reasons for decreases in both the fatality rate and total fatalities include safer vehicles, safety belts, highway safety improvements, child restraints, better medical care, the 55mph speed limit, the imposition of the Federal Motor Vehicle Safety Standards, improved driver skills and attitudes, and the antidrunk driving campaign of recent years. We are doing better and can be especially proud to see fatalities continue to drop at a time when Americans are switching to smaller, lighter cars, and truck size and weight are increasing.

Of the 42,584 highway fatalities in 1983, the latest year for which we have detailed data, 5,475 were in accidents involving medium or larger trucks, that is, all trucks over 10,000 lb gross vehicle weight rating.

Of these 5,475 fatalities, only 18 percent were drivers and passengers in the trucks themselves; 82 percent were pedestrians or occupants of the other vehicle—the passenger car or light truck—in a multivehicle accident.

Among the truck occupant fatalities, 735 were occupants of combination vehicles, usually a tractor-semitrailer combination. Two-hundred and forty-four were occupants of straight trucks(2).

Since 1979, fatalities in medium and heavy truck accidents have generally been decreasing as have all highway fatalities (Figure 2). From 1976 through 1979, the increase in truck accident fatalities paralleled the increase for all highway vehicles (the quality of the National Highway Traffic Safety Administration's Fatal Accident Reporting System data on truck accidents in those early years was questionable, so we have reason to believe the relatively low numbers of fatalities in 1976 and 1977 may be understated).

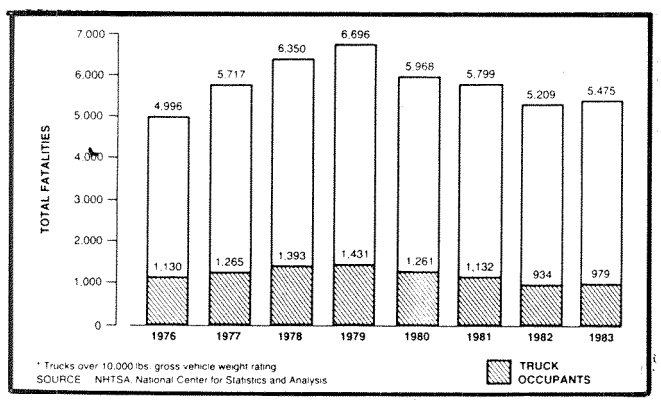

Figure 2. U.S. fatalities—medium and heavy truck accidents

Part of the recent decrease in truck-related fatalities was certainly due to the business downturn of the past few years and the consequent decrease in truck mileage. However, combination vehicle-miles dropped less than 1 percent from 1979 to 1983 while fatalities dropped 15 percent, so there has been a real drop in truck-related fatalities these past few years.

The vast majority of the medium and heavy trucks involved in fatal accidents are tractor-semitrailer combinations(3) (Figure 3). Although doubles were allowed in 36 States in 1981, for example, doubles and triples together were involved in only 3 percent of the fatal accidents for that year.

Combination vehicles as a group have a slightly lower accident rate than do passenger cars, but a substantially higher fatality rate (Figure 4). Although we have a lot more to learn about why this is true, some things we do know.

Because of the wide difference in mass between a heavy truck and a car or pickup truck, a multivehicle accident

	Number	Percent
Single Unit	3,632	24
Tractor-Semi	9,917	66
Doubles/Triples	455	3
Bobtails	383	3
Other, Unknown	631	4
Total	15,018	100

Figure 3. Types of trucks involved in U.S. fatal accidents, 1980-1982

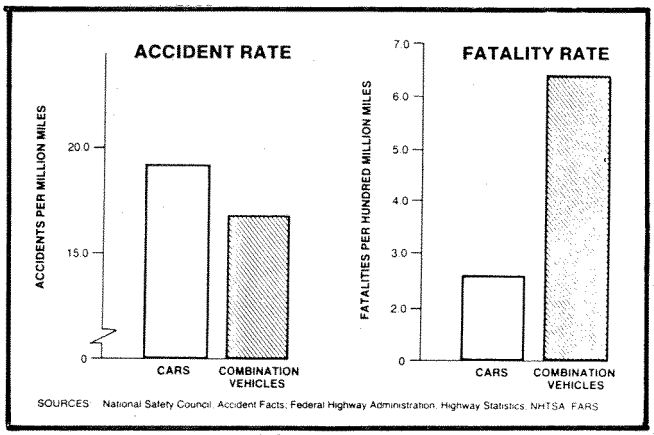

Figure 4. U.S. accident and fatality rates for passenger cars and combination vehicles, 1983

involving those vehicles is especially dangerous to the light vehicle occupants.

Although combination trucks operate more miles on the Interstate highways than on any other kind of highway, Figure 5 shows the greatest number of fatal accidents takes place on two-lane rural roads. Because vehicles are traveling at high speeds in opposite directions on these undivided highways, accidents can be more frequent and more serious than on Interstates or other divided multilane roads.

Combination vehicles travel 63 percent of their miles on rural highways(4), being used primarily to haul goods between cities or from farm or factory to city. This accounts for both a low accident rate and a high fatality rate. Because there is less congestion on rural than on urban roads, there generally are fewer accidents. But, because of higher speeds on rural roads, each accident tends to be more serious than in the city, leading to a higher fatality rate.

Single-vehicle accidents, involving such things as a truck running off a high-speed highway, rolling over, or hitting a stationary object like a tree, are responsible for 70 percent of the heavy truck occupant fatalities, even though they represent only 30 percent of the fatal accidents.

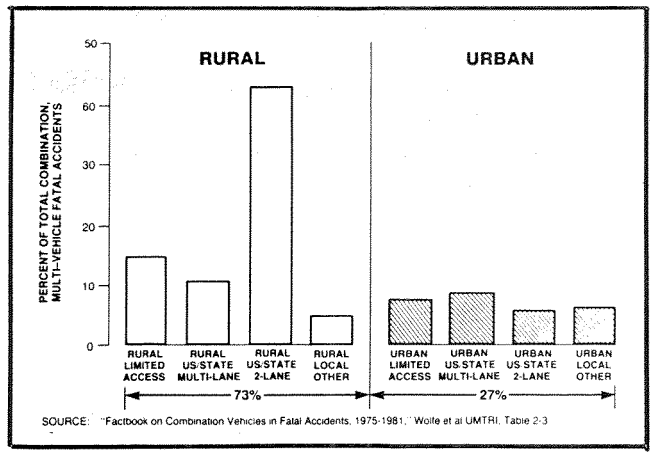

Figure 5. Where do combination multivehicle fatal accidents take place? (1976-1980)

Multivehicle accidents represent 70 percent of the fatal heavy truck accidents, but only 30 percent of the truck occupant fatalities(5). Truck accidents are most dangerous to the occupants of the other vehicles involved.

We mentioned earlier that doubles and triples combined were involved in only 3 percent of medium and heavy truck fatal accidents. Unfortunately, information is not available yet to allow a definitive safety comparison of tractor-semis and doubles operated under identical conditions. The studies that have been done produced inconsistent findings. Four studies found the doubles accident rate lower, two studies found it higher, and three found no significant difference between the two kinds of trucks.

After evaluating studies done by others and all existing data, the University of Michigan Transportation Research Institute has concluded that the involvement rate of the two types of trucks is nearly the same(6).

The Supreme Court agreed with the University of Michigan in cases involving the operation of doubles in Wisconsin and Iowa. The Court found, "The evidence convincingly, if not overwhelmingly, establishes that the 65-foot twin trailer combination is as safe or safer than the. . .55-foot semi."(7)

The use of larger and heavier trucks to increase productivity has raised questions about their safety. As with doubles, studies have produced conflicting conclusions. Reviewing existing studies on the subject, the Ontario Commission on Truck Safety found that an overall increase in safety cannot be effectively achieved by limiting, within acceptable bounds, the weight or size of trucks. The Commission noted that once trucks had reached a weight of from 15 to 20 times that of passenger cars, increasing the weight further did not seem to have any effect on accident severity(8).

Clearly, heavier and larger trucks can move freight in fewer vehicles, reducing fuel usage, costs to consumers,

and the total miles of operation during which the vehicle is exposed to traffic hazards.

Where the truck, the truck driver, or the truck's operating environment were seen as contributing factors to a fatal accident, the University of Michigan found 64 percent were driver-related, 27 percent were environment- or highway-related, and 9 percent were vehicle-related(9).

When the truck driver contributed to the accident, driving too fast was identified 27 percent of the time; failure to keep in lane or driving on the wrong side, 19 percent; carelessness or inattention, 17 percent; failure to yield or to obey traffic controls, 13 percent; and improper following or passing, 7 percent. Drowsiness and fatigue were cited only 6 percent of the time.

The combination vehicle driver in a fatal accident is involved with alcohol only 4.5 percent of the time, compared to a 46 percent involvement in all fatal accidents(10).

When highway or environmental conditions contribute to the fatal combination vehicle accident, obscured vision and swerves, due to weather conditions, highway design problems, etc., are identified as the major factors(11).

When vehicle condition was identified as contributing to a fatal accident, the brake system and tire and wheel problems accounted for nearly 80 percent of the contributing factors(12). Although only 9 percent of the combination vehicle fatal accidents were identified as involving vehicle-related factors, there is no doubt that in many instances good vehicle design and maintenance can allow a driver to safely compensate for his mistakes and avoid an accident.

The experience of the Bureau of Motor Carrier Safety is important in evaluating the role of vehicle condition. The Bureau inspected over 33,000 interstate trucks in 1982. It put 37 percent of those vehicles "out of service" for "imminently hazardous" mechanical problems. The Bureau finds that almost half the maintenance problems that led to putting vehicles out of service were related to brakes, followed closely by lighting or electrical problems, tires, and wheels(13). While the Bureau selects vehicles for inspection based on its estimation that they are in greatest need of inspection, "out-of-service" percentages were not that much lower when vehicles were selected at random.

The Bureau of Motor Carrier Safety's new State grant program, (Motor Carrier Safety Assistance Program), combined with the State and Provincial reciprocal inspection program of the Commercial Vehicle Safety Alliance, will insure that many more vehicles are inspected on the highway from now on. The Bureau found, in a four-State pilot study of increased truck inspections, a 25 to 52 percent reduction in truck accidents from 1979 to 1981(14). If these initial results can be projected to a nationwide program, we can expect a substantial decrease in truck accidents in the future.

The National Transportation Safety Board (NTSB) conducts detailed investigations of individual traffic accidents. From 50 heavy truck investigations, NTSB has isolated these accident causation factors:

- The driver
- Vehicle-braking capability
- Vehicle mechanical condition
- Steering or directional control
- Coupling devices
- Fuel systems
- Truck cab environment

In three-fourths of these investigations, NTSB identified the truck as the primary cause of the accident and, in virtually all 50 accidents, the size and weight of the truck contributed to the severity of the injuries and the number of fatalities. Driver behavior was either a primary or secondary causal factor. This led to NTSB concern about licensing, training, experience, alertness, understanding of vehicle systems, physical health, and the driver's environment in the cab(15).

Earlier we showed that 82 percent of the fatalities in medium and heavy truck accidents were not the occupants of the large truck. They were generally occupants of passenger cars and other light vehicles that collided with the large truck. In summary—

- The fatalities take place in the 70 percent of fatal accidents involving large trucks that are multi-vehicle accidents.
- The accidents are especially serious because of the large disparity in mass between a large truck and the other vehicle involved, usually a passenger car.
- Almost half of the multivehicle accident fatalities occur on rural, two-lane roads where 90 percent are in head-on, angle, and sideswipe accidents(16)

This suggests that further separation of vehicles traveling in opposite directions, especially vehicles of such disparate masses as passenger cars and large trucks, should be investigated. As proof of the effectiveness of separating traffic directions, one has only to look at the divided, limited-access Interstate system, which is credited with having saved approximately 4,600 lives in 1983 alone by cutting the fatality rate in half compared with all U.S. highways(17).

Rollover is involved in 50 percent of combination vehicle driver fatalities, with ejection found in 34.4 percent (Figure 6). Extrication accidents (22.4 percent) are those in which the victim must be physically removed from the damaged vehicle. In some cases, the victim was crushed within the truck cab. Fire is found in few truck accidents overall but is present in about 16 percent of accidents that prove fatal to the combination vehicle occupant—about 125 cases annually(18).

The percentages given add up to more than 100 percent. In many accidents, more than one event is involved, such as a rollover and ejection or a fire and extrication.

	Percent
Rollover	59.0%
Ejection	34.4
Extrication	22.4
Fire	16.1
None of the Above	15.1
Total Number of Fatalities	1964

SOURCE: University of Michigan Transportation Research Institute - from NHTSA Fatal Accident Reporting Systems data.

Figure 6. Combination Vehicle Driver Fatalities, 1980-1982

Research has provided substantial information on the types of accidents that prove fatal to truck occupants and pointed out a number of ways in which lives can be saved. Foremost among them are safety belts. Safety belts are tailor-made for the rollover and ejection accidents, which cause the majority of truck occupant fatalities. Research suggests safety belts could save perhaps 40 percent of the combination vehicle occupants who die each year and reduce injury severity in perhaps 70 percent of the serious-injury accidents(19). Since 1970, the use of safety belts has been required in interstate trucks by the Bureau of Motor Carrier Safety; yet today, only about 6 percent of the drivers wear them—less than half the use rate in passenger cars(20). So, if we can get truck drivers to buckle up, a significant number of lives can be saved.

We now know far more about highway accidents than we did just a few years ago. But there are many problems still to investigate. For example, we have little detail on accident exposure by type of vehicle. A wide range of trucks, having specialized vocational uses, travel on different kinds of roads, with varying loads, at various times of day, under all kinds of environmental conditions. Until we can analyze this exposure information, it is impossible to pinpoint exactly how to identify and break the accident causation chain for specific kinds of vehicles and accidents. We need more detailed information on drivers, highways, vehicles, accident forces, handling, braking, and stability in crisis maneuvers, and specifics of the accidents themselves to consider potential accident countermeasures intelligently.

Research is underway on a wide variety of subjects to get these answers, including continuing accident data collection and analysis; combination truck braking, coupling, and handling; vehicle crashworthiness; and ways of encouraging safety belt use.

Research is being conducted or sponsored by virtually everyone involved in the trucking industry, including insurance companies, motor carriers, various government agencies, organized labor, industry trade associations, vehicle manufacturers, suppliers, and universities.

Our challenge is to use better data and better analysis to find innovative and constructive solutions.

Heavy Trucks Aggressivity for Road Users— In Search of Improved Safety

Maryvonne Dejeammes
ONSER—Laboratoire des Chocs et de Biomécanique

Abstract

For many years, heavy trucks have accounted for a large part of the damaging road traffic in France. To determine ways of improving heavy vehicles so as to diminish the severe score of accidents, the national statistic file of injurious accidents in 1982 and the ONSER bidisciplinary investigation file have been analyzed. The most important risks affect pedestrians, two-wheelers, and car passengers.

It appears research on heavy vehicles should be undertaken at first for—

- Improving lateral vision
- Fitting up of heavy vehicle flanks to avoid falls under rear wheels and to limit underrun
- Fitting up of heavy vehicle front structure to reduce its aggressivity against passenger cars

The purpose of safety measures complementary with energy savings necessity should bring about realizable solutions.

Introduction

For many years, heavy vehicles have been considered a factor of dangerous road traffic in France. Because of their large mass, these vehicles contribute to the severe harm inflicted on their opponent road users. Upon action of the French Department of Transport, the Committee named "For a better safety of heavy vehicle traffic" has recommended research themes to improve the safety of heavy vehicle occupants and other road users.

It is then necessary to define the most dangerous accident situations with respect to the different categories of road users—pedestrians, two-wheel riders, and car occupants. Research axes to diminish the aggressivity of heavy vehicles will emerge from the analysis of national statistics (1982 files) as well as from the detailed study of accident cases (ONSER bidisciplinary investigation). The first lines of an evaluation methodology will be presented in the case of a front crash heavy vehicle/car.

General Traffic Conditions

Heavy vehicles are different from cars by their assignment to goods transportation or people transportation, and consequently by their larger mass. They are divided into three categories: light trucks or delivery vans of less than 3.5t, heavy trucks of 3.5 to 38t, and public service vehicles (transporting more than nine people).

The following table shows the number of vehicles and covered distances:

Category	Number	Covered distance/year in kilometers
Passenger car	20,420,000	13,000
light truck		
1.5t to 3.5t	1,060,000	25,000
heavy truck >3.5t	450,000	15,000 to 70,000
public service vehicle	76,000	25,000 to 62,000

Risks related to the traffic of heavy vehicles can be defined by the involvement of vehicles and the number of fatalities related to the number of vehicles × covered distance in kilometers:

1980	HT (>3.5t)	Car
Vehicles × km	$20\ 10^9$	$250\ 10^9$
Involvement / 10^6km	0.85	1.12
Fatalities / 10^8 veh/km	11.0	4.0

So, the rate of involvement of cars is higher than that of heavy trucks, but the number of fatalities related to

vehicle kilometers is 2.75 higher in accidents involving a heavy truck.

Analysis of General Accidental Statistics

To take into account the types of heavy vehicles involved (different by their design and mass), the categories of road user opponents, and even the type of traffic network, an analysis of the statistical file RESUME, worked out from the basis data of the National Constabulary and the National Police, has been conducted. This combined file has been drawn up from the forms on injurious accidents occurring each year, and it has some limits from its homogenous coding and simplification:

- A maximum of three vehicles is reported in a same accident (1 percent of accidents involve more than three vehicles).
- A maximum of two roads is described for an accident.
- A maximum of four occupants is reported in an accident. Registered occupants are those whose injury severity is the highest.

These limitations may be accepted to analyze the problem of heavy truck opponents. Some reserves must be made for analyzing accidents involving a public service vehicle because of the number of occupants registered.

General Presentation

The analysis of the file RESUME has been made for 1982, which shows 222,047 injurious accidents, among which a heavy vehicle was involved in 21,957 cases.

We take into account heavy vehicles (HV) classified in three categories:

- Light truck (1.5 to 3.5t) noted L.T.
- Heavy truck (lorry and tractor-trailer) noted H.T.
- Public service vehicle (motorbus and motorcoach) noted P.S.V.

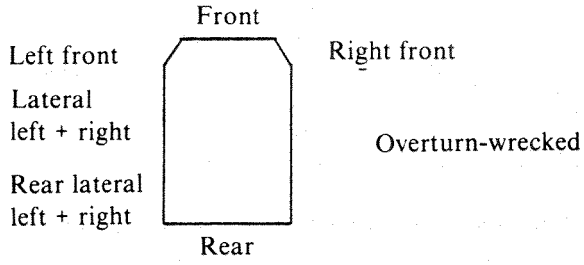
The road user opponents are:

- Pedestrians noted Ped.
- Two-wheelers noted 2-Wh.
- Passenger cars noted Cars

The traffic network is divided into three types:

- Highway
- Nonurban road
- Urban area

Data on collision configurations are more difficult to analyze, and the combination of impact zone of vehicle and impact direction is not considered reliable enough in this file to insure a good description. It was then decided to address the parameter "vehicle impacted zone" with the following distinctions:



Front = Front + Left and Right Front
Lateral = Lateral Left + Right and Rear Left + Right

Accident severity can be determined by the percentage of fatal accidents in relation to the total of injurious accidents. Aggressivity will be given by the rate of external killed and severely injured (other than heavy vehicle occupants) per accident.

The overall distribution of accidents in which at least one heavy vehicle was involved for 1982 is shown in Figure 1.

Accidents Involving Heavy Vehicles/Pedestrians

In this category, 2,620 accidents resulted in 297 fatalities and 765 severely injured pedestrians. The overall external aggressivity is then of 0.40.

The implication is related mainly to the road network:

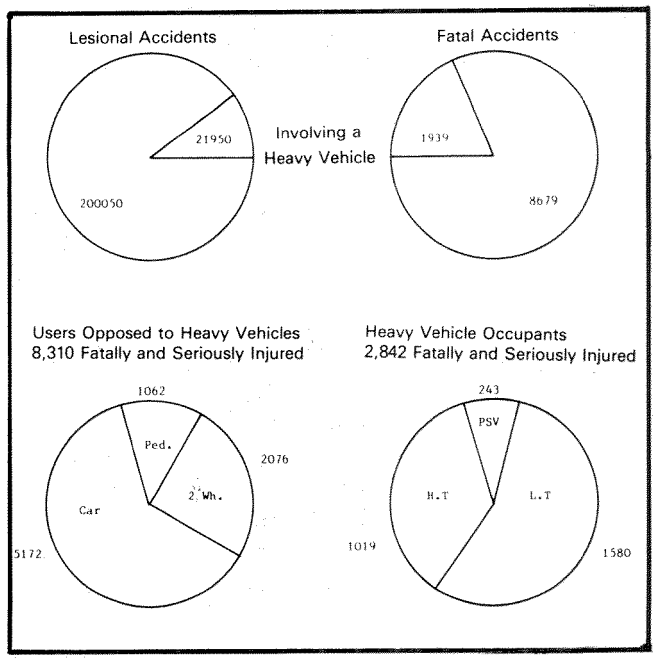


Figure 1. Accidents involving heavy vehicles

1982	No. of acc.	Fatal acc.	Pedestrians Killed	Severely injured	Aggressivity
Highway	17	10	10	6	0.94
Nonurban road	251	74	74	102	0.70
Urban area	2,371	213	213	657	0.37

Urban collisions represent 90 percent of accidents. While they show a not too high aggressivity (0.37 external killed and severely injured people per accident), they total 82 percent of killed and severely injured pedestrians.

As for the category of heavy vehicles, even if public service vehicles run a lot in urban areas, light trucks and heavy trucks are those that cause the most pedestrian victims.

1982	No. of acc.	Fatal acc.	Pedestrians Killed	Severely injured	Aggressivity
Light truck	1,087	100	100	318	0.38
Heavy truck	824	155	155	270	0.52
Pub.serv.veh.	729	42	42	177	0.30

Note the higher aggressivity of heavy trucks, a figure derived from numerous and severe collisions on connection roads passing through an urban area.

Accidents Involving Heavy Vehicles/Two-Wheelers

A total of 4,499 collisions resulted in 394 fatalities and 1,682 severely injured two-wheel passengers. Consequently, the overall external aggressivity is 0.46, which is a slightly higher rate than for pedestrian opponents.

The implication depends on the road network with a large frequency in urban areas:

1982	No. of acc.	Fatal acc.	Two-wheeler Killed	Severely injured	Aggressivity
Highway	27	6	6	8	0.52
Nonurban roads	887	143	146	484	0.71
Urban area	3,585	241	242	1,190	0.40

The aggressivity related to the vehicle category is roughly comparable to the one for accidents against pedestrians, but it has to be noted that severe accidents involving a heavy truck prevail.

1982	No. of acc.	Fatal acc.	Two-wheeler Killed	Severely injured	Aggressivity
Light truck	1,773	90	90	678	0.43
Heavy truck	2,150	271	275	830	0.51
Pub.serv.veh.	576	29	29	174	0.35

The analysis of the heavy vehicle zone impacted by the two-wheeler shows an unquestionable difference between the categories of vehicles:

% 2-wh Fat.sev jured	Impacted Zone Front	Rear	Lat.Front	Lat.Rear	Total
Light truck	59	6	19	16	100%
Heavy truck	43	9	23	25	100%
Pub.serv.veh.	57	8	20	15	100%

Table 1 gives a detailed description of accidents involving heavy trucks/two-wheelers.

The highest frequency and the highest severity of impacts against heavy truck flanks in comparison with light trucks and public service vehicles can certainly be explained by the design of their structures (presence of side fairings flush with axles).

Accidents Involving Heavy Vehicles/Passenger Cars

A total of 11,473 accidents resulted in 1,139 fatalities and 4,033 severely injured car passengers. The external aggressivity is 0.45, similar to the one for two-wheeler opponents, but car passenger victims are 2.5 times more numerous.

The implication is more frequent in urban areas, but the gravity is much more important in nonurban roads as shown below:

1982	No. of acc.	Fatal acc.	Car passengers Killed	Severely injured	Aggressivity
Highway	409	56	69	138	0.51
Nonurban roads	4,564	660	776	2,240	0.66
Urban area	6,500	262	294	1,655	0.30

Heavy trucks are more frequently involved and exhibit the highest aggressivity:

1982	No. of acc.	Fatal acc.	Car passengers Killed	Severely injured	Aggressivity
Light truck	3,453	153	147	1,007	0.33
Heavy truck	6,675	752	857	2,684	0.54
Pub.serv.veh.	1,345	73	95	342	0.32

The analysis of the accident configuration has been made by distinguishing between the various parts of the passenger car that were impacted—front, side left and right, rear. The impacted parts of the heavy vehicle were detailed in the computerized sorting according to the above presentation. Table 2 summarizes registered figures according to the category of heavy vehicles.

The fronto-frontal collision accounts for more than 40 percent of killed and injured car passengers for the three categories of heavy vehicles. Collisions between passenger

	Ext.Agg.	0.40	0.30	0.34	0.06	0.29	0.27

car and heavy vehicle flanks and between heavy vehicles and passenger car flanks represent nearly 20 percent of killed and severely injured car passengers in each case. However, it has to be noted that heavy trucks differ from light trucks and public service vehicles because accidents against their flanks are more severe. As previously stated for two-wheelers, explanation must be found in the chassis structures that stand high and are recessed from the loading frame and make underrun possible.

Detailed Study of Accident Cases

To illustrate the problem of the aggressivity of heavy vehicles toward passenger cars, we have sorted out the accidents from the files of ONSER bidisciplinary survey where heavy trucks of more than 3.5t and public service vehicles (motorcoach and motorbus) were involved from 1975 to 1984. The term "passenger car" is used for any vehicle equipped as a limousine, break, or coupé.

Since it is difficult to get precise data on material damage to heavy vehicles, whose occupants are rarely injured, it has been found in the files:

- 25 accidents front car/front HV
- 13 accidents front car/side HV
- 18 accidents front car/rear HV

Given the priorities that could be drawn from general statistics, the analysis of fronto-frontal collisions is presented. These collisions involve front parts of each vehicle, and impacts are directed at 11, 12, and 01h on a clock dial.

The accident severity noticed in the files of the bidisciplinary survey is higher than that found at the national level. This is even more enhanced for the fronto-frontal configuration between a passenger car and heavy vehicle: 12 out of the 25 accidents are fatal.

The lesional score is given on Table 3, where a distinction is made between front and rear occupants and where belt-wearing by car passengers is mentioned:

Table 3. Car passengers injury severity

	Killed AIS 6	Severely Injured AIS ≥3	Lightly Injured AIS 1-2	Uninjured
Belted front occupant	3	5	6	1
Unbelted front occupant	7	4	4	1
Front occupant belt-wearing unknown	4	1	0	0
Rear occupant	5	1	1	0
Total	19	11	11	2

It is then shown there are more killed occupants among unbelted ones. The severity of this collision type for rear occupants has to be noted also.

These collisions are characterized by the well-known risk of the passenger car to underrun the heavy vehicle structure, which means a limitation of the protective effect of the 3-point belt due to the reduction of the deceleration zone in the compartment. Impact directions and underrun cases are drawn out by analyzing passenger car deformations. Underrun is defined as the case when the car is impacted above its rigid structures, i.e., side-members, motor, and gear-box unit.

Impacts to the left are the more numerous:

- Front left impact: 12 cases
- Center impact: 8 cases
- Front right impact: 5 cases

Cases of underrun are more numerous (13 cases); 6 accidents occurred without underrun. In the 6 remaining cases, the underrun criterion has not been asserted because of the important lateral deformations of the car.

The relationship between deformations of the vehicle and its compartment and injuries to its occupants is shown in the table below:

This table emphasizes the violence of impact with a complete intrusion of the compartment in 10 cases, along with the increasing injury severity according to the level of compartment intrusion.

The description of lesions, which is available except in the 10 cases of fatality (no autopsy), gives evidence of the impact violence against compartment parts such as steering column, dashboard, windscreen frame, pedals, and even an outer object (heavy truck structure). Any body part is then likely to be severely injured.

On the other hand, heavy vehicle occupants are very seldom exposed. In our sample, it appears the injured people found in three heavy vehicles sustained lesions either on ejection (one slightly injured) or during an impact subsequent to the one against the passenger car. During an impact against a tree, 2 front passengers of a motorcoach sustained severe injuries; during an impact against a pole, 12 passengers of a motorcoach were lightly injured.

There are also various categories of heavy vehicles in this sample to draw out behavior tendencies. It can merely be said that trucks of more than 10t and tractor-trailers do not show a very different behavior, which is explained by their similar front profile.

So, the fact that front structures of heavy vehicles are not compatible with passenger cars, as well as the ratio of their masses, explains the severe tribute paid by car occupants. However, speeds and severity levels of these collisions cannot be assessed in a reliable way, either from available data or from present knowledge. As a matter of fact, it is not possible to compare the deformations observed on the passenger car with those found after

Deformed area				Left front	1	5	6	0
Center	3	2	1	2
Right front	4	0	1	0
Killed	0	3	8	4
Severely injured AIS ≥3	3	4	2	0
Lightly injured AIS 1-2	7	1	2	0

impacts against a rigid barrier. Calibrated tests thatwould give a set of data on car deformations and decelerations are lacking up to now, and the estimation of speeds before the impact and of braking distances are not unquestionable factors.

This accident case study, however, bears out the severity and frequency of left frontal collisions (on drivers' side); the analysis of injuries to car passengers points out that factors liable to improve safety are the limitations of underrun and intrusion into the car passenger compartment.

Countermeasure Proposals

The analysis of circumstances of accidents involving heavy vehicles has been carried out to find effective measures applicable to heavy vehicles and likely to limit this dramatic tribute. These measures can be examined in relation to the heavy vehicle opponent:

- Accidents involving pedestrians with very severe consequences occur in urban areas most of the time. It is difficult to think of equipment on heavy vehicles that will prove to be absolutely efficient with the pedestrian looking so small and weak next to a heavy vehicle. It can be recommended that the lateral visual field of the truck driver be improved. Otherwise, primary safety measures need to be worked out, especially concerning road equipment and traffic.
- Two-wheelers are involved in accidents occurring in urban areas and on nonurban roads as well. Often they are victims of impact against heavy vehicle fronts. It would be interesting to estimate how the front structure could be modified to limit underrun, but the closing speeds are often high and do not enable one to think of specific and well-adapted measures. Concerning impacts against heavy vehicle flanks, lateral fairings such as those equipping public service vehicles or light trucks (for most of them) undoubtedly can limit the consequences of this accident type. In France, to further the study made by Favero(1), a first step has been taken that provides for fitting heavy trucks with "protective devices against the risk of falling of two-wheelers on the trajectory of rear wheels" (Decree of June 16, 1979-Art.1). It is now necessary to estimate their effectiveness and even to consider other equipment such as more complete fairings. Would not improving heavy truck aerodynamics contribute to a better safety?
- Car passengers are the most numerous victims. It seems impacts against the heavy truck rear no longer constitute an important risk as in past years. The rear underrun guards provide a certain efficiency, which could be still improved by energy-absorbing devices(2,3).

The work to be done now is to limit the aggressivity of heavy vehicle fronts. The collision severity is in direct relationship with the geometry and the masses of the involved vehicles. As mentioned by Franchini(4), the heavy vehicle does not behave like a rigid barrier since the opponent car often runs under its strong structures. The design of the heavy vehicle front should meet two requirements:

- Compatibility of its structure by lowering the rigid structures of the heavy vehicle, especially the bumpers. And yet recent studies have shown that this design is still not sufficient since the whole collision energy is absorbed by the passenger car(5).
- Energy dissipation by a deformable part. The problem is to know if the energy dissipation is possible only by adding a material of particular size and increasing the vehicle length, even if the compartment design of future heavy trucks is completely thought over. Johnson(6) proposes a deformable part 500mm long.

Some drafts whose credit is to verify the feasibility of devices able to absorb part of the energy have been proposed(7,3). Another research field could focus on the shape of heavy trucks. Having in mind that frontal impacts offset to the left are the most severe, and most frequent as well, it could consider a round-shaped compartment that enables the car to slip aside during such a collision.

The question, then, is to know up to which collision severity level is fair to require heavy vehicle fronts to be less aggressive toward passenger cars. Accident analysis shows that in France, from our study, as well as in the Federal Republic of Germany(7) and in the United Kingdom(8), the more frequent configuration is the one with an angular incidence or an offset on the driver's side. It is more difficult to estimate the closing speed of the vehicles since there are no reference collisions available.

With some tests of fronto-frontal impacts carried out with closing speeds of 40 to 65km/h, it is quite fair to believe that a modification of the heavy truck front can be designed to dissipate part of the energy released during a collision with a closing speed of 60km/h. This would enable belted car occupants to sustain forces that remain within the limits of biomechanical criteria currently admitted.

The second priority lies in the improvement of heavy truck flanks; the risk of underrunning their loading platforms is quite similar to that incurred by two-wheelers. It could then be recommended that lateral protective devices or fairings offer a minimal resistance to act as an underrun guard toward passenger cars.

Conclusion

In France in 1982, 21,950 accidents involving a heavy vehicle resulted in at least 8,310 killed and severely injured among pedestrian, two-wheeler, and car opponents, whereas more than 2,800 truck occupants were killed or severely injured.

The analysis of the circumstances and the consequences of these accidents has produced measures likely to limit this heavy tribute:

- Improve the side visual field offered to the truck driver
- Modify heavy vehicle flanks to limit falls of two-wheelers on the trajectory of rear wheels and also to avoid car underrun under loading platforms
- Modify the heavy vehicle front to make it less aggressive toward passengers cars, especially by avoiding the underrun under rigid structures of the chassis and by providing an energy-absorbing area

Heavy vehicle traffic has been considered a factor of unsafeness for many years. Several countries, like France, admit it is most desirable that solutions to the aggressivity of heavy vehicle fronts and flanks be found. These safety measures can be complementary to current priorities concerning road traffic, such as energy savings. We believe actual outcomes will emerge from international research being carried out at present. Evaluation procedures need to be determined, which necessitates a better knowledge of collision severities to give a more realistic picture of traffic accidents.

P.S.V. Rollover Stability

D.M. White
Cranfield Impact Centre, United Kingdom

Abstract

Nine buses and coaches were tested to experimentally determine various parameters considered to affect rollover stability—principally, spring stiffness, position of centre of gravity, and roll moment of inertia. Utilising these data, a computer simulation of a typical rollover accident was used to compare the relative performance of the different vehicles and investigate the effect of each parameter on the rollover threshold. Height of the centre of gravity and, to a lesser extent, roll centre height were found to have the greatest effect.

Introduction

To get from safe, normal driving in a bus or coach to a fatal rollover accident requires a sequence of events similar to those outlined in Figure 1. It can be seen there are two stages where governmental efforts may be made to reduce rollover accidents, and two further areas in which the severity of an accident, if it does occur, may be reduced. Already significant legislation exists to minimise loss of control. Other factors, such as careful road design and layout, and treating icy road surfaces, may also be added to the measures listed in Figure 1.

However, coaches will not usually roll over without certain other circumstances. These are typically—

- Travelling off the road onto a significantly inclined bank

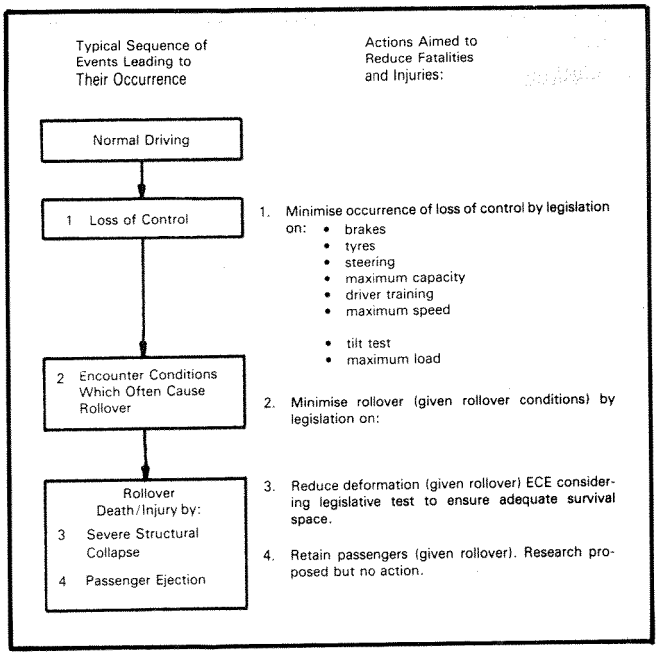

Figure 1. Components of typical bus rollover accident

- Sliding sideways into some form of roadside tripping obstacle (such as a curb, low wall, or soft verge)

Whether or not a coach rolls on an inclined bank would be almost solely dependent on its static tilt limit, as measured on a tilt test. The factors affecting whether a given vehicle would roll if it struck a curb with a given lateral velocity are less apparent and are the subject of this paper.

Description of Computer Program

The Rollover Accident Simulation Program (RASP) was developed to study in detail the design factors that the propensity of a vehicle to roll over when it strikes a curb, low wall, soft verge, or similar roadside obstacle while sliding sideways. As such, it assumes the driver has already lost directional control and, therefore, the program does not include vehicle dynamics routines to model steering, braking, or acceleration modes. Instead, the simulation begins with an initial lateral velocity perpendicular to the curb. Impact between tyres and curb occurs, and the ensuing motion may or may not result in rollover.

Mathematical Model

The vehicle is defined by its mass distribution, inertial properties, spring and damping constants, and dimensions as indicated in Figures 2 and 3.

The equations of motion were formulated by considering the sprung mass as a rigid body with 6° of freedom (that is, longitudinal, lateral, vertical, roll, pitch, and yaw). Each axle was considered to be a beam axle, free to roll or displace vertically or laterally with respect to the body. For a two-axle vehicle, this results in a 12° of freedom model. Simple modifications to the program created a 15° of freedom version for three-axle double-deckers.

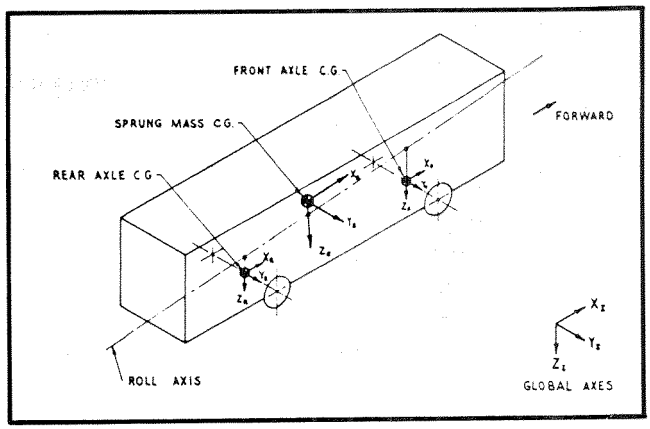

Figure 2. Mathematical model (12 degrees of freedom)

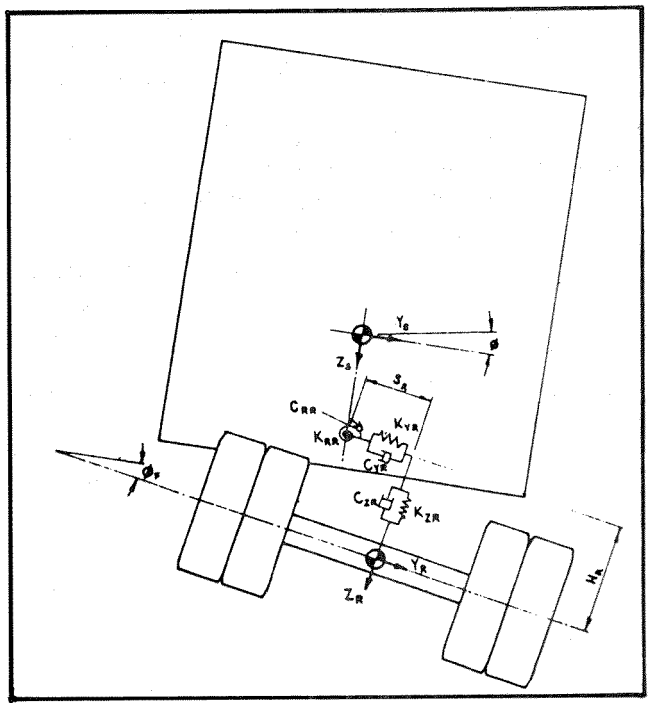

Figure 3. Suspension layout of mathematical model

Assumptions and Features of Model

The features incorporated in the model and assumptions made in deriving the equations of motion are as follows:

1. The road surface is assumed to be uniform and horizontal.

2. The curb is positioned perpendicular to the vehicle's initial velocity.
3. Pitch angle of the sprung mass is assumed to be small (that is, small angle approximations are used: $\sin\theta \doteqdot \theta$ and $\cos\theta \doteqdot 1$).
4. Axle roll angles relative to the sprung mass are also assumed to be small.
5. The relative roll motion of the sprung mass and axles is assumed to take place about a roll axis that is fixed with respect to the sprung mass. It is defined by specifying the initial values of the roll centre heights at the front and rear axles. The roll axis is taken as the line joining these two points. Weir(1) in the bus version of a vehicle dynamics program assumed that the vehicle centre of gravity (CG) must lie on this roll axis. This program, however, enables the CG position to be defined independently of the roll axis.
6. Spring/damper units act at the tyre contact points where the forces from the road and curb are applied, and also between the sprung mass and each axle, simulating the suspension components. Figure 3 shows in greater detail the connection between the sprung mass and an axle. Note that only one vertical spring is employed (with an axle rate stiffness) and the roll stiffness is provided using a separate torsional spring.
7. Linear characteristics are used for every spring with two exceptions: the roll stiffnesses and tyre/curb stiffnesses are as shown in Figures 4 and 5, respectively. The secondary roll stiffness models the effect of bump stops when the relative roll angle exceeds 15°. Similarly, the curb stiffness takes into account the limited tyre lateral stiffness and attempts to account for the increased stiffness when the curb contacts a more solid part of the vehicle, such as a wheel rim.
8. Provision is also made for energy losses at the tyre/curb contact (due perhaps to ground or bus deformation) by allowing plastic behaviour. This is evident in Figure 5, where the deflection increases with constant force and is not recovered when the spring is unloaded (shown as the dashed line).

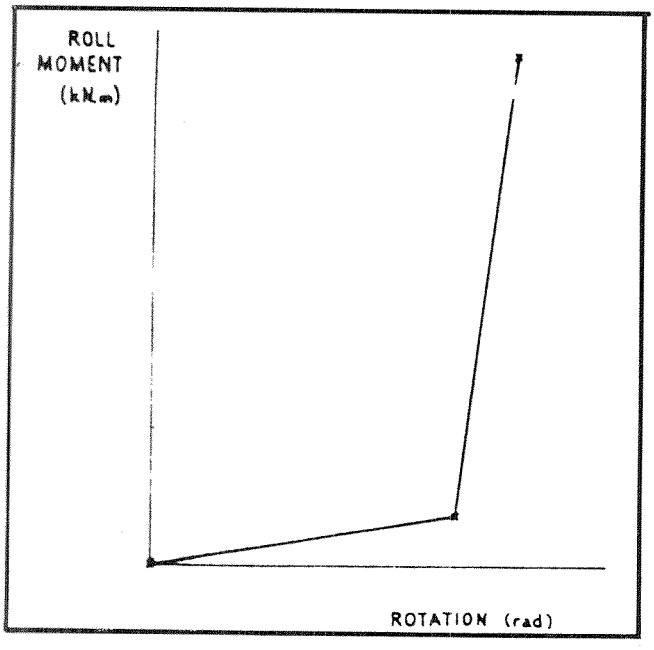

Figure 4. Representation of roll stiffness nonlinearities

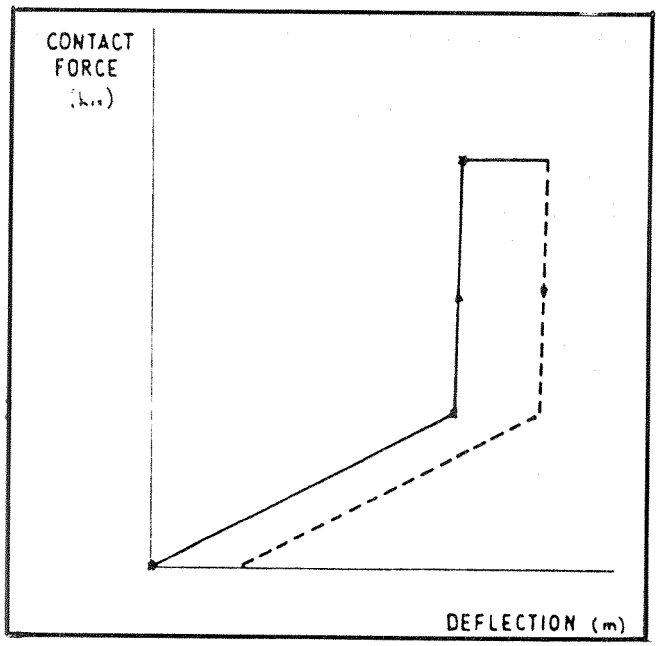

Figure 5. Representation of tyre/curb stiffness nonlinearities

Validity of Model

A full-scale instrumented rollover test was not feasible due to resource limitations, so the simulation could not be checked directly. However, similar earlier work on the dynamic behaviour of buses during superstructure strength tests showed reasonable correlation between measurements of actual tests from high-speed cine film and results predicted by a 6° of freedom model(2). Since RASP contains many routines derived from the earlier model, and an energy checksum insures that the total energy variation is minimal, the results of RASP are considered to be of value, particularly for comparing one vehicle with another.

Data Measurement

Nine different vehicles were tested to determine by experiment the values of the parameters required for the

simulation program. Most were considered to be potentially significant factors affecting rollover performance.

Height of Centre of Gravity

The same method and equipment used for determining CG height as described in "The SDG Bus Roll Moment of Inertia Test Rig"(3) was adopted. To summarise the technique, the vehicle is positioned with each axle supported from a transverse steel beam that has a central roller bearing, allowing the bus to roll if unrestrained. By measuring the reaction force (R in Figure 6) for a range of roll angles from 0° to 3° and plotting a graph of these two variables, the CG height may be calculated from the equation for static equilibrium of moments about the pivot.

The vertical distance from the top of the beam to the pivot is subtracted to give the unladen CG height above the ground. Note that the suspension and tyres are prevented from deflecting by suitable use of jacks or blocks, effectively converting the bus into a rigid body.

The bus rollover simulations were conducted for vehicles in the laden condition defined by current tilt test regulations, as this is intended to be the worst case situation for rollover stability. This means that 63.5kg per passenger must be added at the correct position for each seated or standing passenger, plus the driver. Double-deckers only require the driver (and conductor) plus passengers on the upper deck.

Knowing the average seat height on each deck and given the regulation height for the CG of standing passengers is 2'8" (0.813m), the overall CG height for the laden vehicle can be determined.

Roll Moment of Inertia

With the vehicle on the same test rig as for the CG height measurement, and the suspensions and tyres blocked to effectively insure rigid body motion, the method of determining the roll moment of inertia as outlined in (3) was used. Figure 7 illustrates the important feature, namely, the air springs, which provide a restoring moment when the bus is oscillated about an axis joining the two beam pivots. The moment of inertia about the pivot axis is given by:

$$I_P = (2kl^2 + mgh)\left(\frac{T}{2\pi}\right)^2$$

where

k = combined spring stiffness on one beam
l = distance from spring to pivot
m = total oscillating mass
h = height of combined CG above pivot
T = period of free oscillation

The roll moment of inertia of the vehicle about its CG is obtained using:

$$I = I_P - I_B - mh^2$$

where I_B = moment of inertia of support beams about pivot

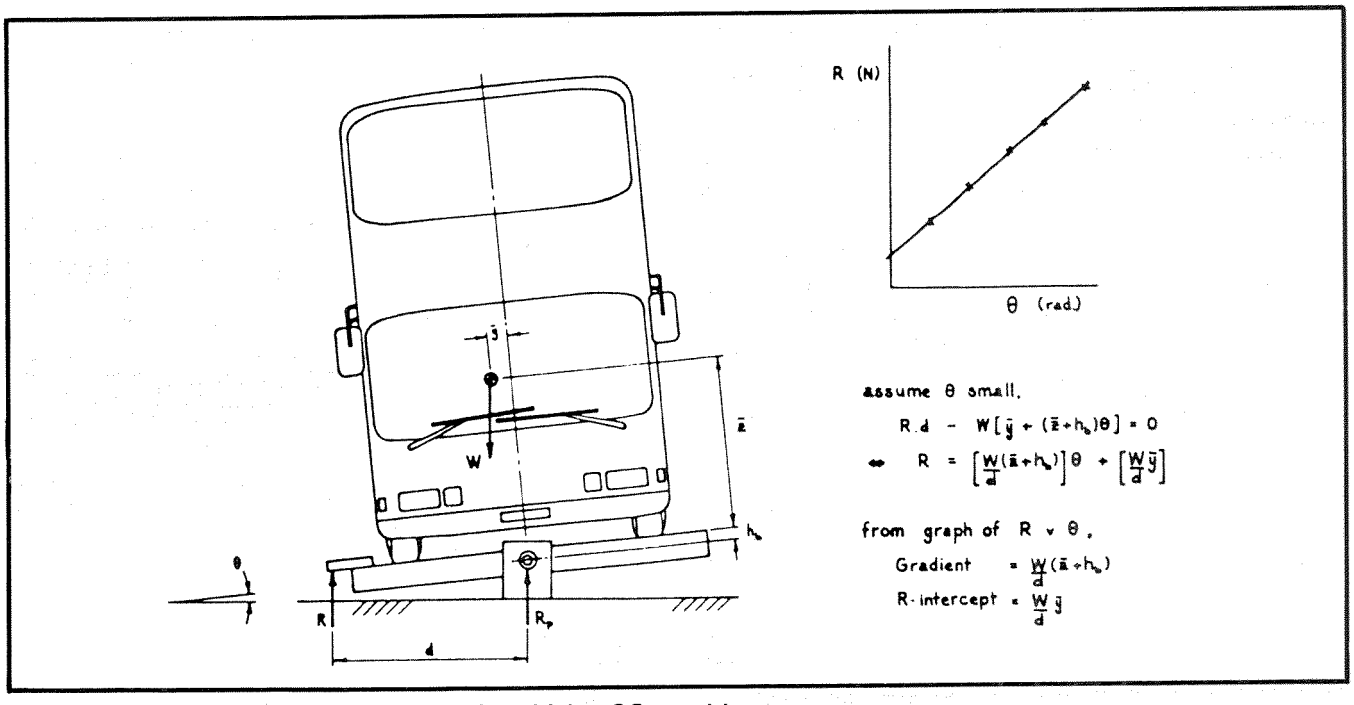

Figure 6. Method of measurement of vehicle CG position

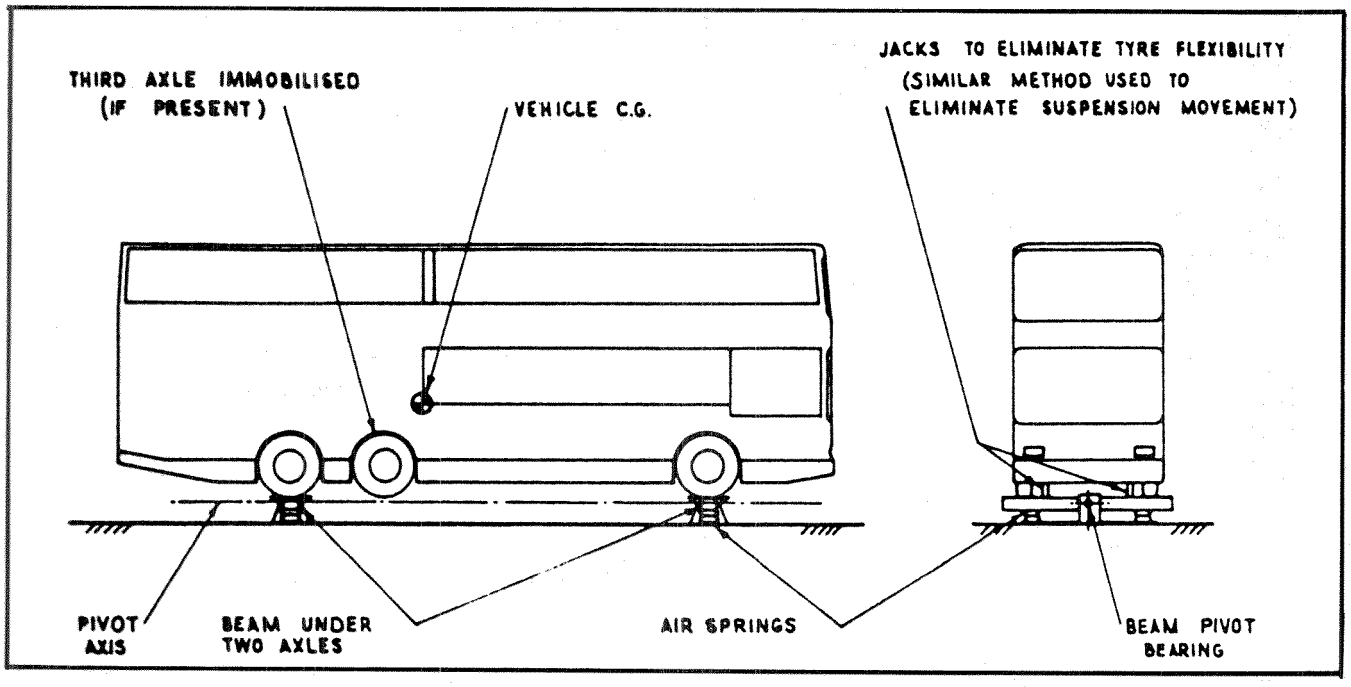

Figure 7. General layout of vehicle on roll moment of inertia rig

The time for several oscillations was recorded and the average calculated from several such measurements. This process was repeated for three different air spring pressures.

Stiffnesses

Vertical, lateral, and roll stiffnesses were obtained for the suspension and tyres of each axle of a vehicle by applying a force in a particular direction, and measuring both the force and the associated deflection in the same direction. Vertical force was applied by loading sandbags and was measured with weighpads—one for each wheel. Roll moment was obtained by shifting the sandbags from one side of the bus to the other. By calculating the difference between weighpad readings and measuring the distance between wheels on one axle, the actual applied roll moment was determined. Gravity supplied the lateral component of force during a tilt test (Figure 8), which was recorded using loadcells to measure the force between the tyre sidewall and the tilt table restraint. Linear bearings under the weighpads minimised friction losses from the lateral force.

By mounting three transducers in the configuration shown in Figure 8 and measuring their initial positions in space, it was possible, using geometric relationships, to extract separately the vertical, lateral, and roll displacements of one body relative to another. Graphs of force v displacement give an indication of linearity. Figure 9 contains typical graphs for each stiffness obtained at one axle.

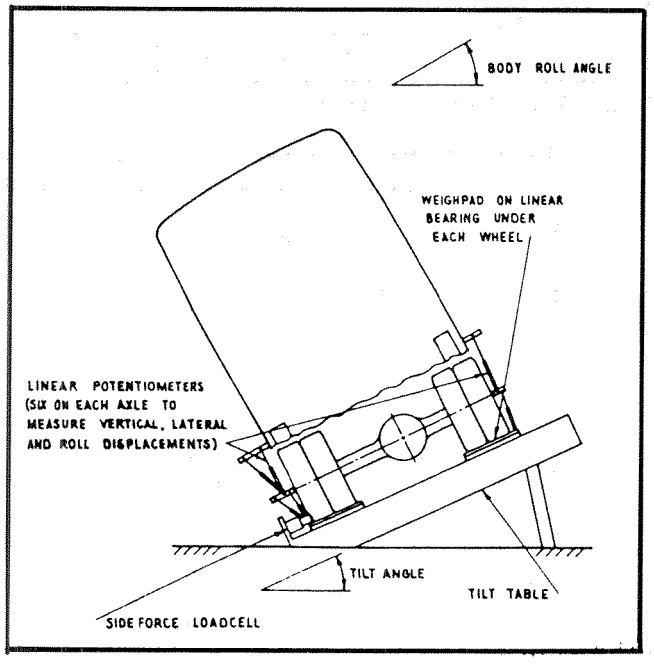

Figure 8. Cutaway view of instrumentation layout for tilt test

Roll Centre Heights

It was possible to also calculate the position of the instantaneous roll centre at each axle, using the successive position of the displacement transducers during the roll moment test.

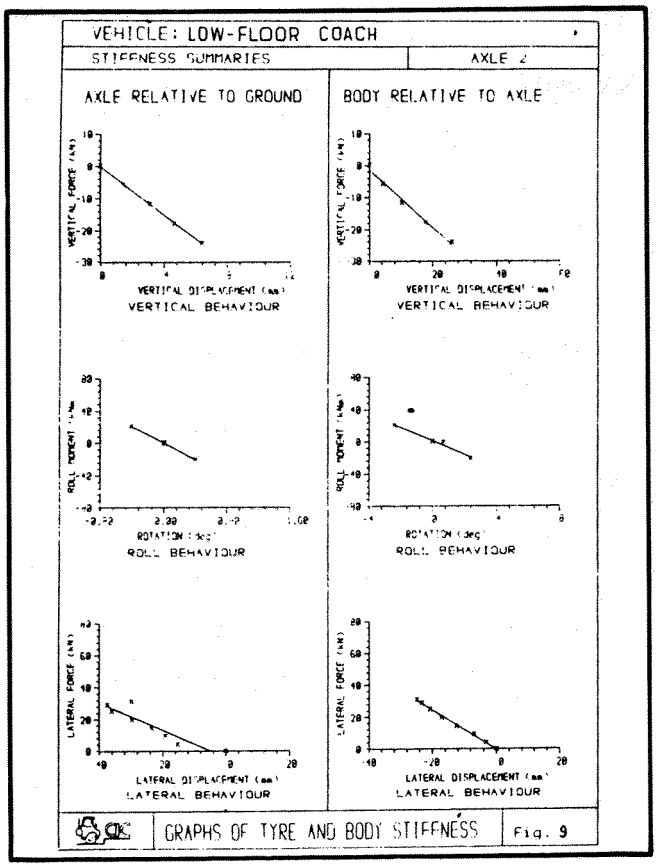

Figure 9. Stiffnesses measured at one axle

Experimental Results

Table 1 summarises the experimental results obtained from tests of nine buses and coaches into the parameters that are typical of three categories of vehicle.

Sample Rollover Simulation

The data from Table 1 were used to determine the threshold impact velocity (that is, the lateral curb-impact velocity that, if exceeded, would cause the vehicle in question to roll over) for each generalised vehicle.

Simulation Results

The rollover accident simulation program was run using the data for the three typical coach categories given in Table 1. By running the simulation with different values for the curb impact velocity, it was possible to determine the threshold impact velocity for each vehicle configuration and these are given (along with the maximum roll angle attained without overturning) in Table 2.

Parametric Study

To determine the factors that most affect the rollover propensity, a parametric study was undertaken. The

Table 1. Experimental data generalised for three typical coach configurations

Parameter		Low-Floor Coach or Bus	High-Floor Touring Coach	3-Axle 2-Decker

Threshold Impact Velocity (m/s)	3.15	2.89	2.95
Maximum Roll. Angle (deg)	38.00	33.70	31.50

magnitudes of the various parameters (mass, moment of inertia, stiffnesses, and dimensions) for the Low-Floor Bus were taken as baseline values. Keeping the other variables at these base levels, each parameter in turn was varied to assess directly its effect on the threshold impact velocity. The preliminary results for the more significant factors are displayed in Figure 10, which uses a normalised horizontal scale, obtained by dividing the parameter in question by its baseline magnitude.

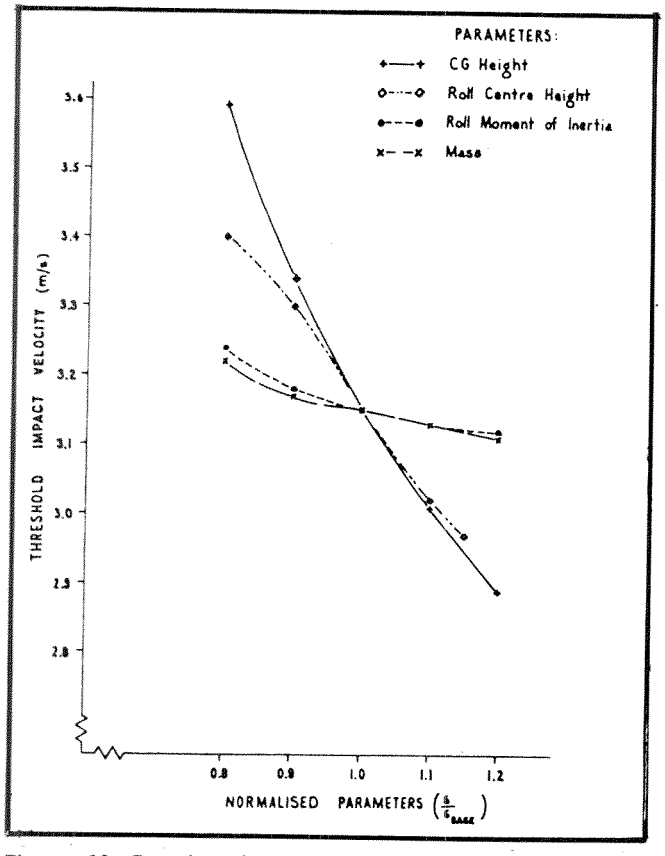

Figure 10. Results of parametric study

Discussion

It is apparent from Figure 10 that the most critical factor affecting rollover propensity is the CG height. Minimising this should, therefore, be the primary goal of vehicle designers who wish to improve rollover safety. The dimensions and mass-related properties would be unlikely to vary more than 20 percent from the baseline values as shown in Figure 10. Other parameters were examined but found to have little influence on rollover behaviour.

The stiffnesses were varied by a factor of two, but early indications reveal only minor effects, with the roll stiffness having the greatest effect.

Applications of This Research

The Rollover Accident Simulation Program is currently being used to investigate bus and coach rollover safety and, in particular, to assess the suitability of UK stability legislation for modern coach designs and travel patterns.

Acknowledgments

The author would like to thank the Department of Transport, London, for permission to publish this paper, and the New Zealand government who provided the doctorate scholarship. Cranfield Impact Centre, and particularly the retiring Director, Guy Tidbury, has been invaluable in coordinating and assisting technically on the experimental phase.

Pedestrian Protection

Franco R. Rossi, Chairman, Italy

General Problems Concerning Car-Pedestrian Collision

Andrea Costanzo

Associate Professor of Traumatology, School of Medicine and Surgery, Rome University, La Sapienza

Abstract

This study was to analyze road accident epidemiology of pedestrians by stressing the age of the injured, vehicle speed, possible trajectories of the impact, location of traumatic lesions on the human body, and environment of accidents.

At the conclusion of the study, recommendations were made to acquire methods aimed at using data in a more rational way, as well as seeking more complete sources.

Introduction

This study outlines accident epidemiology with particular reference to pedestrians. It also describes the most noteworthy aspects of the subject, as well as suggested methods for gathering data.

Problem Analysis

We will concentrate mainly on the following:

- Age of the injured
- Vehicle speed
- Type of vehicle
- Location of traumatic injuries

Another key aspect is to be added; that is, in a given town, find the ratio existing between the number of accidents occurring in certain areas and the total to determine the factors that influence the nature of the accidents.

As far as age is concerned, research carried out so far shows that children (under 18) and old people (over 60) are the most exposed in road accidents (see Figure 1). A logical explanation is that in the case of children, the accident rate is connected with their irresponsible attitude toward danger; the elderly, on the other hand, seem to be unaware of danger. Generally speaking, the solutions found in the past were aimed at better security measures for crossings, stops, signals, etc.

Regarding the influence of speed on accidents, it must be remembered that a higher accident rate occurs at a rather reduced speed.

Figure 2 shows that about 50 percent of the accidents occur at 15km/h while 90 percent occur at 45km/h. It shows also that most of the accidents occur in city traffic within these speed limits. From this standpoint, it would appear a gradual reduction of speed limits is the only way to prevent road accidents.

In a study carried out in Zurich in two stages, where the speed limits ranged from 50 to 60km/h, the number of accidents underwent a 20 percent drop when the 60km/h speed limit was reduced to 50km/h. The 20 percent drop of accidents also brought about a 50 percent decrease in the death toll.

When the driver races at a lower speed, he has enough time to brake.

As for the influence of the type of vehicle and its design, we can sum up the problem by stressing some peculiar features. For example, one category is called V form, a second is called Pontoon form, and a third is called Box form including lorries and buses that represent a wall against pedestrians.

Accordingly, we can say a pedestrian would be hit in his lower body parts by vehicles of the first category. The higher parts would be hit by vehicles of the second category, while the whole pedestrian's body would be endangered by vehicles of the third category.

In Figure 3, we see a subdivision of the types of vehicles mentioned above. The individual's height is also important. More accurate indications are found in Figure 4

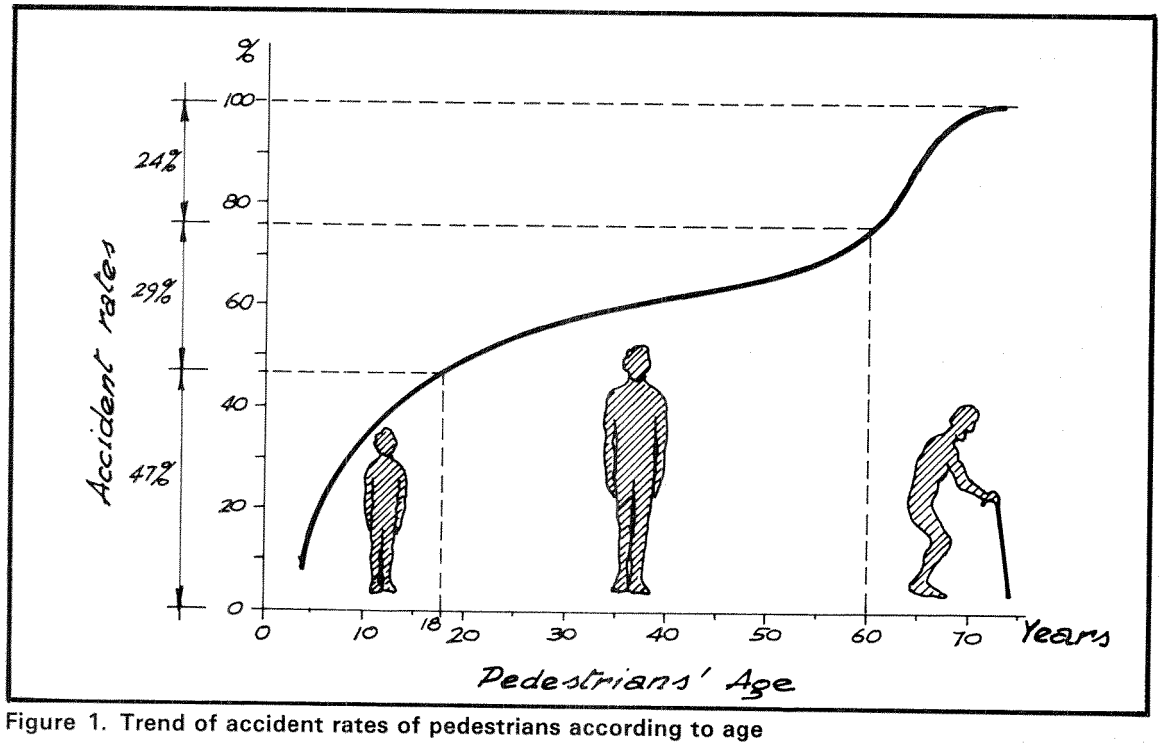

Figure 1. Trend of accident rates of pedestrians according to age

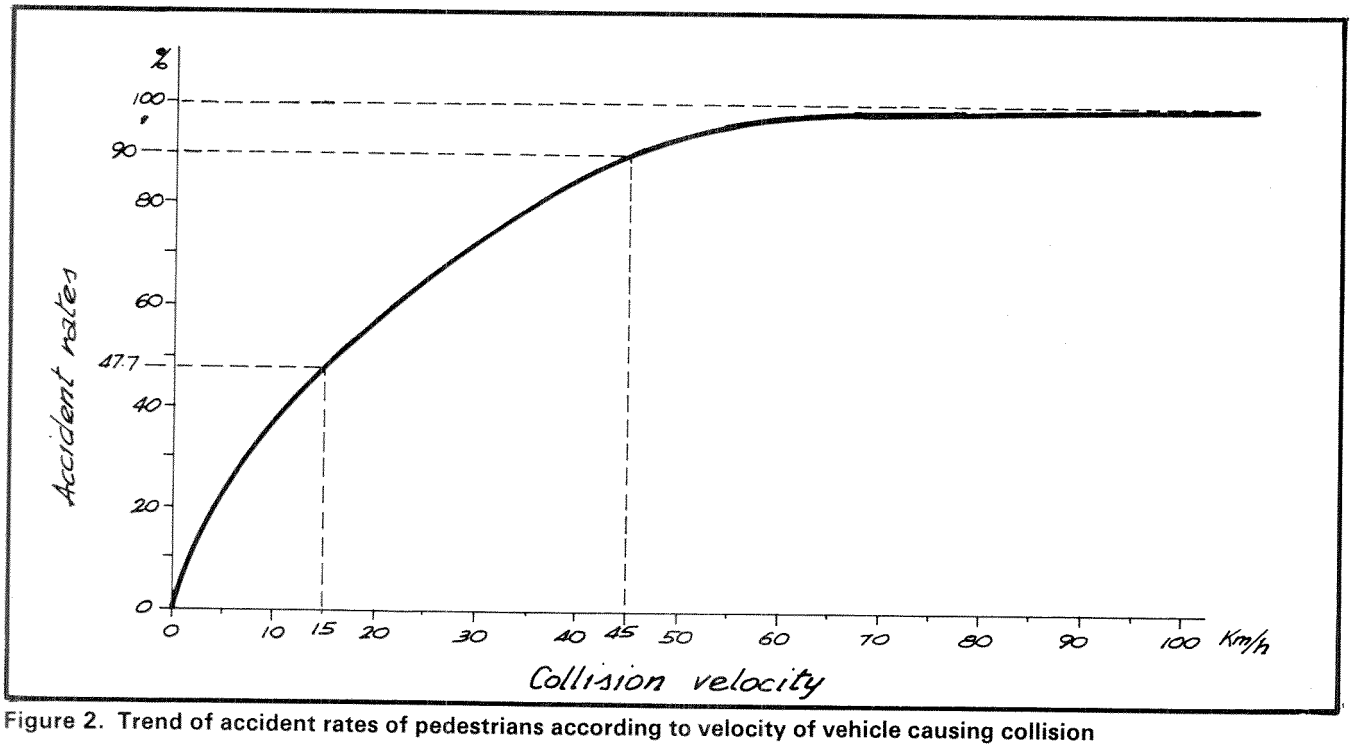

Figure 2. Trend of accident rates of pedestrians according to velocity of vehicle causing collision

where, in a given situation, an adult (Figures 4a and 4b) and a child (Figure 4c) are hit by a Pontoon form vehicle. The comparison between an adult's and a child's height is described in Figure 5.

If we want to foretell the impact result as far as the vehicle is concerned, location of masses on the human body must be taken into account by imagining the human body divided into some areas and indicating their centers. In Figure 6, a chart roughly analyzes this point; however, this should be studied with respect to the possible trajectories shown in Figure 4. It is possible to foretell the impact results by following the chart.

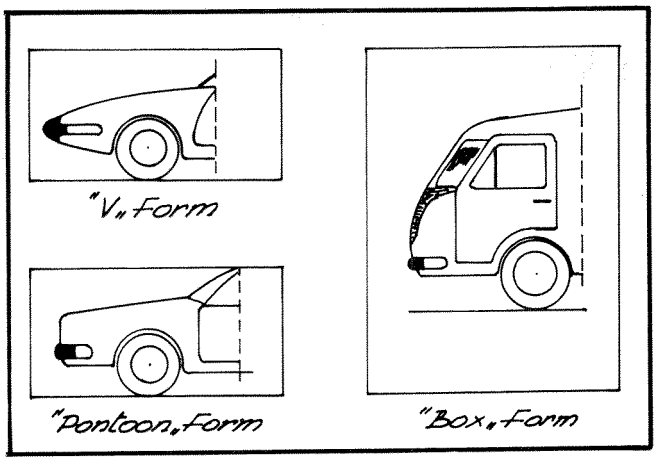

Figure 3. Classification of three types of vehicles causing collision

As far as location of traumatic injuries is concerned, many studies have proved that the gravity of an accident is often ascribed to the part of the vehicle causing the accident.

It is possible to locate some particular areas of the human body where seriousness of the accident relates to different conditions; this fact helps to get information for the survey.

A brief comment of these aspects would include a percentage of the injuries on a person connected with the impact area on the vehicle; the most serious accidents obviously occur in the front area (about 70 percent).

In Figure 7, the accident rate of pedestrians connected with the impact area on a vehicle is shown. Many studies have concentrated on the injured rate, and a case referring to a survey of 2,582 injured is described in Figure 8. From this figure, we see that the rate of injuries to the head is particularly impressive compared to other cases; the same is true of the most serious accidents, which involved head shock. Other cases concerning accidents involving one or more parts of the body have been included; therefore, the total percentage is higher than 100 percent (227.2).

Such an accurate subdivision describes the organic parts of the human body, but it demands a particular effort to obtain further data. Otherwise it would lend itself to errors of interpretation. We will give only a broad picture of the subject; we will describe the 15 subdivision parts of the human body.

As previously outlined, the purpose of this study is to examine accident epidemiology of pedestrians, as well as to work out other concepts that will enable us to complete

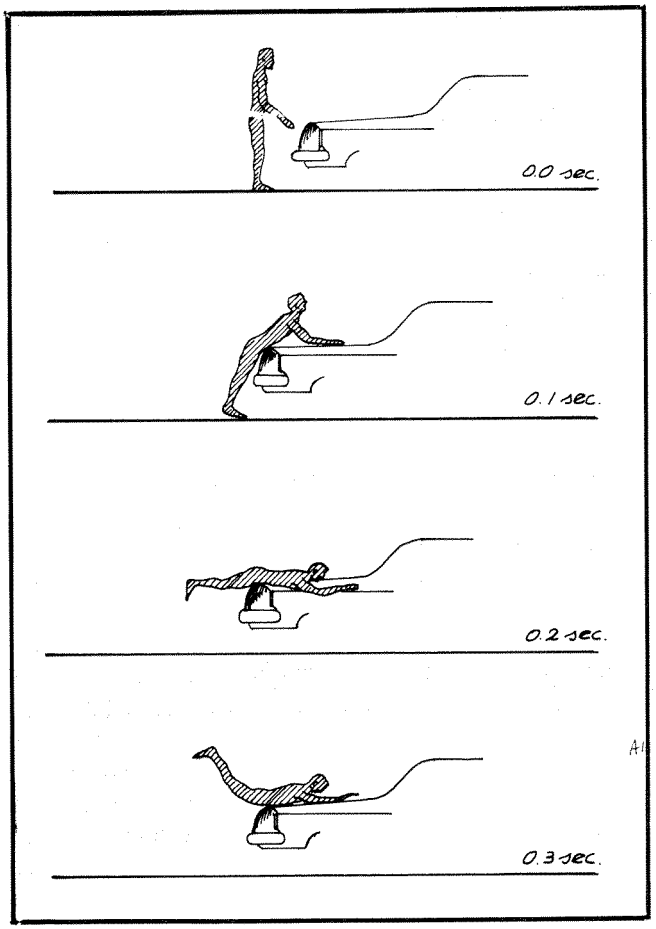

Figure 4a. Sequence of events referring to a standard situation of collision between an adult and a Pontoon form vehicle

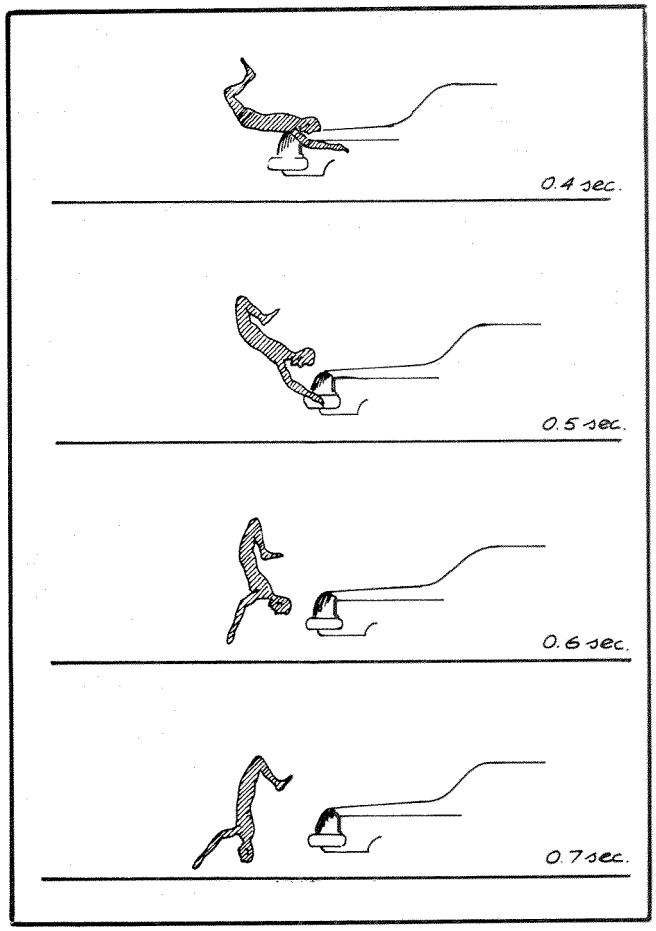

Figure 4b. Sequence of events referring to a standard situation of collision between an adult and a Pontoon form vehicle

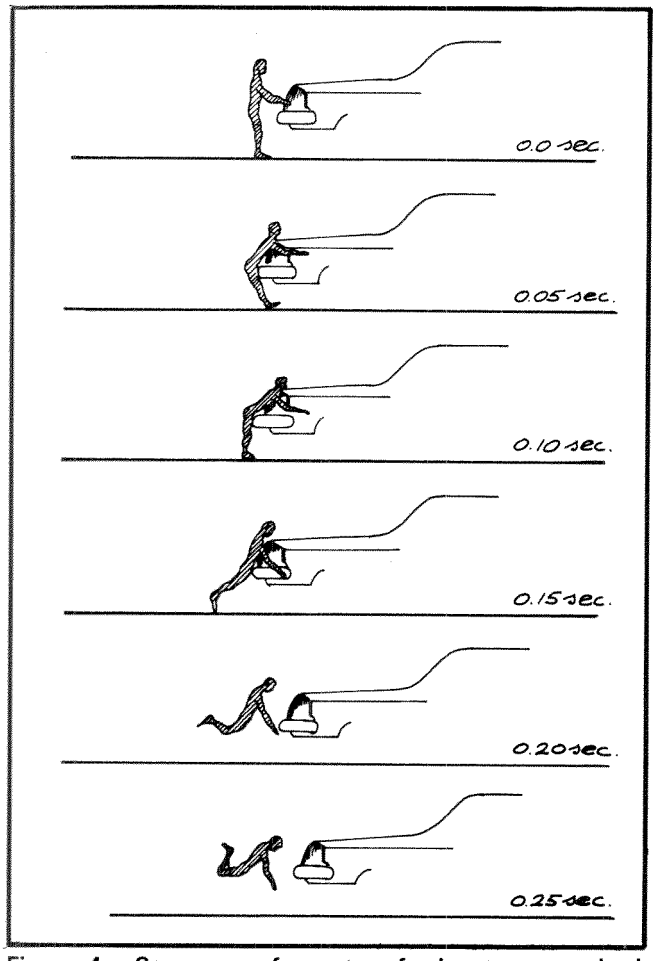

Figure 4c. Sequence of events referring to a standard situation of collision between a child and a Pontoon form vehicle

a thorough picture of accidents involving pedestrians. This can also give indications on the procedure followed.

So far we have examined the solutions found in three points: age of pedestrian, speed and vehicle distribution, and location of traumatic injuries in the human body. It is pointless to obtain information and data on subjects already studied; on the other hand, location of the accident environment is also very important.

To give a clearer picture, we will examine certain situations that are similar to those already set forth as far as children and old people are concerned. For example, we will examine an accident occurring in an urban area where certain social services, such as schools, bus stops, hospitals, and shopping centers, can be found. We will focus on two particular areas:

- Central area near school buildings, bus stops, hospitals, shopping centers, and railway stations
- Suburban areas close to highway exits

In the first area, we see data showing a higher percentage of accidents involving access to social facilities; therefore, regulations must be adapted for vehicles and road crossings that will considerably reduce the number of hazards. It is advisable to build overbridges or subways linking the school entrance to the road; furthermore, what is needed also is a responsible policeman at work!

In the second area, estimates show a higher percentage of serious accidents; therefore, we need a series of laws enforcing speed reduction of vehicles, especially those coming up from the outskirts to the town and v.v., and racing at speed levels higher than the average security level.

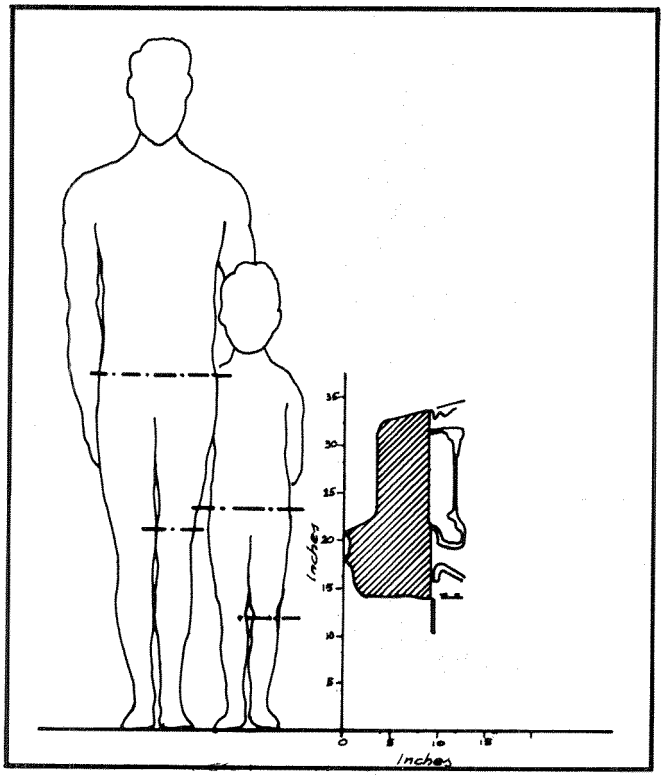

Figure 5. Rough comparison between an adult's average height and a child's average height with respect to a Pontoon form vehicle

Methodology of Data Acquisition

As has already been stated, the aim of such an analysis is to examine first those problems arising from pedestrian accidents and work out conclusions to outline a methodology of data acquisition. This methodology should make the information more reliable and give a thorough picture of all centers acquiring and providing data.

It is to be stressed that in the analysis previously carried out, we pointed out certain concepts such as environment that have not been mentioned in other studies. They should be taken into account. We have carried out an analysis including the most significant yardsticks that characterize accident collision to sum up what has already been set forth. Once a certain amount of information following our methodology is gathered, a publication containing the basic elements of this study will be issued.

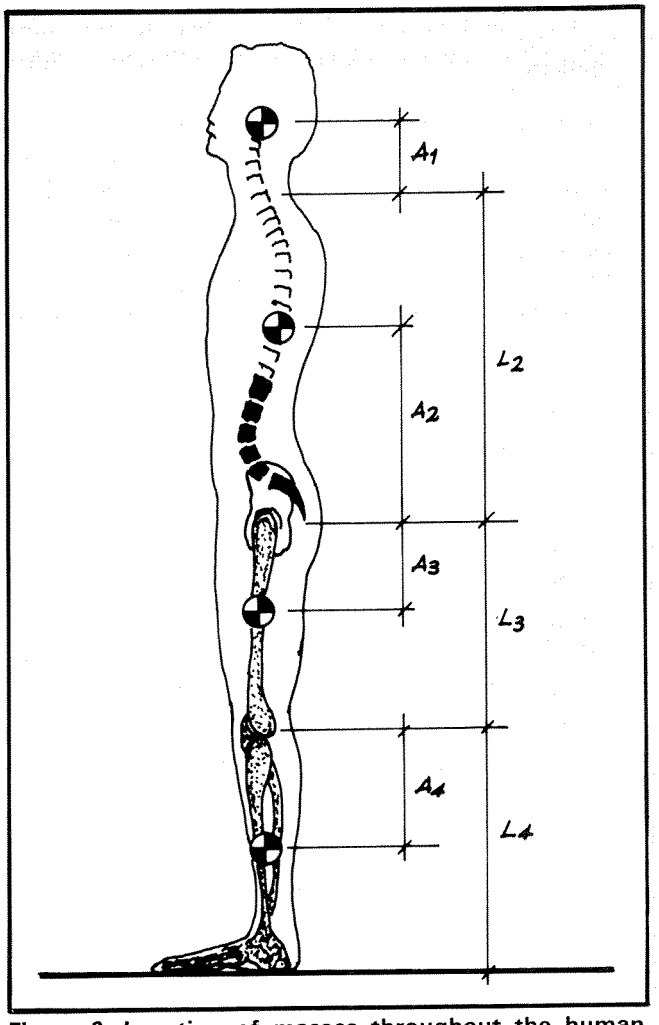

Figure 6. Location of masses throughout the human body

Conclusion

A reduced number of accidents is directly connected with a good number of laws aimed at establishing a deeper respect for the highway code, a strict application of speed limit regulations, and improved service capacity (especially crossings in traffic-impacted areas).

A more rigid enforcement of speed limits in the suburban areas is to be envisaged.

Furthermore, the analysis and considerations concerning the influence that the vehicle type exerts on the severity of an accident involving a pedestrian cannot be modified. In fact, suggestions for technical changes with no supporting grounds cannot be made to motor companies. Some slight changes are instead envisaged without affecting the technical elements of an automobile design; they certainly might reduce some hazardous situations.

While stressing the seriousness and importance of such a problem, we need to go on gathering reliable data from different sources to concentrate more on the elements of accident epidemiology of pedestrians.

Abstract

No method based on experiments is convenient for evaluating globally the potential risk of a given vehicle for the whole population of pedestrians at risk, which encompasses the smallest children and the tallest adults simultaneously, when a large range of impact speeds has to be considered.

Mathematical models are also inadequate, due to the large number of runs required for obtaining the probability of impact on each section of the front end profile.

This paper describes first a recently improved mathematical method for defining the head trajectories yielded by experimental simulations or by a validated mathematical model. Then, a computer program is presented that simultaneously uses this method and statistical data concerning real accidents. The output of this program is a distribution of the impact probabilities for a given profile. The head impact velocities can be utilized for weighing the results.

Possible improvements and application of this method are discussed.

Accidentological Review

1. Between 1970 and 1980, the number of pedestrians killed in France decreased by 28 percent, stabilizing in 1980 at 2,277 killed and 42,490 injured, including 14,000 seriously injured(1).

   Between 1980 and 1984, the number of pedestrians killed on the road continued to fall, reaching a total of 1,760 in 1984 (Figure 1). This drop can be explained by a number of different simultaneous developments:

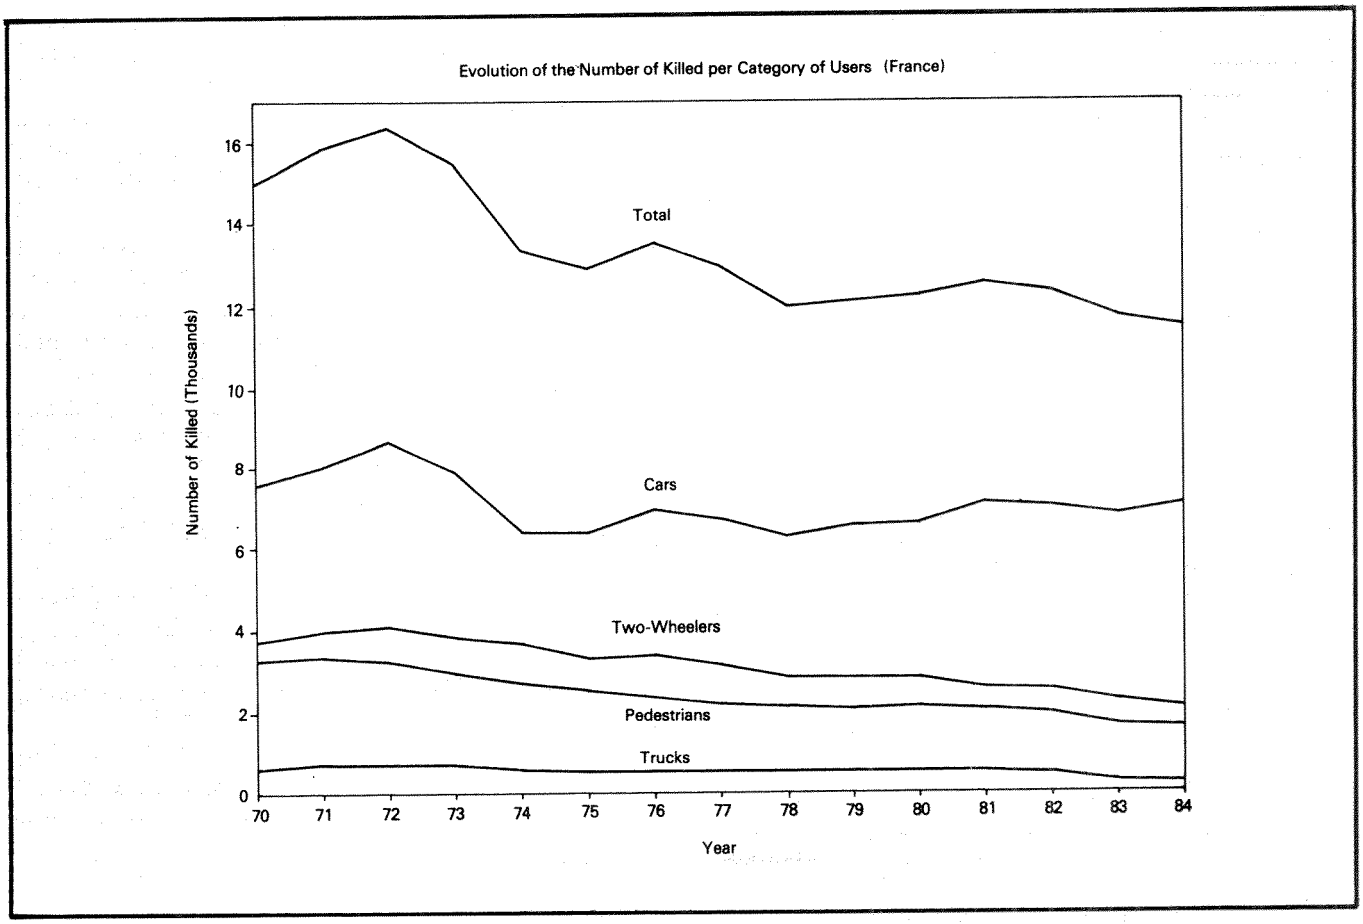

Figure 1. Evolution of the number killed per category of users (France)

- Extension of school bus services in the country
- Fewer pedestrians and more cars
- Increased separation between pedestrians and motor vehicles
- Less aggressive modern vehicles in terms of their more streamlined design and their greater deformability, etc.

This favorable evolution has also been observed in other industrialized countries (West Germany, Great Britain, and the United States).

2. The body segment most frequently and most severely affected is the head (see Figures 2 and 3).

Moreover, at speeds lower than 25 or 30km/h, the lesions due to secondary impact with the ground are more severe than those inflicted by the vehicle (primary impact), but the opposite applies at higher speeds. The head-vehicle impact is, therefore, the predominant feature of pedestrian accidentology, for the speeds at which severe or fatal injuries can be observed.

3. The great majority of pedestrian accident victims are adults with a maximum density height of 1.64m (Figure 4). However, it should not be forgotten that 16 percent of the pedestrian accident victims are children.
4. The size of the pedestrian and speed of the vehicle are the essential determining factors in the site of impact of the head with the vehicle and the relative speed between the head and the vehicle just prior to the impact.
5. Two age groups are at high risk in a pedestrian accident, in relation to the general population (Figure 5) (frequency of involvement greater than the demographic distribution).

It is concluded that priority must be given to a child's and an adult's head, which justifies this presentation.

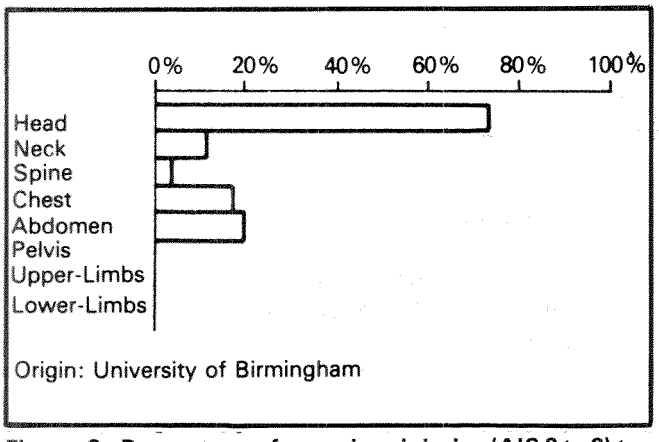

Figure 2. Percentage of nonminor injuries (AIS 2 to 3) to the different parts of the body of 739 pedestrians sustaining injuries of a moderate degree (OAIS 2 to 3)

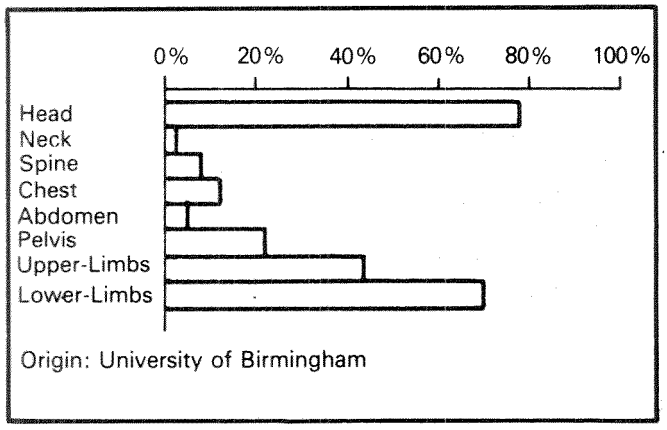

Figure 3. Percentage of very serious and fatal injuries (AIS 4) to the different parts of the body of 253 pedestrians seriously injured or killed (OAIS ≥ 4)

Scatter of the Results of Experimental Trials

The scatter of sites of impact of the head obtained during experimental simulations with dummies and performed under identical conditions, i.e., with the same

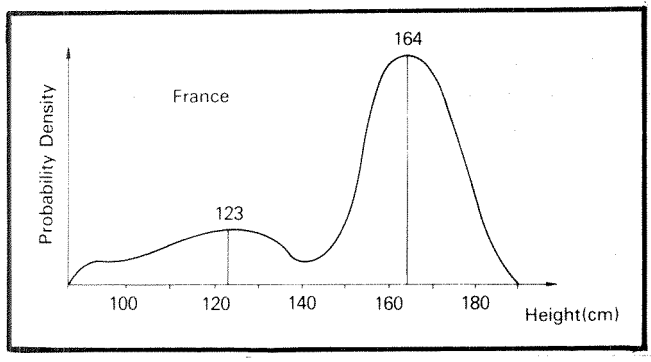

Figure 4. Distribution of pedestrians involved in accidents according to their size

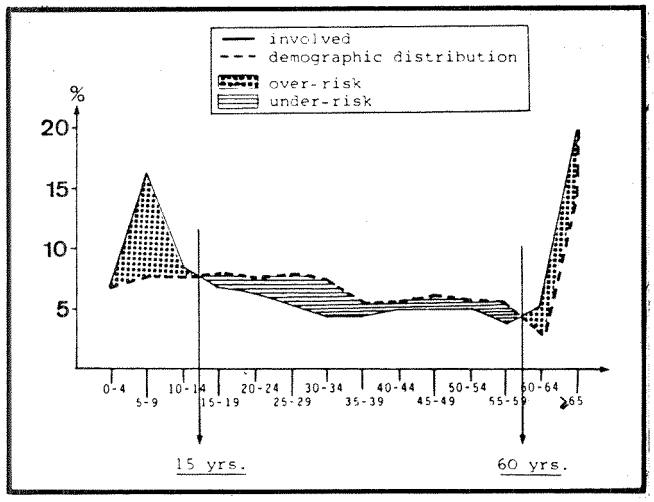

Figure 5. Risk of accident according to age of pedestrian

dummy and the same vehicle traveling at the same speed at the moment of first impact and with the dummy in the same position in relation to the vehicle (in particular, the position of the feet) and without any risk of interposition of elbow, cannot be neglected: in the order of 10cm for a sample of five trials.

The scatter of the velocities of head/vehicle impact is even greater. Under the same test conditions, the ratio of the velocity of head/vehicle impact to the initial velocity of the vehicle, which is in the order of 1, can vary within a range of 0.5 or even 1.

In the case of real accidents, it is obvious that the scatter of the sites and the velocities of head/vehicle impact for the same vehicle at the same initial velocity and the same height of the pedestrian will also be very wide.

One should not, therefore, be excessively demanding about the accuracy of the results provided by a mathematical model of simulated shock or by a system of equations of trajectory of the center of the head, such as the one described in this paper. The essential point is that these results lie within a scatter of experimental results.

System of Equations of the Trajectory of the Head: TRAJ Program

In a previous paper, we explained how we validated the two-dimensional PRAKIMOD mathematical model in the context of pedestrian shock on the basis of experimental tests (some of which were reconstructions of real accidents). These tests involved the use of vehicles of various sizes and shapes traveling at a wide range of velocities—from 16 to 48km/h(2). We investigated a mathematical form of CG kinematics of the head, obtained by means of PRAKIMOD, for 24 simulations consisting of those performed during the phase of validation of the model and the complementary simulations with 6-year-old pedestrians or pedestrians with a height between that of a 6-year-old and a 50th percentile adult(4).

The form initially selected(3) consisted of 18 terms adjusted by least squares for each coordinate:

$$\frac{X}{T} = \frac{Xo}{T} + \frac{Vot}{T} = A_{1,1}t^2 + A_{1,2}t^3$$

$$\frac{Z}{T} = \frac{Zo}{T} + A_{2,1}t^2 + A_{2,s}t^3$$

or, in polar coordinates:

$$x = x_o + \rho \cos \vartheta$$

$$z = \rho \sin \vartheta$$

with

$$\frac{\rho}{T} = \frac{\rho o}{T} = A_{3,1}t^2 + A_{3,2}t^3$$

$$\vartheta = \frac{\pi}{2} - \frac{Vot}{Po} + A_{4,1}t^2 + A_{4,2}t^3$$

where the constants A (two per coordinates X, Z or ρ or) were functions of V, T and G:

$$A_{i,1} = B_{i,1,1}\frac{V^2}{T^2} + B_{i,2,1}\frac{g}{T} + B_{i,3,1}\frac{V}{T}\sqrt{\frac{g}{T}}$$

$$A_{i,2} = B_{i,1,2}\frac{V^3}{T^3} + B_{i,2,2}\frac{V}{T}\frac{g}{T} + B_{i,3,2}\frac{V^2}{T^2}\sqrt{\frac{g}{T}}$$

the constants B (2 x 3 = 6 per coordinate) were functions of H and T:

$$B_{i,j,k} = C_{i,j,k,1} + C_{i,j,k,2}\frac{H}{T} + C_{i,j,k,3}\left(\frac{H^2}{T}\right)$$

and the constants C (18 per coordinate) were determined by a least squares method on the basis of the coordinates of CG of the head with a time interval of 10ms from the output data of the 24 PRAKIMOD simulations.

A form of equation was then obtained using fewer terms (12 instead of 18 per coordinate), but remaining close to the given points(4) by replacing T by Po in all of the denominators and by eliminating the terms containing G.

Simultaneously, for the polar coordinates, the center of the system, initially at ground level, was raised to the level of the front of the hood.

The pole of the polar coordinates was displaced because, if we consider that on first approximation the part of the pedestrian situated above the hood of the car would pivot around the anterior border of the hood, it seemed preferable to make the pole of the polar coordinates coincide with the center of rotation than to place it at ground level.

When the pole was placed at the level of the anterior border of the hood, the description of the movement by polar coordinates generally gave better results than the description by means of cartesian (rectangular) coordinates for all the forms tested.

A further improvement has recently been added to this form:

- By further reducing the number of degrees of freedom of the model from 12 to 8 per coordinate (suppression of the terms involving $(H/P)^2$)
- By replacing H/P with its inverse Po/H

- By replacing the height of the edge of the hood (H) with an equivalent hood height equal to H decreased by the projection (Dx) of the bumper bar over the anterior edge of the hood

(A detailed description of the calculations will be in the final paper.)

Most of the original trajectories were well fitted by these equations (Figure 6), except for those that involved vehicles with a high and angular hood border (Figure 7). This demonstrates that the present form of the equations is not optimal. They can certainly be improved while retaining the general principle of a statistical, nonlinear model for all of the trajectories used in the input data.

Application: The Program PROF for the Determination of the Sites and Velocities of Impact Between the Pedestrian's Head and Any Vehicle Profile

These new equations can be used by the PROF program simulating the bombardment of the front profile of any vehicle by spheres with a given radius simulating the heads of pedestrians. The kinematics of the center of these spheres are controlled by the equations, in which the coefficients have been determined by the TRAJ program and which involve the height of the pedestrian, the projection of the bumper bar, the height of the anterior edge of the hood, the initial velocity of the vehicle, and the time.

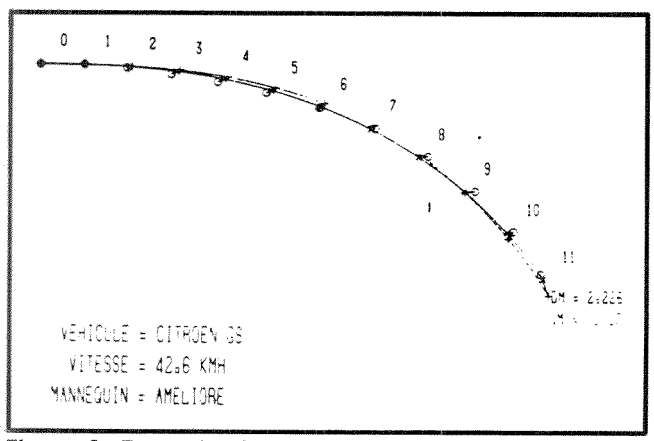

Figure 6. Example of good adjustment of the trajectory by the TRAJ equations

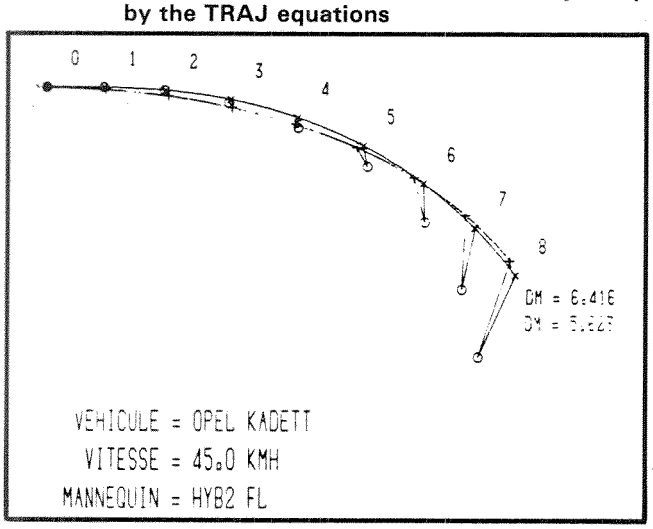

Figure 7. Example of poor adjustment of the trajectory by the TRAJ equations

The immediate typical applications for use with the PROF program are—

1. Determination of the site and velocity of head/vehicle impact for a particular impact characterized by—
   - A vehicle profile
   - The height of the pedestrian
   - The velocity of collision (Figure 8)
2. The same operation for—
   - A given vehicle profile
   - A series of pedestrian heights defined by the user at the beginning of the program
   - A series of velocities of collision defined in the same way

   The program determines the head impacts for all sets (height of the pedestrian and velocity of collision) obtained by combination of the elements of the two series (Figure 9).
3. The computerized statistical data can be used as input data for the heights of the pedestrians and the velocities of collision so as to attribute to a density distribution of the probability of impact of the head of a pedestrian belonging to the population described by the statistical data (Figures 10 and 11).

At the stage of conception of a vehicle, the attention of the constructor's research department can, therefore, be drawn to the zones with the highest risk of impact to make them less rigid.

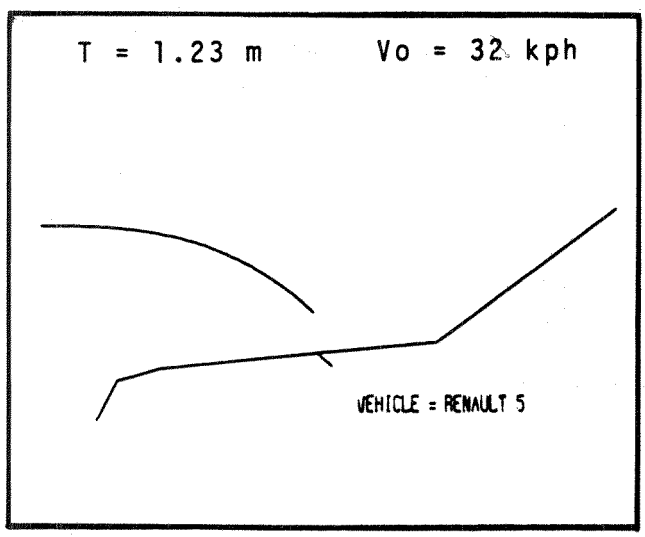

Figure 8. PROF output examples—determination of the site and velocity of head/vehicle impact in different cases

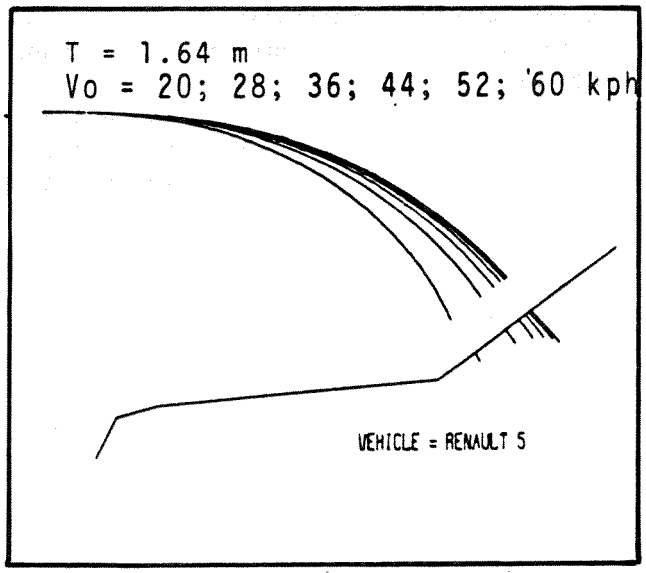

Figure 9. Determination of the site and velocity of head/vehicle impact in different cases

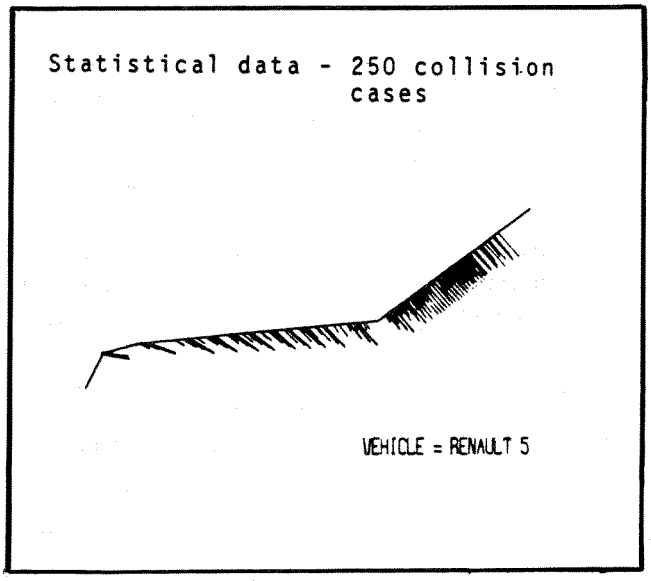

Figure 10. Determination of the site and velocity of head/vehicle impact in different cases

Validation of the TRAJ and PROF Programs

A validation of these programs has been attempted by using them to determine the site and velocity of head/vehicle impact in cases of collision between a Volvo 244 and a 50th percentile adult in the middle zone of the front of the vehicle at a velocity of 40km/h. Figure 12 shows the impact obtained—

- By the PROF program (using the coefficients previously determined by TRAJ)
- By mathematical simulation by means of PRAKIMOD
- In five experimental collisions with mannequins

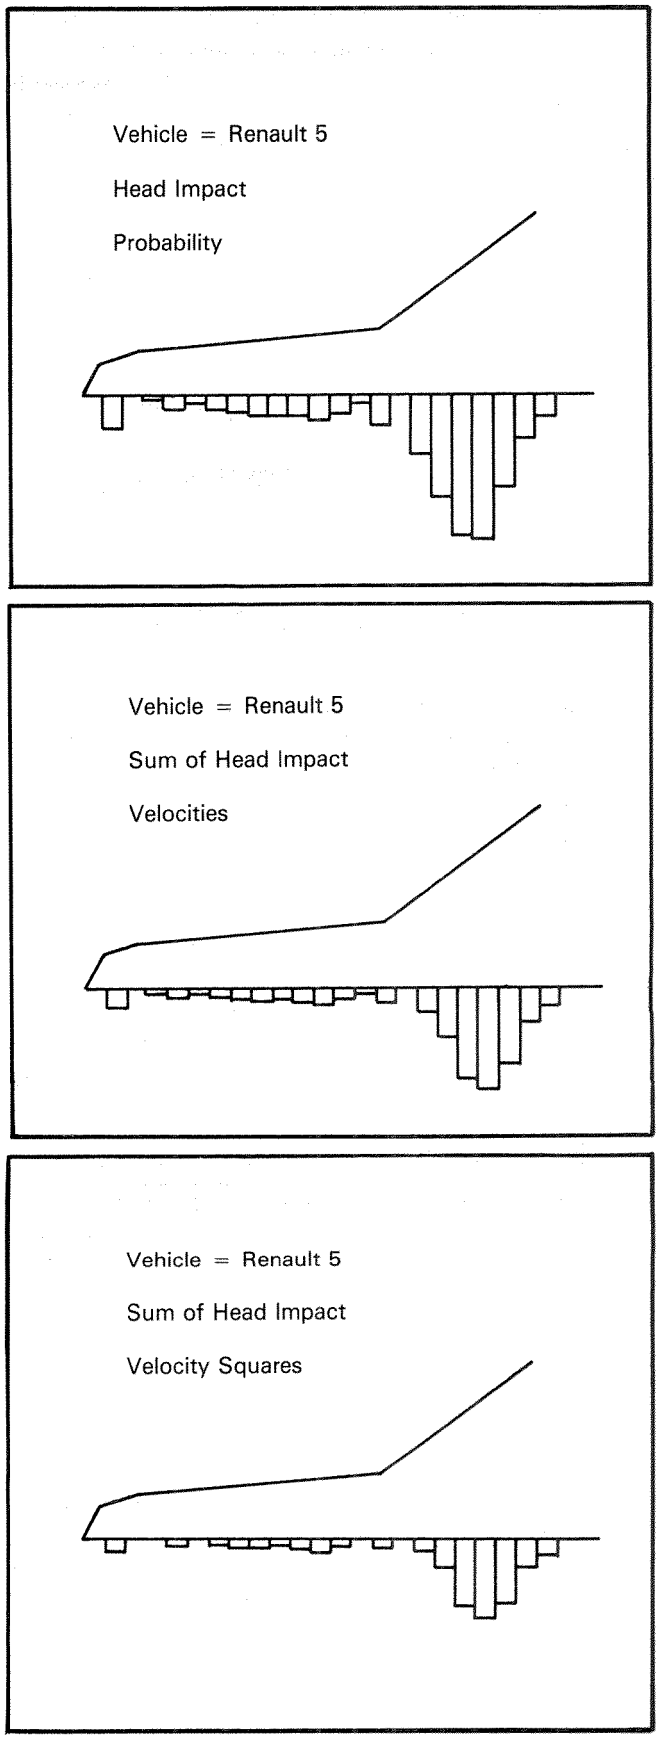

Figure 11. Weighting of the results shown on Figure 10 by the impact velocity

The site and the velocity of impact predicted by PROF were within the scatter of the values obtained by PRAKIMOD and by the experimental trials.

This attempted validation can be considered to be successful.

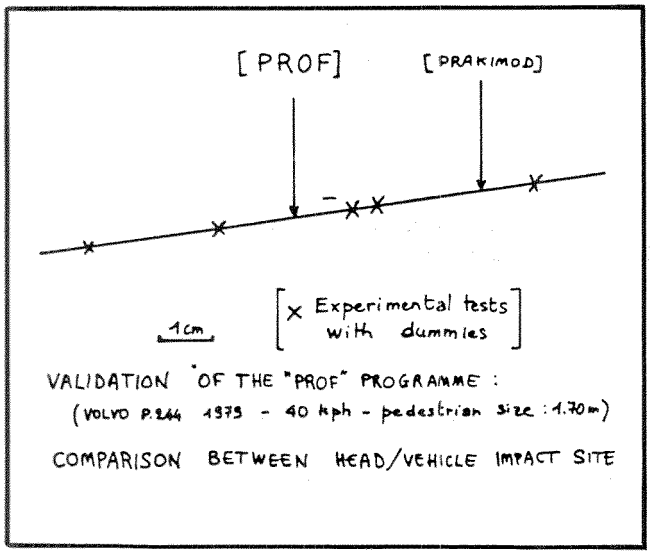

Figure 12. Comparison between head/vehicle impact site

Discussion

To obtain a better reproduction of the kinematics of the pedestrian's head induced by high or angular vehicle profiles, as described above, we need to find a better statistical model.

However, it is true this type of profile is tending to disappear and is being replaced by more aerodynamic profiles, which are well simulated by our model.

To be able to supply research departments with the means of associating each part of a planned vehicle (or at least those parts most frequently involved in accidents) with the optimal rigidity and a depth associated with deformability, we would need to have a value for the mass equivalent of the head in relation to the position of the body of the victim at the time of head/vehicle impact, as well as the height and age of the victim. We also need to have a better understanding of the tolerance of the human head to such impact, as a function of age.

The Mass Equivalent

The PRAKIMOD model allows the mean mass equivalent of the head to be determined during impacts conducted under well-defined conditions.

Unfortunately, in this model, the neck is reduced to a simple articulation. The simplicity of this model of the neck does not prevent good simulation of the kinematics of the head up until head/vehicle impact, but it does not allow good simulation of the behavior of the head and neck unit during the head/vehicle impact if the trunk exerts a force in the axis of the neck.

Until more detailed data are available, we can recommend that the mass of the head alone or that of the head and neck together be used as the mass equivalent of impact.

Tolerance of the Head to Impact

Although the tolerance of the head of a middle-aged adult is beginning to be defined, the tolerance of children and elderly people is less well known. The tolerance to linear acceleration is probably greater in children than in adults and less in elderly people.

In the absence of any precise information, we could adopt the criterion of adult head protection for all the pedestrian population.

Conclusion

Following a more detailed validation and, if necessary, an improvement in the statistical model used, the TRAJ and PROF programs described in this paper may constitute a very valuable computerized tool to determine the zones of a vehicle at greatest risk of impact with the head of a pedestrian.

The relative potential dangers of the corresponding impacts can be rated by means of an experimental procedure using a model of the head.

Computer Simulations of a Range of Car-Pedestrian Collisions

G.D. Suthurst
Ford Motor Company, United Kingdom

R.N. Hardy
Cranfield Impact Centre, United Kingdom

Abstract

Realistically, the only way to significantly improve the pedestrian injury situation is by separation of the vehicle and pedestrian population to prevent collision occurring, since injury to a pedestrian is inevitable if hit by a car travelling at even low speeds.

However, it is important to assess the contribution that vehicle design characteristics can make to minimise the consequences of such collisions for a variety of pedestrian types, and to establish the various vehicle parameters that can influence pedestrian injury.

This paper describes the initial stages of an investigation into these parameters by means of computer simulation.

First, the joint, inertia, and contact characteristics of a 50th percentile adult dummy and a 6-year-old child dummy were established by tests. The contact characteristics of a range of car fronts were also determined from pendulum tests at speeds of 24 and 40km/h. A vehicle-pedestrian interaction model was then established, and simulations of previously staged tests were carried out by means of the Calspan Crash Victim Simulation (CVS) program. This paper shows the comparison between tests and simulations for adult and child representations with a range of front end parameters. The particular effects of the various parameters are also discussed.

Introduction

Accident statistics relating to traffic accidents involving pedestrians are well documented in many countries(1,2,3,4,5,6,7). In these accidents, approximately 80 percent of the pedestrians are struck by cars, representing 25 percent of all fatalities in road traffic accidents and 16 percent of all those seriously injured. These statistics show the need to reduce the number and severity of car-pedestrian collisions. In the future, the pedestrian percentage figures are likely to increase as safety measures currently implemented for vehicle occupant safety begin to be reflected more in the accident data.

It is self-evident that injury is inevitable if a pedestrian is hit by a car even at low speeds and that major improvements can only be achieved through accident avoidance measures. It is, however, worthwhile to determine whether any realistic action can be taken in car design to reduce the severity of the injury that the pedestrian is likely to sustain.

Examining the car-pedestrian accident data further, several features can be highlighted:

- 60 to 70 percent of the pedestrian fatalities are inflicted by the car(8).
- 70 to 75 percent of pedestrian injuries are due to primary contact with the front of the car(1,4,5,10).
- 60 to 75 percent of AIS 4 and 5 injuries are due to head impact against the car(3,9).
- Age groups 6 to 9 years (40 percent) and over 65 years (20 percent) are most at risk(3,4,10).

It is, therefore, necessary that pedestrian studies should concentrate on the car front end and its effect in collisions with both adult and child pedestrians.

The car front end has been receiving increased attention in recent years due to the influence of front impact legislation and/or company policy on frontal impact performance. The need to reduce weight and the cost of ownership has also influenced front end design.

Reviewing the list of constraints on the front end, we have—

- Aesthetic appearance
- Engine and accessory packaging
- High-speed front impact performance for occupant protection
- Low-speed front end damageability performance—low cost of ownership
- Reduced overall weight
- Pedestrian impact performance—6-year-old child and adult
- Aerodynamics

The final design will need to be a compromise as some of these factors work for each other while others work against.

With such a list of constraints, a design and test exercise to achieve the compromise would be a mammoth task as each item would need to be optimised and then its effect on each of the other constraints would have to be checked, modified, and rechecked for an acceptable overall effect.

Mathematical modelling of the impact situation is the obvious solution to such a problem. Parametric studies can be conducted rapidly, and each optimised item can then be assessed relative to the other criteria prior to a build-and-test program.

This paper describes the initial stages of an investigation into these parameters by means of a computer simulation. Included are descriptions of a test program simulating car-pedestrian collisions, necessary for the validation of the prediction program details of dummy and car contact characteristic tests, and the development of a vehicle-pedestrian interaction model using the Calspan CVS program. Comparisons are shown between tests and simulations for adult and child representations with a range of car front end parameters. The particular effects of the various parameters are also discussed.

Technical Approach

To provide an experimental data base for the development and validation of the simulation model, a test program was conducted using four different cars in collision with pedestrian dummies of a 6-year-old child and 50th percentile male.

Previous studies of pedestrian impacts have shown there are normally two impacts in the typical car-pedestrian collision that can cause injury: first, the vehicle impacting the pedestrian, and then the pedestrian impacting the ground. Ashton(11) shows that contact with the vehicle is the main cause of nonminor injury and that severity is dependent on vehicle speed whereas ground contact severity is independent of speed. Other studies have shown that the majority of serious/fatal injuries are caused by head impact against the car. In tests using the present generation of pedestrian dummies, it is unlikely the response of the dummy would be accurate enough to reproduce the actions of a pedestrian for kinematics of the duration and complexity necessary to include the ground contact.

For these reasons, the analysis of the tests was concentrated on the car-dummy contact period, i.e., from initial dummy contact up to head contact with the upper surfaces of the car exterior. This is the period in which car design, size, and stiffness characteristics provide the major influences on dummy kinematics and eventual head-to-car contact.

The Calspan 3D CVS program was selected for the development of the vehicle-pedestrian interaction model. This choice was based mainly on its three-dimensional capability, which was considered essential to allow for a rotation about the vertical axis of the dummy, and on previous experience gained using Calspan CVS for another crash simulation investigation.

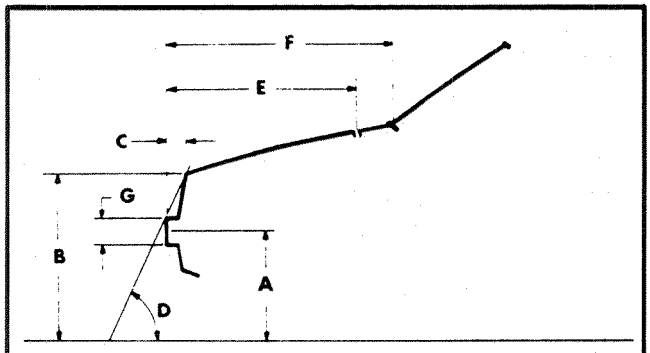
Input to the Calspan CVS program includes dummy and vehicle data; therefore, tests were conducted to establish the joint, inertia, and contact characteristics of the 50th percentile adult and the 6-year-old child dummy. The contact characteristics of the selected car fronts were also determined from pendulum tests at speeds of 24 and 40km/h.

Previous vehicle-pedestrian interaction models have utilised planes to represent the profile of the vehicle. Some researchers have used 5 or 6 planes to represent the front of the vehicle(12,13,14), while others have used up to 10 planes to achieve the correct geometry of the vehicle front(15). As an alternative, TNO has written a hyper-ellipse contact model(16) that eliminates some of the problems inherent in ellipsoid-plane contacts. Ellipsoids were selected to represent the front of the vehicle for this interaction model as the authors had a relatively short time scale available for this stage of their research—too short to allow a new contact model to be written, implemented, and debugged—and to avoid the problems associated with ellipsoid-plane contact models that have previously been reported(17).

Car-Pedestrian Test Program

Test Vehicles

The vehicles were selected primarily to include differences in front end design, stiffness, materials, etc. Figure 1 shows the main dimensions of the models. The model identifications A to D are in descending order of front end stiffness.



DIMENSIONS	MODELS A	B	C	D
A	450	444	423	435
B	667	682	702	760
C	70	59	196	205
D	73°	73°	56°	65°
E	923	1028	1157	1200
F	1042	1128	1275	1330
G	45	35	120	40

Figure 1. Vehicle dimensions

Data Analysis Criteria

To assist in the evaluation of the car front ends, dummy data from the primary contact up to the time immediately prior to head contact with the car were compared. Head velocity (a function of front end design/stiffness) immediately prior to head contact with the car was compared rather than head acceleration at head contact. The head velocity was considered to be a more valid comparison than acceleration data because of the considerable differences in stiffness of possible head contact areas in close proximity to each other; for instance, due to the location, at some point on one car, of an engine component beneath but close to the hood surface or in areas where joints occur, e.g., fender/hood opening lines. The influence of these variables on the head acceleration data could give quite a false assessment of a particular front end parameter, such as bumper stiffness, on pedestrian injury.

Dummies

As the age group 6 to 9 years accounts for 40 percent of the injured pedestrian population, it was necessary for the test program to assess impacts on a child, as well as on an adult, to enable areas of possible conflict in design to be determined. The dummies currently available for pedestrian impact tests have been criticised for several reasons, but mainly due to a lack of compliance in the segments and joints. As dummy development was outside the scope of this investigation, a 50th percentile standing adult male dummy (Part 572) and a 6-year-old child dummy, both manufactured by Humanoid, USA were selected.

Impact Speeds

In European countries, collisions between vehicles and pedestrians occur in built-up areas at speeds below 50km/h. Of cases involving serious injury, 50 percent occur at speeds less than 35km/h and 85 percent at speeds below 40km/h.

Two impact speeds were selected for the test program, a lower speed of 24km/h—typical of the below 35km/h range—and a higher speed of 40km/h. This was considered a suitable range to include up to 85 percent of accidents where serious and fatal injuries occur and also to provide a means of validating the mathematical model prior to parametric studies.

Dummy Stance

Seventy percent of pedestrians injured in collision with a car are struck by the front of the car(1,3,4,5,10); the majority are struck on the side of their body by the inner or outer third of the car front(1,3,4). The dummies in this test program were positioned for impact essentially on the side of the body but with the dummy rotated toward the car by 30° and with the legs in a walking stance with the impacted leg in the rearmost position (Figures 2 and 3). This position was selected for the following reasons:

- Impact on the side represents the major directional frequency in the real accident situation, and this position also gives the most severe leg impact condition as there is no natural rotation in the knee joint in that direction. However, in a collision using dummies, it gives an unrepresentative level of protection to the head due to shoulder and/or elbow impact with the hood as these parts of the dummy are far more rigid than on a human.
- The rotation of 30° gives representative loading on the legs while allowing the dummy to rotate during the impact to insure head contact without prior shoulder contact.

Figure 2. Initial adult dummy stance

- To eliminate the elbow influence, the dummy arm nearest to the car was lightly attached to the torso.
- The car centre line of car considered to be preferable for repeatability reasons.

Vehicle Attitude

To insure comparable and repeatable test conditions, a brake dive attitude was simulated with braking of 0.7g at impact with the pedestrian. The brake dive position was constant throughout the impact test as the procedure involved bodyshells mounted on a trolley. This eliminated any rapid change of ride heights that might occur at impact and enabled a consistent impact velocity to be achieved.

Dummy Test Program

The characteristics of the adult (Part 572, 50th percentile) and child (Part 572, 6-year-old) dummies were measured by a series of tests to establish—

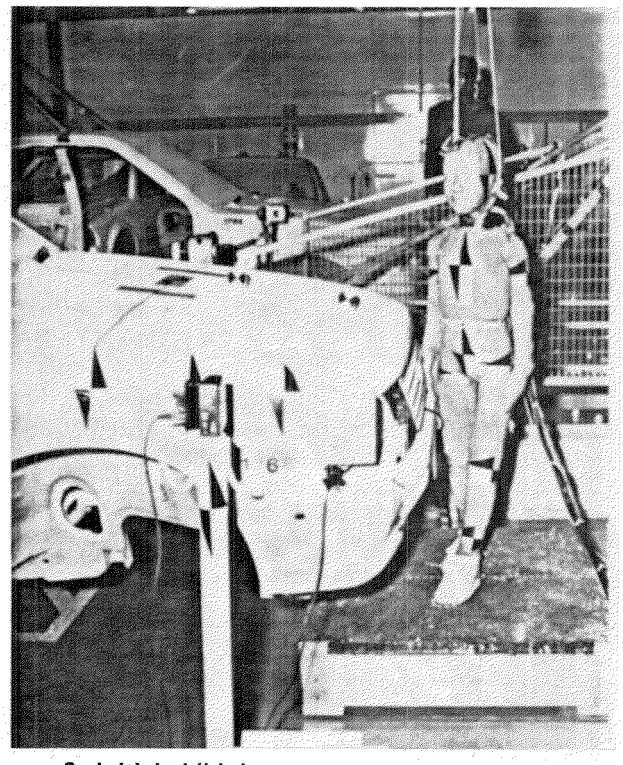


Figure 3. Initial child dummy stance

- Mass and moment of inertia of each limb
- Link dimensions and external limb sizes
- Joint characteristics at 1g settings
- Skin and limb compliance characteristics

Principal moments of inertia were measured for some body segments (e.g., lower torso, head, upper legs, and arms).

Car Front Contact Test Program

Dynamic force-deflection characteristics of the bumper, hood top, and hood edge of each of the cars were determined experimentally using a pendulum. To allow tests to be carried out at both 24 and 40km/h, the pendulum consisted of a centralised mass and shaped wooden former hung on a wire suspension. An accelerometer was mounted on the pendulum to determine the forces on the car, and deflections were measured with a linear potentiometer. The mass of the pendulum and shape of the wooden former were varied to determine characteristics for both dummies at the two speeds. Typical setups prior to testing are shown in Figures 4 and 5. An after-test situation is shown in Figure 6.

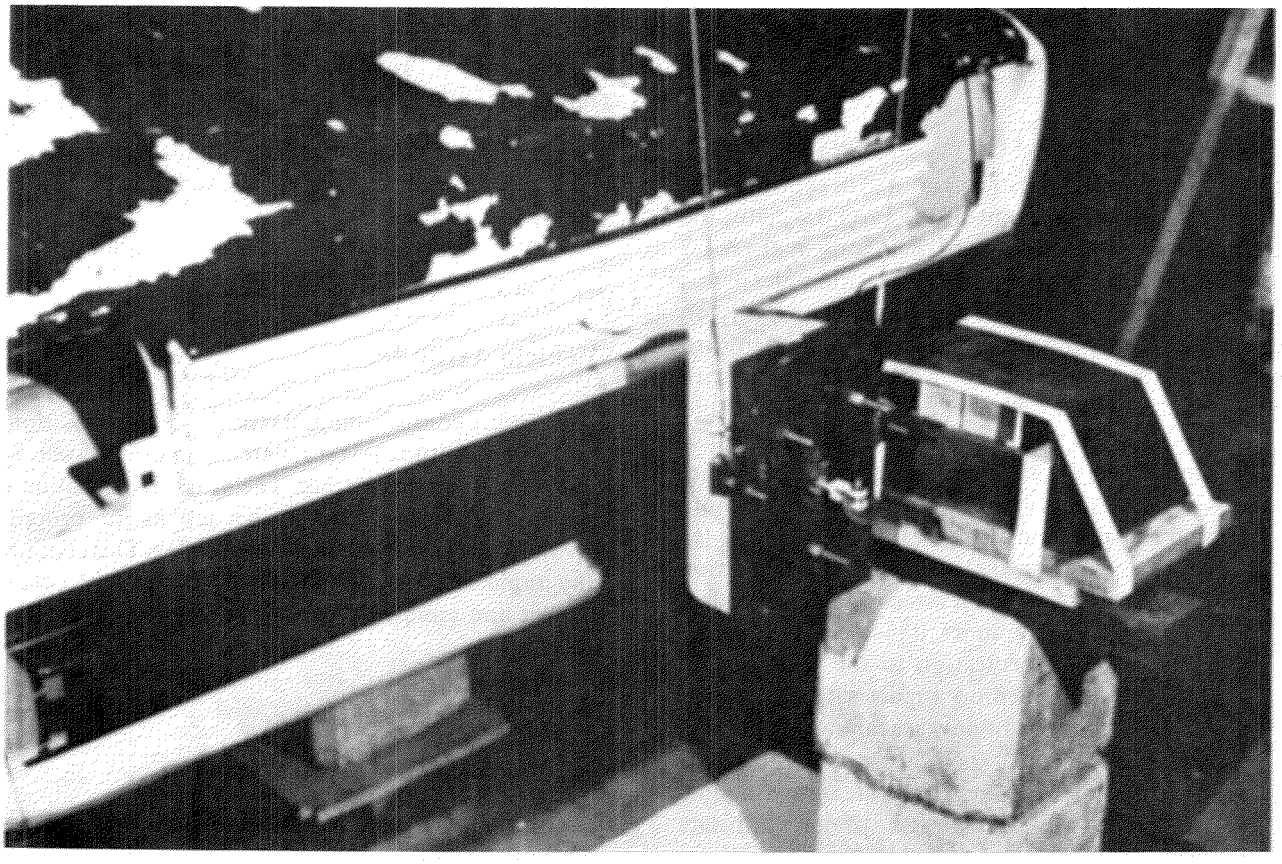

Figure 4. Bumper prior to pendulum test

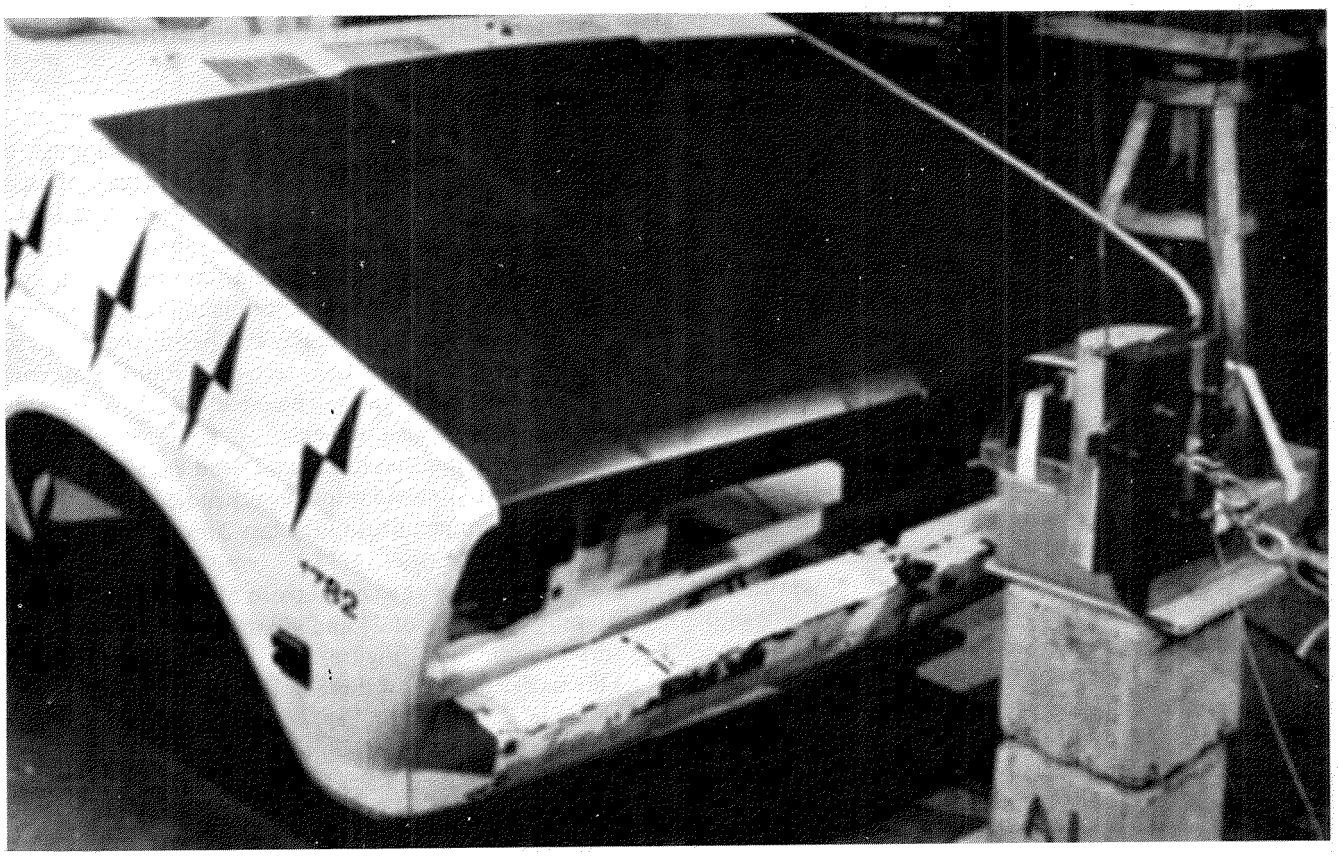

Figure 5. Hood edge prior to pendulum test

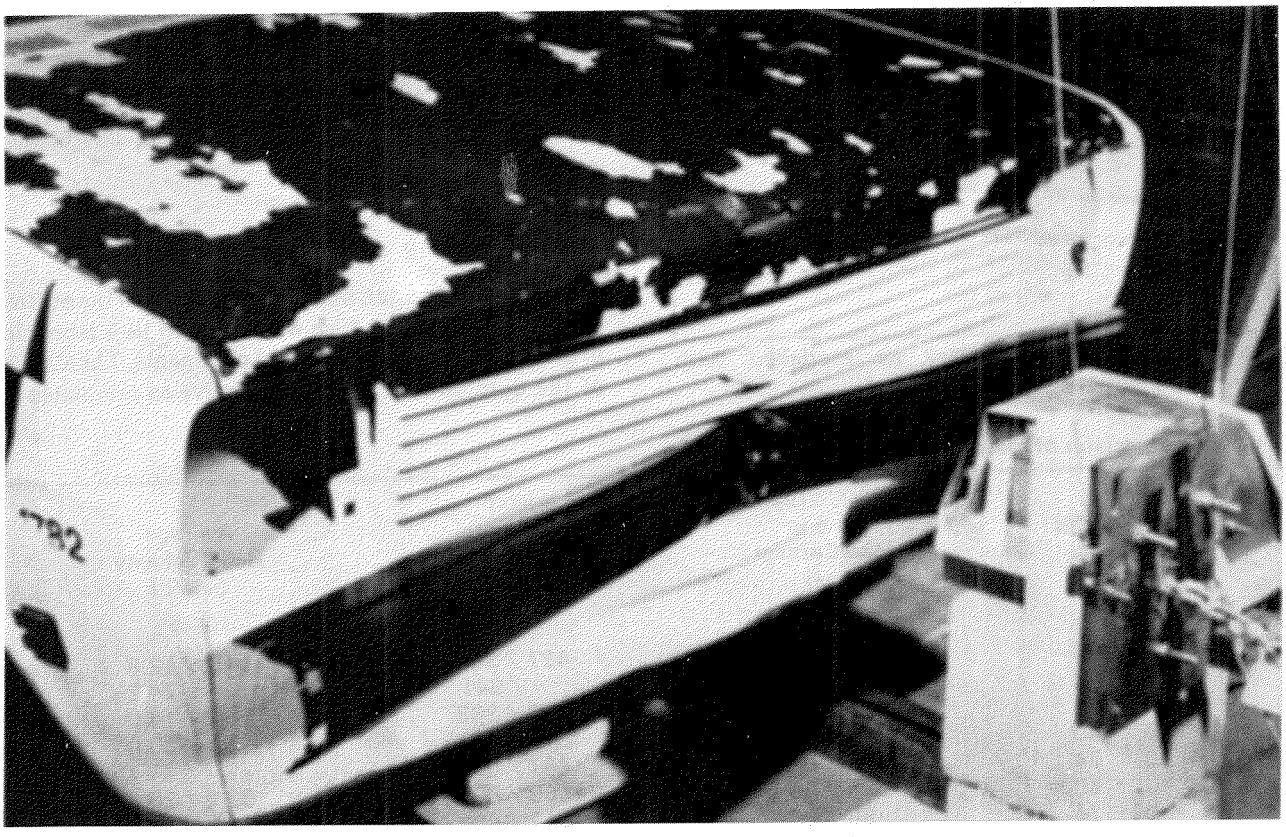

Figure 6. Bumper after test

Car-Pedestrian Interaction Model

The use of ellipsoids to model to the front of the vehicle has worked well. Where there have been problems, they often related to contacts at the end of the elongated segments, such as arms or legs, and especially when the penetration was a high proportion of the semi-axes of the two contacting ellipsoids. The most severe was most obvious during the leg-to-bumper contact for both the child—due to the small limb size—and the adult—due to the penetration. At one stage, artificially large leg segments were defined for the bumper-leg contact phase. The final solution adopted was to use the correct leg geometry and have a bumper ellipsoid having a longitudinal semi-axis up to an order of magnitude greater than the semi-axes of the leg. The curvature of the foremost edge of the ellipsoid was adjusted to the geometry of the front of the car bumper by having a lateral semi-axis that projected beyond the side of the car. In a similar manner, the semi-axes of the ellipsoid representing the hood top were chosen to reproduce the correct geometry over the full width of the car but were of necessity greater than the width of the car (Figure 7).

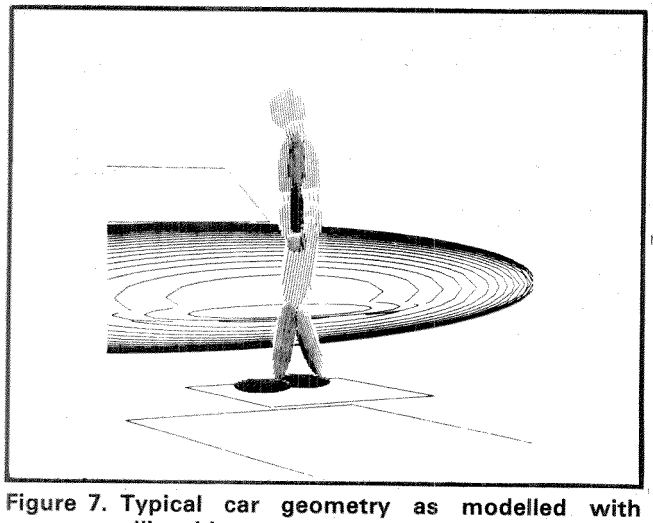

Figure 7. Typical car geometry as modelled with ellipsoids

Comparison Between Test and Simulation

Prior to this work, it was difficult to quantify by experimental tests the gains, for a pedestrian, of small variations in vehicle geometry, due in part to problems of repeatability. To assess these changes, it was essential to establish that a computer simulation could accurately reproduce the results from experimental tests. The simulation method was validated by comparing the results for several parameters between tests and simulations for a range of dummy impacts. These parameters were—

- Time to head impact
- Longitudinal horizontal head excursion
- Average head velocity perpendicular to the point of contact during the last 20ms prior to contact
- Kinematics

Table 1 shows the comparison of results for the child dummy at speeds of 24 and 40km/h and covers the first three parameters. Figure 8 shows the comparison of kinematics for one of these impacts.

Table 2 shows similar comparisons for the adult dummy. At this time, the adult simulations have not been completed, but Figure 9 shows the comparison of kinematics for one of the completed simulations.

It was concluded that, in general, there was good correlation between the simulation results and experimental tests. The repeatability of the experimental tests was an important consideration here, and until a more repeatable test could be devised it was sufficient for the computer prediction to be within the order of variation normally associated with the equivalent dummy test.

Discussion

Dummy Setup

Setting up the adult and child dummies in the attitudes specified in the procedure was found to be a labourious process and is worthy of several comments. The attitudes of the dummies are specified relative to templates that

Table 1. Comparison of child test and simulation results

Model & Speed (km/h)	Test/Simulation Comparison: Time to Head Contact (ms)	Horizontal Head Excursion (mm)	Average Head Velocity (km/h)
A 24	84 / 87	427 / 384	14.2 / 12.8
A 40	- / 56	- / 341	- / 24.2

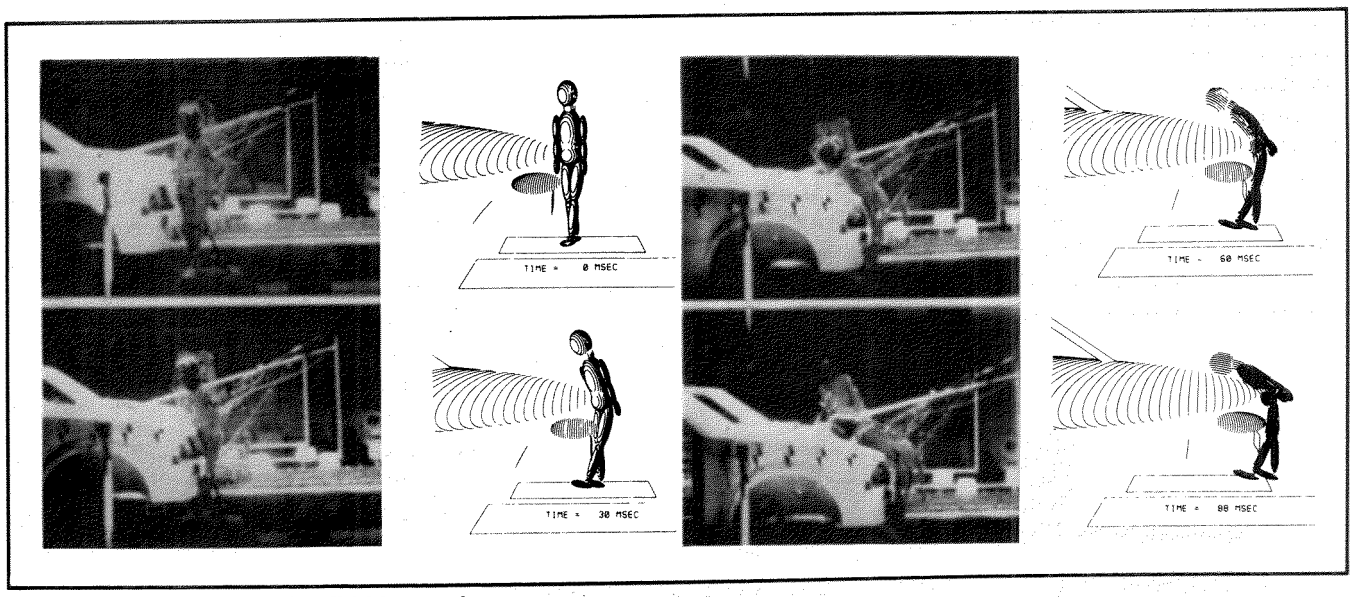

Figure 8. Comparison of child kinematics

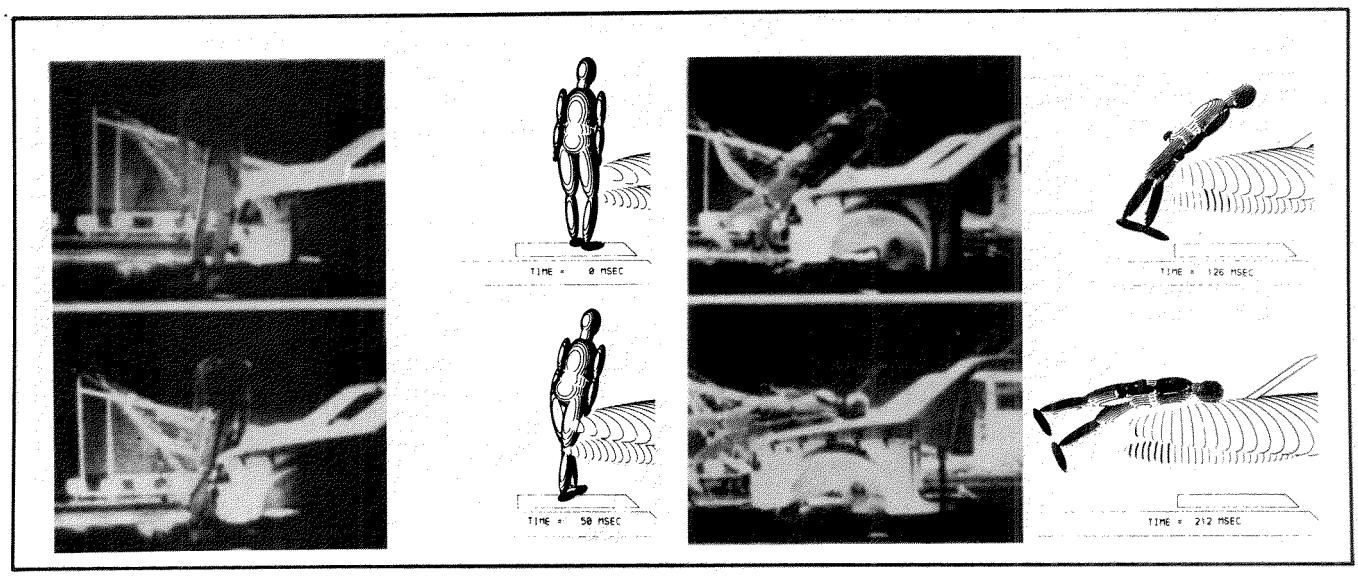

Figure 9. Comparison of adult kinematics

show the feet location, the lateral axis of the pelvis, the axial plane of the dummy, the Z-point, and the direction of impact. The accuracy with which the lateral axis of the pelvis—the axis passing through the centre of the femur heads—can be positioned so that its orthogonal projection on the template is correct must be open to question, as is the ability to position the shoulder axis parallel to the lateral pelvis axis and to locate the orthogonal projection of the head's hook hole Z as specified on the template. In addition, weight distribution between the feet is not specified, and the dummy joints can be tightened beyond the standard lg settings should the dummy fail to stand of its own accord in the specified attitude. While it is appreciated that measuring the weight distribution as part of the setup would be extremely awkward, it is possible that it could vary quite considerably between various test houses. Indeed, even within one test house, variations of upward of 10 percent have been recorded despite best efforts to achieve repeatable attitudes.

With these variations, the repeatability of the whole setup procedure is in doubt, and this has been confirmed by the results from supposedly identical tests. One improvement would be the use of a body jig to locate the key features of a dummy (e.g., lateral axes of pelvis and shoulders, head hook hole, etc.). This may well enable weight distribution, as well as attitude, to be controlled more accurately.

Adult Dummy Attitude at Head Contact

During all the tests with the adult dummy, a shoulder-hood top contact was noted. The extent of this contact varied from model B at 24km/h, where the dummy almost achieved a face-down attitude at head contact (Figure 9), to model D at 40km/h, where the shoulder-shoulder axis was 45° to the lateral axis of the car with the left shoulder raised (Figure 10).

However, the initial stance of the dummy was specifically chosen to eliminate shoulder and elbow impact with the hood top. This was because these parts of the dummy are far more rigid than on a human and would otherwise give an unrepresentative level of protection to the head.

Consequently, the initial stance recommended in the test procedure was not achieving its desired aim. One of the reasons for this seems likely to be connected with the position of the right (leading) leg. To achieve the correct positioning of the dummy features as on the template the right knee is forward of the hip (i.e., right upper leg

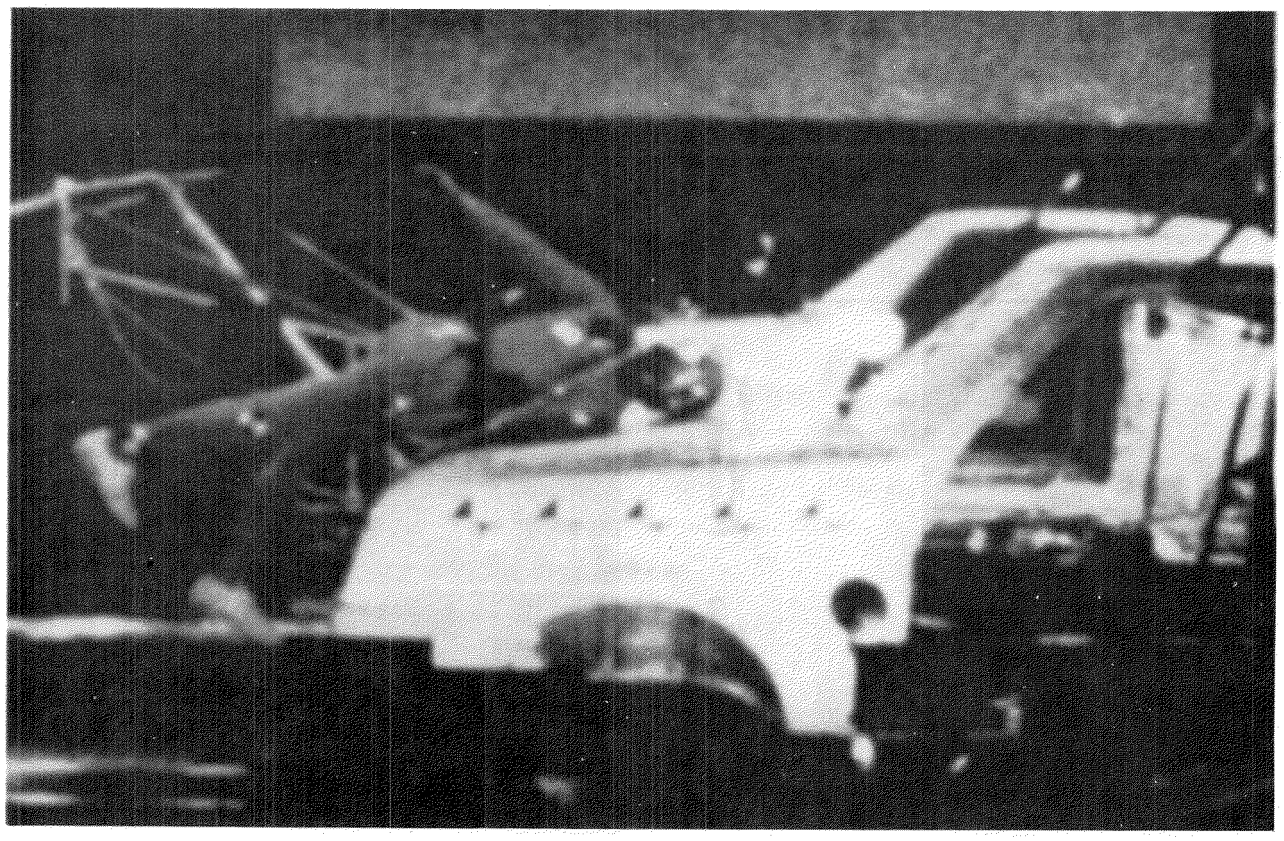

Figure 10. Adult attitude at head contact—model D

rotated forward). The right ankle is behind the knee (i.e., right lower leg rotated backward) (Figure 7). During the initial period of leg-bumper contact, this causes the right leg to rotate at the hip, about an axis parallel to the right upper leg, in an anticlockwise direction (lateral rotation). This rotation is eventually checked and reversed as happens during a test. However, this initial lateral rotation may help maintain the torso of the adult dummy in its initial attitude.

An alternative leg position could be with both left and right legs straight, while maintaining the footprints on the template, which would probably cause the full weight of the dummy to be more evenly distributed. In this stance, the right knee would be behind the right hip and may well cause a face-down attitude at head contact.

Front End Parameters

The severity of the initial impact and the resulting kinematics are influenced by the car front end design and the stiffness of the contacted car components.

The initial car-dummy impact location is nearly identical, that is, at the knee of the adult dummy and the femur of the child. However, there are considerable differences in the actual contact depth, ranging from 72 to 165mm.

Tests at 40km/h were restricted to the models with softer front ends, i.e., models C and D, to validate the computer simulations at the higher speeds. Simulations have been completed for most models.

24km/h Impact—Adult

The cars with softer front ends, models C and D, had definite beneficial effects with respect to the major areas of the dummies. The softer, deeper bumper faces reduce initial leg contact acceleration and more effectively spread the impact load.

The position of the front edge of the hood is a major influence on the dummy kinematics after initial impact. The more vertical front ends of models A and B produce a pronounced knock forward effect due to the distinct leading edge of the hood. This produces high pelvis accelerations but minimises head velocity and the horizontal excursion of the head relative to the front of the car.

The models with a lower or less distinct hood leading edge—models C and D—produce a wraparound effect, which tends to result in lower pelvis accelerations but higher head velocities and greater horizontal head excursions.

24km/h Impacts—Child

As with the adult, head velocities show the same upward trend for models C and D. Dummy kinematics were also similar, with models C and D producing the wraparound effect and consequent reductions in accelerations in the secondary impact areas.

40km/h Impacts—Adult

Head velocities did not show a significant variation between models. They were considerably higher than the vehicle velocity at impact. Dummy kinematics were similar to those of 24km/h except that events occurred earlier.

40km/h Impacts—Child

The benefits of the softer front end models were reflected in the head velocities, with only modest increases from these at 24km/h. However, the models with distinct hood leading edges caused head velocity increases of around 100 percent. As with the adult, kinematics were similar but events occurred earlier.

Head Velocity

Generally, the head velocities from the computer simulations were lower than those from the practical tests. The reasons for this are not clear, especially as the times to head impact show good correlation, but this has been reported elsewhere when three-dimensional dummy representations are used(16).

At the higher impact speeds, head velocity tends to approach or exceed 30km/h, and it is necessary to examine whether realistic vehicle design can prevent serious or fatal injury at such speeds.

If a half sine wave deceleration pulse shape is assumed with decelerations not to exceed 80g, then the contacting surface will need to deflect approximately 65mm for a head impact velocity of 30km/h (8m/s). It is debatable if this amount of deflection is realistic without some underhood component being contacted. Consequently serious head injury is inevitable. An upper limit for the head velocity for which vehicle designs can realistically be expected to prevent serious or fatal injuries must be less than 30km/h.

Conclusion

The trend toward the use of more resilient bumper materials with larger contact areas will have a significant part to play in reducing the initial impact severity to the lower limbs of adult and child pedestrians involved in collisions with automobiles.

Cars with lower, less distinct hood leading edges, while giving benefits with respect to injuries due to the wraparound effect, may not produce the same benefits in

reducing the head velocity at the time of head contact with the car.

Lower, less distinct hood leading edges and the use of more resilient bumper materials should, overall, make significant reductions in pedestrian injury levels at speeds that are considered to be survivable.

At collision speeds of more than 30km/h, the velocity of the pedestrian's head, irrespective of the car front end characteristics, tends to approach or exceed 30km/h; hence, it is unlikely head injuries can be reduced to an acceptable level by realistic changes to the head contact areas of the car.

This confirms the need to concentrate attention to avoid the car-pedestrian collision occurring. This is best achieved by segregation of the vehicle and pedestrian populations wherever possible. This, combined with realistic contributions from vehicle designs, will produce an improvement in the overall pedestrian injury problem.

Ellipsoids have been used successfully to represent the geometry of the front of the car and provide a smooth, continuous surface.

A more repeatable method of setting up the dummies is needed if changes in vehicle parameters are to be assessed by means of practical tests. The use of a body jig to locate key features of the dummies would be of great benefit.

An alternative initial dummy stance with both legs straight would cause a face-down attitude at the time of head/hood top contact and minimise or eliminate shoulder and elbow contacts with the hood top.

Acknowledgments

The authors would like to express their thanks to colleagues at the Ford Motor Company and Cranfield Impact Centre for their assistance and support.

Pedestrian Injury Protection by Car Design

Report by an ad hoc group of the European Experimental Vehicle Committee

Abstract

Remaining concerned with the problem of pedestrians hit by cars, the European Experimental Vehicle Committee (EEVC) has set up an ad hoc group on pedestrian accidents, with the following tasks: formulation of appropriate recommendations with regard to car design, survey and coordination of European research projects and activities, and cooperation with the National Highway Traffic Safety Administration (NHTSA).

The report will present the conclusions of this group:

1. Progress that has been made in the relevant knowledge since EEVC Working Group 7 published its report (presented at the Ninth ESV Conference):
   - Accident analysis, injury mechanisms, and tolerance levels
   - Development of tools for protection assessment: mathematical models, pedestrian dummies, and component impact devices
2. Means and prospects for improving pedestrian protection:
   - Guidelines to be considered for protection policies and future regulations
   - Short-term recommendations
   - Priorities for future research

Introduction

In the European countries that are taking part in the work of EEVC, pedestrians account for a major proportion of road accident victims: ranging from 13 to 33 percent of those killed. Even accidents that are not fatal are often serious, and, because of the cost of treatment and rehabilitation and the permanent disabilities they engender, their consequences are extremely severe.

This is why EEVC was anxious to examine specific problems involved in protecting pedestrians struck by cars to determine what conceptual improvements might be applied to such vehicles to reduce the number and severity of the injuries resulting from such accidents.

Thinking has focused on those features that play a role during the intracrash phase of the accident. In fact, those countermeasures that have to do with avoiding pedestrian accidents either do not concern vehicle design characteristics (for example, speed limits in built-up areas) or, when they do concern the vehicle, are not specific to this type of accident (braking capacity, handling characteristics, field of vision).

In 1980, therefore, EEVC set up Working Group 7 to review pedestrian accident data in Europe and to make recommendations and decide priorities. The report produced by this working group was approved by EEVC's Main Committee in 1982 and presented at the Ninth ESV Conference (Kyoto, Japan, November 1982).

To pursue still further the making of concrete proposals, EEVC then set up an ad hoc group to fix the main avenues where progress in improving protection levels might be achieved, such progress being based on the report from Working Group 7 and other gains in knowledge.

Participation of NHTSA in this ad hoc group was agreed on, but unfortunately the NHTSA representative was not able to attend the group meetings.

In parallel with this, EEVC had set up Working Group 8 to deal with the problem of the safety of cyclists and lightweight motorized two-wheelers. The ad hoc group was, therefore, asked to insure the countermeasures recommended for pedestrian protection would have no unfavorable consequences for cyclists and lightweight two-wheeler riders.

The work of the ad hoc group had two main facets: an inventory of advances in knowledge achieved since the 1982 report and proposals for safety improvements. Before setting these out in detail, it may be helpful to recall the salient features of the report by Working Group 7.

Report of Working Group 7

After setting out an overview of the statistics showing the share of pedestrian victims among road accident casualties as a whole in the six EEVC participant countries (Federal Republic of Germany, France, Italy, Netherlands, Sweden, and United Kingdom), the report gave a profile of pedestrian accidents: especially those involving children between 5 and 15 years (who make up the greater part of the injured) and elderly persons over 60 years (who make up the majority of those killed). In order of frequency, the injuries concern the head, the legs, the arms, the thorax, and the pelvis. It is difficult to determine accurately the role played by impact against the ground. As far as impact against the vehicle is concerned, the contact zones are, in particular, the bumper and leading edge of the bonnet for lower limb injuries and the bonnet and windscreen area for head injuries. Secondary impacts against the ground are difficult to clarify but can be the prime determinant of injury severity in relatively low-speed impacts. Last, a complex subject but an important one to study in depth is the influence of vehicle-front configuration on overall pedestrian kinematics, which determines the kind and

speed of impacts against various body segments, whether these are against the vehicle or at the time of falling to the ground.

The report then examined knowledge in the field of human tolerances and the protection criteria to be considered for the head, lower limbs, thorax, and pelvis. A fourth chapter listed the vehicle design features where improvement could be envisaged: the overall configuration and local dynamic stiffness of the zones likely to be impacted by a pedestrian's body. The wide range of pedestrian heights and the inadequacy of knowledge of the impacted pedestrian's kinematics did not, however, permit making definitive recommendations concerning the best configurations and dimensions. Progress is, however, possible in reducing aggressivity of the vehicle zones struck by isolating the stiff structural members and by using new plastic materials that absorb energy. Last, the report analyzed test and evaluation methods suitable for dealing with the problem of protecting struck pedestrians and bringing out the complementary role of global tests, vehicle component tests, and mathematical models.

A Summary of Pedestrian Protection Research Reported Since 1981

General

This chapter summarizes the advances made in research on pedestrian protection since the first EEVC Group 7 report was prepared in 1981(1).

Generally the research has been based on accident investigation, accident reconstruction, accident damage reproduction, and mathematical computer simulation studies to gain further knowledge on the many detailed aspects of the problem.

This chapter has been compiled with respect to the following of these aspects: accident investigation, the performance of dummies, human tolerance, test methods, component tests, design recommendations, mathematical simulation, and other unprotected road users.

Accident Investigation

Accident studies have given added emphasis to the need to design cars with improved safety for pedestrians and have also provided more information on the cause of head injury and the severity of leg injury.

Traffic Schemes

In South Australia after a widespread increase in the use of pedestrian controlled road crossings, a study(2) suggested that traffic schemes have a significant effect but on their own are not capable of reducing the pedestrian casualty rate to a tolerable level. In the survey area, the number of pedestrian casualties per 100,000 of population who suffered fatal injury fell by 30 percent after implementation of the traffic scheme, with an 18.8 percent reduction in the rate for all casualties.

Head Injury

An analysis of the U.S. Pedestrian Injury Causation File (PICS)(3) gives the distribution of causes of head injury, as shown in Table 1. Contact with either the vehicle or ground were both judged to be major causes of head injury. This compares with the first report of Working Group 7(1), which reported that in early studies head injuries were thought to result from secondary impact with the ground, but more recent studies show a different result. The changes in the importance of the different causes of head injury in all these studies may illustrate the difficulty of determining the true source of head injury.

It was also observed from the data that, as a pedestrian's age increases, a stiff structure becomes increasingly more dangerous to the head than a soft structure.

Table 1. Percentage cause of head injury (PICS) file

Injury Source	Head Injury	
	AIS 2-3	AIS 4-6
Car structure	33	55
Ground	60	42
Other or unknown	7	3
Total	100	100

Leg Injuries

Leg injuries are a major feature of pedestrian accidents and a frequent cause of pedestrian disability.

A study of 463 pedestrian accident cases(4) reported that bumper shape has an important influence on leg injury.

Multiple fragmentation fractures were seen from higher speed contacts with wedge-shaped but not rounded bumpers. Wedge-shaped bumpers were also found to cause fractures at lower impact speeds than rounded shapes.

As we know, the AIS scale is designed for evaluating threat to life, and a clinical study of typical accidents to the lower limbs(5) suggested that the existing AIS scale has poor correlation with respect to resulting working days lost and percentage permanent disability.

Dummies

In general, present dummies have shown some unacceptable limitations in performance, which are most

clearly demonstrated by bonnet leading edge impact conditions.

Dummies are reported to cause considerably more damage to the bonnet leading edge than occurs in road accidents, while cadavers in contrast cause slightly less. This difference has been attributed to the cadaver showing a greater tendency to slip over the leading edge(6,7) compared to a dummy, which has more of a rolling action. The resulting difference of input energy between the two at this stage influences both the location and severity of subsequent head impact to the rear of the bonnet.

It has been suggested that the different kinematic characteristics result from the excessive lateral stiffness of dummies and, consequently, the thorax and legs have been modified in an attempt to improve the performance.

Thorax

Dummies with the thorax developed for an impact to the side have been assessed in three sets of full-scale tests.

In one, the performance of dummies developed by ONSER, MIRA, and HSRI were compared with that of cadavers and Part 572 dummies(8). It was observed that all the side impact dummies have a better response in a pedestrian impact than a Part 572 dummy, but they are still too rigid in lateral bending of the spine. The neck of the ONSER dummy was reported as too stiff, and the collapse force of the MIRA shoulder was too high.

The second set of tests assessing HSRI and APROD 82 side impact dummies(7) initially noted that the hip of a standard Hybrid II dummy rolled around the bonnet leading edge, whereas the cadaver showed a greater tendency to slip over it, as mentioned previously. This difference was attributed to the lateral bending of the cadaver's knees and also to its more flexible hip.

To improve lateral flexibility, laterally compliant knees, as described below, were fitted to the side impact dummies for all subsequent tests(9).

With the modified knees fitted, the side impact dummies were reported as having a more cadaver-like behavior.

A summary of the dynamic performances is shown in Table 2.

The third set of tests(10) at 40km/h, using cadavers and ONSER APROD and Hybrid II dummies all struck on their sides, showed that the head trajectory was more horizontal for the cadavers than for the dummies, particularly at head impact.

The head impact velocities of the Hybrid II and APROD dummies were significantly lower than those of the ONSER dummy and the cadavers. These variations may result from the arms of the dummies, which frequently became interposed between the thorax and the bonnet, thus modifying the head and thorax impact characteristics.

Similar accelerations were recorded from all the dummies and cadavers at head, thorax, and pelvis, but differing values were obtained from the knee and ankle as shown in Table 3.

Table 3. Comparison of cadaver and dummy accelerations for tests at 40km/h

Body Region	Cadaver	Dummy		
		Hybrid II	APROD	ONSER
Head*	61	65	74	84
Thorax*	31	38	28	35
Pelvis*	39	42	42	49
Knee#	104	58	53	98
Ankle#	71	181	169	95

* 3ms acceleration
\# maximum acceleration

Legs

A need for lateral compliance at the knee was given in the first report of Working Group 7(1), and two examples have been produced.

One of these referred to above (9) allowed ±30° of rotation and utilized a rubber block to simulate knee ligaments. With this configuration, a deformed knee will return to its normal orientation when the impact forces return to zero.

Table 2. Head impact location and velocity for comparative tests at 40km/h

Car		Cadaver			Dummy Hybrid II		HSRI		APROD 82	
Citroen	V(km/h)	53	58	40	43	47	52	53	65	58
	L/H (m)	1.09	1.11	1.0	.97	.89	1.11	1.17	1.07	1.08
Audi	V(km/h)	33	35	36	40	40	35	39	43	59
	L/H (m)	1.14	1.17	.84	.85	.86	1.07	1.06	1.02	1.08

V — Head impact velocity normal to surface contacted
L/H — Wraparound distance from ground to head impact point/surrogate height

The second example allowed ±20° of lateral rotation with the ligaments simulated by a friction pad, which was set to give a friction torque of 200Nm(11). When the impact forces return to zero, the maximum angular displacement is maintained and its amplitude may be used to assess the severity of the simulated injury. In some instances with this arrangement, subsequent ground impact will alter the angular displacement resulting from vehicle impact.

To further improve the lateral compliance in the pelvic region of this dummy, the hip joint was also modified to allow up to 28° of adduction. In standard dummies, hip adduction is normally 5 to 10°, but for the human body it is approximately 40°.

Human Tolerance

It was noted in the first report that the aged have lower tolerance levels, and investigations have continued (to find representative values) for the head, thorax, pelvis, and legs.

Head

The head studies have concentrated primarily on a reassessment of acceptance values for HIC. The results of work with cadavers(12) suggested that an HIV tolerance level of 1,000 is appropriate when striking a rigid structure, but a value of 1,500 is acceptable when striking a compliant structure. This proposal has caused some disagreement internationally. The value of HIC 1,000 has been widely used in the past for automobile research, and HIV 1,500 is in accordance with tests for motorcycle helmets, which can result in peak headform acceleration of up to 250g. The difficulty arises with structures that have a rapidly changing stiffness, which may give very high localized loadings. This situation is potentially injurious and exists at the bonnet and wings of existing cars.

Comparative HIC and injury values have been reported from reconstructions of actual accidents and also from accident damage reproductions using headform component tests.

A report of component tests using a Part 572 headform weighted to 4.5kg to reproduce accident head impact damage(13) gives the result shown in Table 4.

Results from a similar series of tests(6) are shown in Table 5 for comparison.

Table 4. Accident head injury AIS compared with HIC's from damage reproduction tests

Accident AIS	Accident Damage Reproduction Test HIC		
	<1000	1000-1500	>1500
0	764		
1	538		
2	107	1082	2278
5		1191	1919
		1392	2578

Table 5. Accident head injury AIS compared with ranges of HIC's from damage reproduction tests

Accident AIS	Accident Damage Reproduction Tests HIC
2	2278-2596
5	1392-1648
	4890-7630

Similar comparisons were reported from accident reconstruction tests(14) using a Part 572 dummy and from damage reproduction component tests, again using a Part 572 headform of 4.5kg weight. The results of both these sets of tests are shown in Table 6.

In an accident reconstruction, it is difficult to insure that the simulation headform strikes the vehicle in exactly the same location as a victim's head, although it is important because of changing stiffnesses that it should do so. Nevertheless, the accident reconstruction results do not support the suggestion that the tolerance level for the head should be higher than HIC 1,000, when measured by existing dummy headforms striking bonnet structures.

Table 6. Headform HIC from damage reproduction and accident reconstruction tests, compared with AIS from head injuries in accidents

Accident AIS	HIC Values	
	Dummy Test Accident Reconsruction	Component Test Damage Reconsruction

The poor relationship between AIS and HIC in the tests to reproduce accident damage illustrates the difficulties currently experienced in setting up and assessing the results of components tests. It is possible that the difficulties may in part result from the use of headforms with unrepresentative effective masses, and a possible method of driving an appropriate mass is outlined later.

Thorax

Lateral impact tests on the thorax of cadavers(15) to determine suitable tolerance values for the ribcage suggested that the degree of lateral deflection of the ribs with respect to the spine gives the most satisfactory correlation with injury. A half thorax deflection of 30 percent is reported as corresponding to an injury of eight rib fractures, having a rating of AIS 3. The report proposed a tolerance level of 35 percent deflection.

A tolerance method of this type is, of course, only relevant to a pedestrian dummy if the impact between the dummy and the bonnet top is essentially to the side of the thorax and not to its front or rear.

Pelvis

A further series of cadaver tests(16) to study tolerance values for lateral impacts to the pelvis suggested the severity of injury is best assessed by force measurements. In the tests, the 3ms force on the pelvis to cause skeletal injury ranged from 3.24 to 12.92kN and showed a correlation between fracture force and cadaver weight. The average force value for female cadavers was 5.6kN and about 8.6kN for males.

Based on weight variations, the appropriate tolerance value for the 50th percentile male was reported as 10kN and a value of 4kN for the 5th percentile female, which gives a tolerance force of approximately 5.0kN for the average pedestrian casualty.

Legs

Femur samples have been subjected to static lateral bending tests(17). The femurs are reported to have been mounted on supports 0.126m apart and loaded at midspan. The bending, breaking loads ranged between 276 and 1,131kg f, which gives, by calculation, bending moments of failure of 82 to 347Nm.

Test Methods

Recommendations for test methods generally agreed on a combination of full-scale simulations allied with component tests(6,7).

The simulation may be full-scale testing or mathematical computer simulation, both having the objective of determining the directions, locations, velocities, and effective masses of surrogate impact at each stage of the impact. This information is to be used to provide a sound basis for defining the requirements of the associated component tests.

To overcome the difficulty of establishing the effective mass of the part of a dummy instantaneously in contact with a car, it has been suggested(6) that accidents may be reproduced by a successive interaction between mathematical computer modeling and component impact testing.

The process would initially involve a component test to the bumper of a car under assessment to determine leg forces and bumper deflection characteristics.

These values are to be used in the mathematical simulation to determine the impact velocity to the bonnet leading edge and this velocity will be used for a component test to obtain the force and deflection characteristics of the bonnet edge. These values, in turn, will be used in the mathematical simulation to calculate velocity, location, and direction of head impact for defining head component tests.

Component Tests

Further studies have been made of component tests representing the pelvic and head impact stages of a full-scale test.

Pelvis

Analysis of cadaver tests(18) suggested that the effective mass of the hip or upper leg when striking bonnet leading edge ranges between 5 and 9kg. From this, an impactor was designed having a mass of 7.3kg and a contact face of 152 by 203mm.

The velocity of the upper leg or hip when striking the bonnet leading edge varied in the tests from 100 to 36 percent of the initial impact velocity, depending on the location of the leading edge with respect to the bumper.

Headform

Headform to bonnet top component tests to reproduce accident damage(6) were reported as showing that accident dents may be reproduced, but that each case could be achieved by a range of combinations of effective mass and velocity of the headform impactor.

This difficulty has already been mentioned, and a method of overcoming it is suggested in the Test Methods section.

Vehicle Design

Research into the design of cars for pedestrian safety includes studies of idealized shapes and stiffnesses by

mathematical modeling simulations, an investigation of the design of the bonnet for head impact and of the bumper for improved safety for the legs, plus an experimental safety car study.

Vehicle Shape

Car shape or localized stiffness can influence the severity of pedestrian injury. In 50 tests in which cadavers were struck by five different types of car(19), it was noted that all the cars tested—Citroens 2 CV, VISA, GSA, and BX, plus a Peugeot 505—were equally injury-producing, but the location of the major injury varied with respect to the different car types. It was deduced that improvements for the pedestrian necessitate making innovative changes to either small areas, in which case only localized improvements in injury will result, or major alterations that could give overall improvement.

Mathematical three-dimensional simulations of different idealized shapes and stiffnesses of vehicles(11) studied the importance of the location and stiffness of the bonnet leading edge. In general, a low bonnet leading edge, 600mm aboveground, showed high loading in the region of the knees of adults. The medium height profile at 720mm indicated severe direct loading to the femur and indirect loading to the knee of adults and to the pelvis of children.

For the high bonnet at 850mm, severe loadings were noted for both the pelvis and the thorax of children. The profile height also influenced the nature of head impact. As the height increased, the location of head impact moved further forward and the velocity of head impact decreased. This change was particularly significant in the range 720 to 850mm high.

A similar study involving dummy and cadaver tests and mathematical simulations(20) showed similar characteristics. It was concluded that, since accident studies suggest severe injury occurs more frequently to the head than to the pelvis, a relatively high and near vertical compliant front would be an advantage in reducing head injury.

Head Protection

In a study of head-to-bonnet impacts, the distribution of heights of pedestrians struck by cars in France were divided into 50 groups and related in a mathematical computer simulation to five representative impact velocities to give a range of 250 accident conditions(21).

The simulation demonstrated the probable distribution of head impacts to the bonnet and windscreen of a car type, also showing the direction of motion and the velocity of the head at impact. For the typical car profile studied, the impacts were shown to be uniformly distributed over the length of the bonnet and particularly concentrated in the lower half of the windscreen.

The performance of current bonnet tops was assessed by head impact component tests to eight different types of bonnet tops at eight locations on each bonnet(22). The impactor was a Part 572 headform of 4.45kg mass and accelerated by a pneumatic gun to strike the bonnet tops at 40.25km/h.

The resulting levels of HIC were strongly influenced by the amplitude of dynamic deformation, and typical values are shown in Table 7.

Table 7. Comparison of headform HIC and bonnet deformations in headform component tests

HIC	Bonnet Displacement (mm)
1000	84
2000	60
4000	42
6000	33
8000	23

The stiff wing-to-bonnet seam gave HIC's of 4,000 to 6,000 and most central regions of the bonnet produced values of 1,000 to 2,000, but this rose at times to 6,000 when the bonnet top bottomed out on rigid understructures.

It was noted in cadaver tests(23) that impacting either laminated or toughened windscreens resulted in only moderate head injury, whatever the collision speed, except for one impact close to the A-pillar. Head injuries were seen, however, to become more serious as the speed increased for impacts against dashboards or steering wheel systems after windscreen failure.

Leg Protection

An experimental study of the causes of leg injury using ordinary human leg specimens(24) gives some insight into the influence of the bumper on the severity of leg injury. Test specimens were impacted by a sled fitted with bumpers of rigid and compliant construction mounted at heights of 450 and 325mm above the ground. Five tests were conducted at each condition and a summary of the results is shown in Table 8. The lowest overall frequency and lowest severity of leg injury occurred with a low deformable bumper, but the low rigid bumper caused less injury to the knee.

Safety Structures

Studies on an experimental pedestrian safety car were reported as giving the following conclusions(25). A flexible polyurethane integral skin foam, backed by energy-absorbing foam, may be designed to give good impact characteristics that overcome the stiff sections

Table 8. Frequency of injury AIS ≥2/bumper height and stiffness

Bumper Height mm Stiffness		Summation of Injuries for 5 Tests (AIS ≥2)				Peak Force kN	
		Long Bone	Ankle	Knee	Total	Bumper	Bonnet
450	(R	4	2	10	16	7.9	2.6
	(C	4	—	6	10	2.6	2.7
325	(R	9	2	2	13	5.3	1.6
	(C	1	1	5	7	2.4	1.6

R — Rigid
C — Compliant

that develop in a collapsing conventional steel-skinned structure. There are still, however, impact stiffness problems where a rigid support structure extends to or close to the outer surface.

For soft fronts made of the above polyurethane construction, difficulties may be experienced in reaching a suitable compromise between flexibility to insure safety and stability to give a durable product. There may also be difficulty achieving a suitable finish free from distortion.

The experimental bonnet top consisted of a 30 to 50mm-thick energy-absorbing panel, sandwiched between an aluminum under skin and an upper skin made of glass fiber-reinforced synthetic resin. The upper surface was covered by a thin integral foam polyurethane skin to contain glass fibers in an impact.

A headform component test with a mass of 5kg and at a velocity of 13.2m/s gave peak decelerations of about 100g and approximately 95g at 3ms duration.

Safety Benefit

Various attempts have been made to quantify the possible reduction of injury to pedestrians that will result from changes in car design.

A study (26) of the experimental pedestrian safety car, described above, estimated that the reduction of injuries at speeds up to 45km/h would result in a 40 percent reduction in fatalities to pedestrians struck by cars.

A different study(27) that considered designs giving protection at speeds up to 40km/h estimated a 33 percent reduction in serious injury.

A manufacturer(28), however, reported that the upper head velocity limit at which it might be realistic to expect design measures to prevent severe or fatal injuries certainly falls short of 30km/h, which would give benefits significantly lower than those quoted above.

These estimates will be influenced by the percentage of head injuries resulting from impact with the ground, and this is not clearly understood, as previously stated.

Mathematical Simulation

A simulation model MADYMO(29), which is based on hyperellipsoid contact models, was used to study its relative accuracy with respect to the number of segments that represent the dummy and also with regard to the option of two- or three-dimensional operation.

The simulations of 2-, 5-, and 7-segment 2D models and a 15-segment 3D model were compared with the results of tests with a Part 572 dummy. The comparisons in Table 9 show that at least a 7-segment model giving separately represented legs is necessary to give realistic leg accelerations.

The head impact locations were closest for the 7-segment 2D and the 15-segment 3D models, but the 2-segment model gave the most realistic head impact velocities. The velocities of the 5- and 7-segment models were too high and the 15-segment too low.

In a further study(30) including the MVMA 2D model and also MACDAN, a simplistic representation, correlation with head and thorax impact velocities was reported as poor. It was suggested that, to reduce excessive stiffness in the lateral direction, the modeling should be improved to simulate lateral flexure at the knee and include displacement due to fractured leg bones.

Other Unprotected Road User

Cyclists are frequently involved in accidents with cars, and concern has been expressed that improvements in the design of car fronts for the benefit of pedestrians should not be to the disadvantage of cyclists.

The accident characteristics of cyclists were considered in an EEVC study(31) that reviewed accident data for two-wheeled vehicles and made recommendations, including priorities for action on the vehicle to reduce the severities of such accidents and injuries.

Simulations of car-to-cycle frontal impacts suggest, however, that any improvements for pedestrians will also be to the benefit of cyclists(32). A further study that

Table 9. Head impact velocity and head impact point for four models, along with experimental results

	2D-Model			3D-Model	Experimental
	2-Segment	5-Segment	7-Segment		Test-Range
v = 30km/h Resultant head-impact velocity (m/s)	9.1	12.3	11.4	6.1	6.7-9.2
Distance head-impact point/ hood-edge (m)	0.91	0.90	1.02	0.96	0.82-1.00
v = 40km/h Resultant head-impact velocity (m/s)	12.7	16.6	15.6	9.9	11.2-12.5
Distance head-impact point/ hood-edge (m)	0.96	0.95	1.08	1.03	1.00-1.07

simulated impacts by cars into the sides of stationary bicycles(33) reported that the distance between the leading edge of the bonnet and the location of head impact is 300mm greater for the cyclist, which was attributed to the higher center of gravity of cyclists.

Proposals for Improving Pedestrian Protection

Guidelines To Be Considered for a Pedestrian Protection Policy

Analysis of pedestrian accidents (see EEVC Working Group 7 report) helps find the guidelines to improve pedestrian safety. The passenger car is the vehicle most frequently involved in pedestrian accidents, and it is therefore appropriate to give priority to the study of car-to-pedestrian collisions.

The age distribution of pedestrian casualties is important. Children between 5 and 10 and elderly people constitute a great majority of pedestrians involved in accidents, the children involved mainly in nonfatal accidents.

Moreover, pedestrian accidents can cause injuries with long-term consequences. Proposals to improve pedestrian safety should give special attention to the requirements of both children and old people whose tolerance levels and, to some extent, injury mechanisms are different from those of the normal adult.

With regard to injury distribution, it is clear that injuries to the head and to the lower limbs must be considered as priorities in pedestrian protection measures.

Generally, lower limb injuries are associated directly with impact against the front of the car (bumper, bonnet edge, head lamps, etc.). Several head injuries are often related to impacts against the windshield frame for adults, whereas head injuries of children are due mostly to head impact against the bonnet edge or the front of the bumper.

Long-term Recommendations

The aims of long-term recommendations should be the protection of pedestrians from severe and fatal injuries. The protection against injuries of AIS 3 and over occurring in pedestrian accidents with an impact speed up to 40km/h seems a reasonable goal. These recommendations would consider first the injuries of AIS 3 and over that are the most frequent in pedestrian accidents—mainly injuries to the head and injuries to the legs.

Long-term Recommendations for Head Protection

As the mechanisms of head injuries are not well established, it is not possible to make precise long-term recommendations for head injury protection. Head injuries concerned with this protection level are mainly head trauma with unconsciousness, skull fractures, and some face fractures. However, facial fractures are less frequent than other head injuries.

The presently used injury criterion is the HIC with a limit of 1,000 to 1,500. To give better head protection to pedestrians in car-to-pedestrian collisions, it is important

to consider the areas of the car that could be hit by the pedestrian's head and produce head injuries. These areas are mainly around the windshield, especially the A-pillar, lower windshield frame, and the scuttle area for adult pedestrians, and in the front end of the bonnet for children. It has been shown in experimental safety vehicle studies that it is possible to reduce considerably the value of HIC by changing the design of these areas(25,34,35,36). In these cases, HIC values seem to remain below 1,000 in car-to-pedestrian dummy tests at an impact speed up to 40km/h, whereas this value was clearly exceeded in many tests conducted with mass production cars. However, the value of HIC recorded during a pedestrian test depends on the type of dummy used. Present dummies have a bad repeatability and are generally too stiff, especially in the neck and shoulder areas. Redesigning a dummy for use in pedestrian tests seems, then, of great importance. Although the HIC is still under review, there is at present no other validated criterion for head injuries. Besides the HIC itself, there is a general uncertainty of head injury mechanisms and human tolerance to head injuries. Biomechanical programs aiming to increase the knowledge in this field are to be encouraged.

A series of experimental car-to-pedestrian collisions at impact speeds of 30 to 40km/h gave head impact velocities (normal to the surface contacted) that ranged from 1 to 1.2 times the vehicle impact speed(37).

However, the values published vary considerably; for example, values of 0.5 to 1.0 times the car speed have been found on American cars(22). As an alternative, the dynamic response of the area hit by the head may be assessed by a headform drop test at the range of speeds shown above, during which an HIC value (or a maximum acceleration value) is not exceeded.

Long-term Recommendations for Lower Limb Protection

Most leg injuries have an AIS value equal to or less than 3; moreover, several leg injuries with the same AIS value could have completely different long-term consequences. Permanent disability appears, therefore, to be more important than AIS as a factor for assessing leg injury protection.

Several mechanisms can induce leg injuries. The impact point between the car front and the pedestrian legs, as well as the mechanical properties of the car element that hits the pedestrian legs, are of great importance in pedestrian injury causation.

It has been found experimentally that lowering the bumper close to the center of gravity of the lower leg would minimize the bending moment applied at the knee level(38). Such a measure would then decrease the risk of knee ligament rupture and other knee articular injuries, which are severe injuries for their long-term consequences. The corresponding value seems close to a height of 350mm above the ground. Lowering of the bumper seems effective for adult pedestrians but is not yet proved for children with respect to their injuries.

To decrease the bending moment and the shearing force applied to the leg and thereby reduce the number of tibia, fibula, and/or knee fractures, it seems desirable to use a compliant bumper. However, the preferred stiffness is dependent on the height of the bumper above the ground and its vertical depth. The bonnet leading edge also has an important influence on the severity of femur and/or pelvic injuries to adults and, in some cases, to child pedestrian thorax and/or head injuries.

However, there is an interaction between the bumper and bonnet leading edge characteristics, and it is important that the influence of these elements on pedestrian behavior is taken into consideration.

Short-term Recommendations

It is important that short-term improvements go in the same direction as long-term recommendations, even if the long-term goal cannot be completely reached.

Many improvements for pedestrian protection could be included in the design of new cars, with particular attention given to avoiding, wherever possible, localized areas of the bonnet and the top of the wings, which are too rigid.

The design of a front bumper is also of great importance, and, even if it does not seem possible to lower it for a short-term improvement, fitting an air dam that limits the leg-bending process by impacting the leg below the knee would decrease the risk of knee injuries. A softer and deeper bumper that decreases the impact force and gives a better distribution of the impact force could also improve the situation for pedestrian injuries.

It is possible, however, to give general performance recommendations for the bumper/air dam.

A mathematical analysis of pedestrian accidents proposes maximum forces as listed in Table 10 when the bumper is hit by a 50mm diameter cylindrical rigid impactor of 10kg mass at a velocity of 11m/s(25).

Table 10. Maximum bumper impactor force

	Vertical depth of bumper	
	100mm	300mm
Max force (kN)	5	7

If the forces shown in Table 10 are not exceeded, serious leg injuries will probably be avoided. Typical values of energy that the bumper would absorb are approximately 380J in 32km/h impact and 600J at 40km/h.

In addition to shearing forces, other criteria such as bending moment at knee level are to be considered.

The stiffness characteristics of the leading edge of the bonnet are dependent on its location with respect to the ground and to the bumper. From the same mathematical analysis, it seems the stiffness is suitable if an impact force of 5kN is not exceeded when the leading edge is deformed to absorb the energy values shown in Table 2.

The impact energy shown in Table 11 is dependent on bonnet leading edge height, the distance that the bumper is in front of the bonnet leading edge (bumper/bonnet lead), and impact velocity.

Table 11. Impact energy of bonnet leading edge for different edge locations and impact speeds

Impact Velocity (km/h)	Bumper Bonnet Lead (mm)	Height of Bonnet Edge Aboveground (mm)	Impact Energy (J)
32	0	600	200
		720	450
		850	650
	250	720	80
		850	270
40	0	600	310
		720	700
		850	1020
	250	720	130
		800	420

Need for Further Research

To be able to define precise long-term recommendationa and procedures and to determine the resulting improvements, it is important to continue research, especially in the field of injury mechanisms, human tolerance, and test methods.

Prospective in Pedestrian Biomechanical Research

Experimental and computer simulation methods to evaluate pedestrian protection standards are based on the results of research studies of human tolerance and injury mechanisms. So it is of great importance that an extensive and well-validated bank of biomechanical data is compiled, especially for the most severe and most frequent injuries occurring in pedestrian accidents.

The problem of head injuries is of great importance, not only for pedestrians but also for other road users. It is also a very difficult matter, and to improve the knowledge in this field it seems advisable to propose a harmonized program of research. This program would include detailed analysis of injuries sustained by traffic accident victims, evaluation of injury mechanisms, especially the relative importance of linear and rotational accelerations, in order to propose and validate head injury protection criteria.

Long-term consequences of some injuries sustained by pedestrians are considered to be of great importance and need further investigation to be quantified more precisely.

Most pedestrian accidents involve children and the elderly, and it is clear there is a change in human tolerance according to age. Existing studies are concerned mainly with bone strengths; it is, therefore, of great importance to clarify the effect of age on human tolerance for both bones and internal organs.

Validation of test procedures would be aided by an investigation into the influence of pedestrian posture on the risk of leg injuries, particularly with respect to standing with all the body weight supported by one leg. Walking pedestrians spend almost all the time on one leg whereas, until now, tests are generally performed with a pedestrian model standing on both legs.

Further Research Needed To Improve Test Procedure

Validated test procedures should first consider a biomechanical analysis of pedestrian accidents. Other important parameters include the specification of dummy characteristics and the interactive effects of car components, all of which have a great influence in the choice—and the results—of pedestrian test procedures.

Dummies currently used to reconstruct pedestrian impacts have been criticized for their lack of realism and poor repeatability. Clearly, there is a need for a pedestrian dummy having good repeatability, acceptable reproducibility, and a high sensitivity. This dummy should include the measurement of parameters directly associated with important injury mechanisms, especially the legs and the head. It is hoped that work in progress in Sweden and France(40) will contribute toward the design of such a pedestrian dummy.

One alternative to a full-scale test is a range of component tests. However, on their own, component tests do not consider the overall behavior of the pedestrian; therefore, it is also of great importance to assess the effect of the interaction between car component characteristics on pedestrian kinematics.

Prospectives in Mathematical Modeling

Mathematical models have gained acceptance as a research tool and as a possible method for the approval of passenger cars regarding pedestrian safety.

The accident process of the pedestrian (and two-wheeler rider) in collision with a passenger car is very complex. One must therefore use all available research methods to obtain comprehensive and reliable information that may be used as a basis for the formulation of

proposals leading to the reduction of injuries to pedestrians (and two-wheeler riders). This is even more important as all research methods deal with approximations of the accident process.

It is important that all research methods are rigorously validated. Mathematical models should be validated against all other appropriate research studies, including tests with dummies, cadaver tests, and accident studies, even though they yield only approximate values. Besides validating the model, it is important that input data defining the performance characteristics of the dummy and vehicle structure are accurate and complete.

When further developed models can be used to give better approximations of accident investigation data, it is hoped to obtain a statistically significant relationship between accident parameters and the probability of certain groups of road users being injured. Models can also be used to examine cars with novel and untested design features.

In general, models generate mechanically defined output such as acceleration. Information about internal forces, e.g., bending moments in bone structure (legs of a pedestrian), can be found by introducing, for instance, a simplified kind of finite element structure.

The mathematical models currently in use simulate single events in which vehicles and victims are each characterized by a specific selection of properties. The results are valid only for that single event and cannot be as a general assessment of risks of a population of pedestrians. e.g., in accidents. Therefore, a method to combine the results of a sequence of single victim predictions into a valid general prediction (injury prediction model) is required in the near future.

Mathematical models, in combination with subsystem tests, can be used for the approval of passenger cars. Disadvantages and advantages have been summed up in the report of EEVC Working Group 7.

One of the main advantages is the test results can be determined when the car is in the drawing board stage, and testing the full population at risk can be performed quite cheaply and easily and incorporated in a CAD/CAM procedure.

Experimental and Mathematical Simulation of Pedestrian-Vehicle and Cyclist-Vehicle Accidents

E.G. Janssen and
J.S.H.M. Wismans
Research Institute for Road Vehicles TNO, Delft, The Netherlands

Abstract

In several European countries, unprotected road users form a significant proportion of road accident casualties. The Research Institute for Road Vehicles TNO has started a long-term research program on pedestrian and cyclist safety. Up to now, 38 full-scale dummy tests with simulated vehicle fronts and real passenger cars were performed. Furthermore, 3D mathematical model simulations were conducted with the MADYMO Crash Victim Simulation (CVS) package. A part of the program is presented in this paper. The influence of vehicle geometry and speed on pedestrian and cyclist kinematics in a lateral impact is shown, as well as the influence of bicycle mass and speed. The results of cyclist and pedestrian tests will be compared with each other.

Introduction

In several European countries, unprotected road users form a significant proportion of road accident casualties. In almost every country, the pedestrian is the most frequently involved unprotected road user. In The Netherlands, however, the bicycle is very popular, and more cyclists than pedestrians are killed or severely injured. In the past years, international research has focused mainly on pedestrian safety. Based on this research, various recommendations for the front structure design of passenger cars were developed. Discussions about future international regulations in this field have also started. Cyclist safety, however, should be included to avoid development of regulations concerned only with pedestrian safety.

The Research Institute for Road Vehicles TNO has started a long-term research program on this topic. The final objective of the study is to reduce the number and severity of injuries sustained by unprotected road users in a vehicle impact, by decreasing the aggressiveness of vehicle fronts. A research program is developed in which several research methods, including full-scale tests, body segment impactor tests, and mathematical model simulations, are integrated. A relatively simple experimental test setup, based on accident analysis studies, is defined, and the influence of several test parameters has been analyzed. The tests were performed with simulated vehicle fronts to improve the repeatability. Some tests with real passenger cars were performed to validate these tests. Simple standard dummies were used to simulate child and adult unprotected road users. Furthermore, 3D mathematical pedestrian and cyclist models were formulated with the MADYMO CVS program and verified experimentally to support the analysis and to extrapolate to situations that are not experimentally evaluated. In the near future, the program will be extended to human cadaver tests under similar test conditions as the dummy tests. The mathematical models will be refined by simulating the cadaver tests. The influence of the victims' anthropometry will be analyzed in detail. All test methods will be evaluated with respect to future regulations in this field. Comparison of pedestrian and cyclist accidents is an important objective in all phases of the research program.

This paper presents the results of experimental and mathematical simulations of a number of cyclist and pedestrian impacts. The influence of vehicle geometry and speed will be illustrated and the results of cyclist and pedestrian tests compared with each other.

Accident Statistics

Table 1 shows that approximately 20 to 30 percent of the killed road users are pedestrians and cyclists. The percentage of killed cyclists among all killed road users is high in The Netherlands compared to other countries. International studies show that, in most cases (60 to 85 percent), passenger cars are the opponent in the pedestrian and cyclist casualties(1,2). The pedestrian is struck by the of the car in 70 to 80 percent of the reported car-pedestrian accidents. In almost all these cases (90 percent), the pedestrian was hit from the side. Most of the cyclists (50 to 65 percent) were also hit in the side by the front of a car.

In The Netherlands, most car-pedestrian and car-cyclist accidents occur within built-up areas where a speed limit of 50km/h or less exists. From accident analysis, it is known that many cars were braking before hitting the pedestrian; the impact speed in 90 percent of pedestrian accidents was in the range of up to 60km/h(1). The speed variety is larger for bicycle accidents, and it is always clear if car speed or relative car/bicycle speed is The safety benefits to be expected from improvements in vehicle design, however, seem to be most important for the speed range up to 40km/h.

The legs and head are the most frequently injured body areas of pedestrians as well as cyclists. Head injuries are more serious and life threatening at short term; leg

Table 1. Percentage of pedal cyclists and pedestrians killed in road traffic

Countries	Percentage of Killed Pedal Cyclists in Traffic in 1981(2)	Percentage of Killed Pedestrians in Traffic in 1979(1)
Federal Republic of Germany	9.2	23.9
France	4.8	17.1
Great Britain	5.3	33.3
Italy	7.6	21.5
The Netherlands	19.7	13.3
Sweden	9.7	22.7

injuries, however, can also lead to serious injuries at long term (disability). The age distribution of the victims shows two peaks; children and elderly people are often involved in pedestrian and cyclist accidents. Elderly people are more frequently killed, and children are more frequently injured(1,2).

Experimental Simulations

Test Method

Introduction

The general test setup has been described earlier(3) and will be reviewed briefly in the next sections. Most of the conditions were selected on the basis of analysis of real vehicle-cyclist and vehicle-pedestrian accidents. The test program to be analyzed here is summarized in Table 2.

Vehicle Front

To determine the influence of test parameters, the best approach is to keep all test parameters constant and to vary only the parameter of interest. Therefore, it was decided to define one standard test (test number 8303/8306) and to change parameters with respect to this test. Each variation was tested twice. With regard to the vehicle, important parameters are the geometry and dynamical stiffness of the vehicle front. To vary these parameters and increase the repeatability of the tests, a moving barrier with simulated vehicle fronts was used. The vehicle front consists of three sections simulating the bumper, the grill, and the hood (see Figure 1) and is made

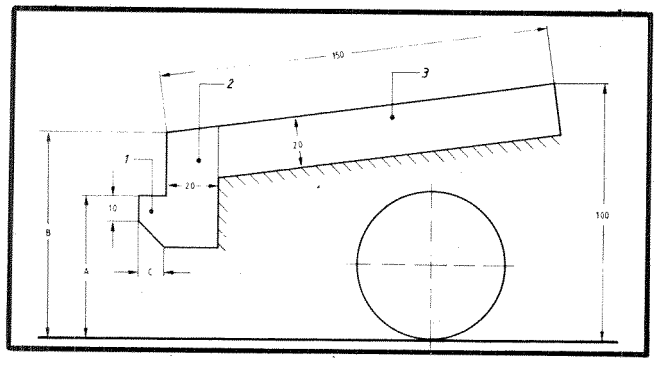

Figure 1. Simulated vehicle front consisting of bumper (1), grill (2), and hood (3)—geometry changed by variation of bumper height (A), hood-edge height (B), and bumper protrusion (C) (see Table 2)

Table 2. Variations of test parameters (see also Figure 1)

Test Number	Test Code	Dummy	Vehicle Impact Speed (km/h)	Vehicle Front Geometry (cm) A	B	C
8303	C30H	Cyclist	30	55	80	10
8306	C30H	Cyclist	30	55	80	10

8404R	P30H	Pedestrian	30	55	80	10
8407	P40H	Pedestrian	40	55	80	10
8408	P40H	Pedestrian	40	55	80	10

of homogenous polyurethane foam (density of 50kg/m^3 in tests presented here). The bumper height, hood-edge height, and bumper protrusion are varied in the test program. Only two geometric variations are included in this paper: a high vehicle front with a bumper height of 55cm and a hood-edge height of 80cm, and a low vehicle front with a bumper height of 35cm and a hood-edge height of 60cm.

Dummies and Bicycles

In these tests, the cyclist and pedestrian are represented by a 50th percentile anthropomorphic adult male dummy. The standard Part 572 dummy was chosen because it is a well-defined dummy and often used as a research dummy, in spite of its disadvantages, such as limited lateral flexibility. Other, more representative dummies are not available yet. To use this dummy as a cyclist dummy, some modifications were necessary. The range of motion in the hip joint was increased by cutting away some buttocks flesh. The knees, lower legs, and feet of the standard Part 572 dummy were replaced by special pedestrian body parts, supplied by Humanoid Systems. These body parts are reinforced and easily replaceable. Furthermore, the ankles have a lateral flexion possibility, and accelerometers can be mounted into the knees and feet. For the pedestrian, additionally, the pelvis of the Part 572 dummy was replaced by a special pedestrian pelvis, which allows a standing position. The neck bracket of the Part 572 dummy was also replaced by a special bracket to hold the pedestrian head in a vertical position. The pedestrian dummy was standing in a prescribed position (see Figure 2) with the impacted leg (left) slightly backwards and the body weight equally distributed over both legs (controlled by femur force transducers). The lower arm at impact side (left) was removed, and the upper arm fixed to the thorax to avoid disturbance of the dummy kinematics by elbow/hood impact. The cyclist dummy was sitting in a prescribed standard position on the stationary bicycle (see Figure 2). The pedal cranks were fixed in a vertical position, and the leg on impact side was stretched downward. The bicycles are standard Dutch men's bicycles (frame height 58cm, wheel diameter 28in) but without chain, mudguards, lighting, etc. The remaining bicycle mass was 12.5kg.

Impact Direction and Speed

As most pedestrians and cyclists are laterally impacted by the front of a car, the impact direction selected for the standard tests is therefore 90° to the longitudinal bicycle axis (left side). The vehicle impact speed in these tests was 30 or 40km/h, in accordance with the findings of accident analysis. The moving barrier with the simulated vehicle

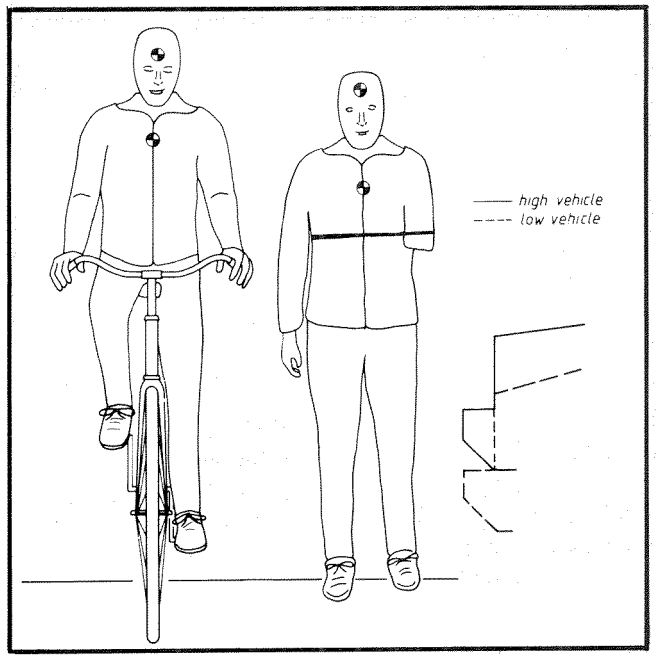

Figure 2. Initial position of pedestrian and cyclist compared to vehicle front height

front (total mass 930kg) started braking at vehicle-dummy contact. The moving barrier does not dive during braking because it is constructed without any suspension. Therefore, the vehicle front height is maintained during the complete test. To simplify the test setup in this phase of the research program, the initial bicycle speed was taken zero km/h. The influence of this will be analyzed in this paper by means of mathematical simulations.

Instrumentation and Measurements

The dummy was instrumented with triaxial accelerometers in the center of gravity of the head, thorax, and pelvis. Additionally, triaxial accelerometers were mounted into the knees and uniaxial accelerometers into the feet (lateral direction). The pedestrian dummy was also instrumented with femur force transducers to measure the body weight distribution at impact. The throwing distance of the (c.g. of the) dummy and bicycle were measured, as well as the permanent deformations of vehicle components. Eight high-speed film cameras were used to measure and analyze the motions of the dummy and bicycle during the impact. To extend the analysis of the tests, an imaginary windshield, consisting of a target-plane for high-speed film analysis, was added to the vehicle front (see Figure 3). The chosen length of the hood (dimension D is 100cm) leads to a head impact approximately on the center of the imaginary windshield in the cyclist tests with the high vehicle front. Therefore, the hood length is typical for vehicles with a short hood.

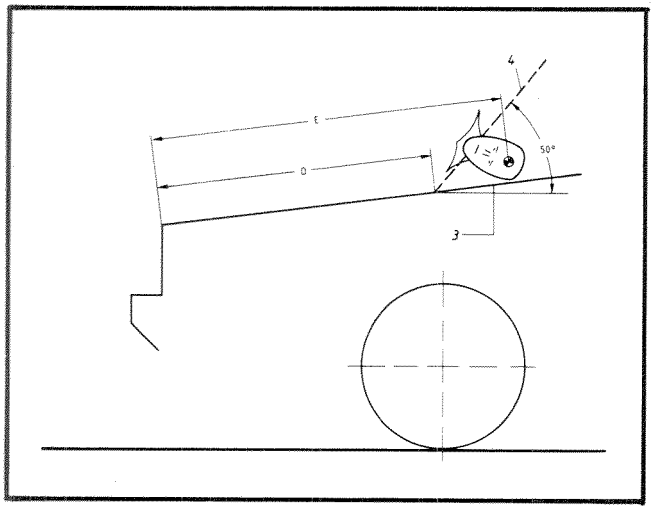

Figure 3. An imaginary windshield (4) added to the vehicle front for film analysis (hood length (D)—100cm; distance (E)—impact location of head on hood)

Test Results

General

The permanent deformations of the vehicle front and the bicycle, and the location of these deformations,as well as the throwing distance of the dummy and bicycle, were all found to reproduce very well. The overall kinematics of the dummy and the acceleration-time histories of the head, chest, and pelvis also reproduced very well. Due to dummy construction (e.g., joint-stops) and due to the contact with stiff bicycle parts, the acceleration-time histories of the knees and feet showed more differences in identical tests. In one pedestrian test (8403), the left knee was broken due to direct bumper impact. Table 3 summarizes some important test results.

Influence of Vehicle Geometry on Dummy Kinematics

The motion of a cyclist or a pedestrian as a result of a vehicle impact is above all dependent on the position of the victim relative to the vehicle. In this lateral test setup, the motion is influenced by the position of the legs of the pedestrian or the cyclist. In the cyclist tests presented in this paper, the bicycle pedal cranks were fixed in a vertical position and the impacted leg was stretched downward (see also Figure 2). This means the impact locations of the bumper and grill on the cyclist's legs are located in or close to a vertical plane through the dummy's c.g. and parallel to the vehicle direction of motion. Therefore, the motion of the dummy is an almost purely latera! one in this vertical plane, without rotation around the dummy's longitudinal axis. The vehicle front impacts the left leg, which is compressed between bicycle and vehicle front. Then the bicycle starts rotating and strikes the right leg. The cyclist rotates around the hood edge, and successively the left side of the hip, the left arm, the left shoulder, and finally the left upper side of the head strike the hood. When the legs are horizontal, the bicycle starts moving away from the dummy and vehicle. In the pedestrian tests, the leg on the impact side was positioned a little backward. Therefore, a forward rotation around a longitudinal axis could be observed, resulting in a frontal-lateral impact of the head on the hood. Furthermore, the whole (left) upper arm of the pedestrian is compressed between chest and hood, instead of only the shoulder in the cyclist tests.

The vehicle front height appears to have a predominant influence on the kinematics of the cyclist and the pedestrian. Figures 4 and 5 show the trajectories of the head, chest, and ankles of a cyclist and a pedestrian, struck by a high and low vehicle front. It can be seen that the distance between hood edge and head impact location strongly increases if the hood-edge height and bumper height are decreased. In this test setup, the head impact on the hood is located approximately 30cm closer to the windshield, for both pedestrian and cyclist, if the vehicle front height is 20cm lower.

The acceleration-time histories are also influenced by the vehicle geometry. The increase of the dummy's rotational velocity, caused by a decrease of the vehicle front height, leads to an increase of the maximum head and chest accelerations, as well as HIC and SI, for both pedestrian and cyclist. The HIC, for instance, is doubled

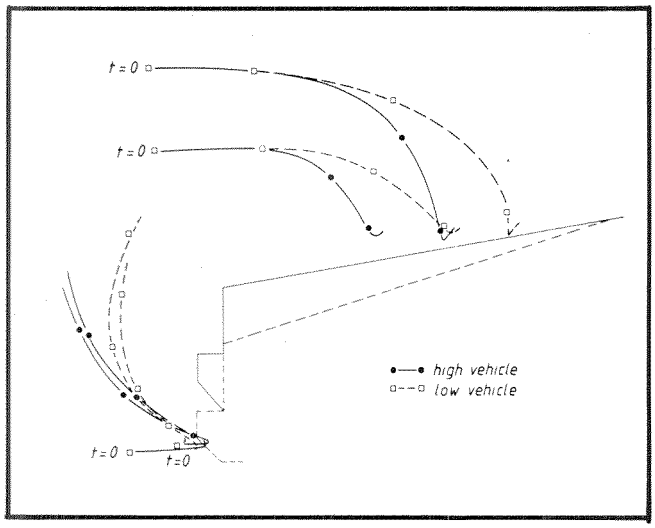

Figure 5. Influence of vehicle front height on trajectories of head, chest, and ankles of pedestrian (vehicle speed—30m/h; time intervals—50ms)

if the vehicle front height is decreased by 20cm. However, the maximum pelvis accelerations of the cyclist and pedestrian are reduced by approximately 50 percent if the vehicle front height is decreased. The vehicle geometry does not have much influence on the maximum knee and foot accelerations of the pedestrian. In the cyclist tests, however, these accelerations are lower in the tests with the low vehicle front (especially for the right leg).

Table 3 shows the head impact velocities on the imaginary windshield. In the pedestrian tests with the high vehicle front, no contact occurred. If the front height is decreased, the rotational dummy velocity increases, resulting in a higher head/windshield impact velocity and a lower throwing distance (see also Table 3). The throwing distance of the pedestrians appears to be somewhat higher than that of the cyclists.

Influence of Vehicle Speed on Dummy Kinematics

An increase of the vehicle impact speed from 30 to 40km/h also influences the head impact location on the hood. However, the influence is smaller than described before in the geometry variation tests (an increase of 11cm for the cyclist and only 2cm for the pedestrian). Table 3 shows that the throwing distance of the dummy and the head/windshield impact speed of the cyclist strongly increase if the vehicle impact speed is increased.

Accelerations and injury prediction parameters of pedestrian and cyclist are increased if the vehicle impact speed is increased. The HIC and SI are (sometimes more than) doubled if the vehicle speed increases from 30 to 40km/h. However, the maximum foot accelerations of the pedestrian seem to not be influenced by the vehicle impact speed.

Comparison of Pedestrian and Cyclist Tests

The trajectories of the pedestrian and the cyclist look quite similar (except for the right cyclist's leg in the low vehicle test). However, the head impact on the hood is located approximately 30cm closer to the windshield for the cyclist (see section Parameter Variations for the influence of the bicycle speed!). In the 40km/h tests, the difference was even 40cm. This is caused by the slightly higher position of the cyclist's head and the higher position of the cyclist's center of gravity (see also Figure 2). Therefore, in real road accidents, a head impact on the windshield (or roof) is more likely for cyclists than for pedestrians. The results show that increasing the victims's (c.g.) height has the same influence on the head impact location as decreasing the vehicle front height. This is illustrated in Figure 6, which shows that the head impact location of a cyclist impacted by a high vehicle front almost coincides with the head impact location of a pedestrian impacted by a low vehicle.

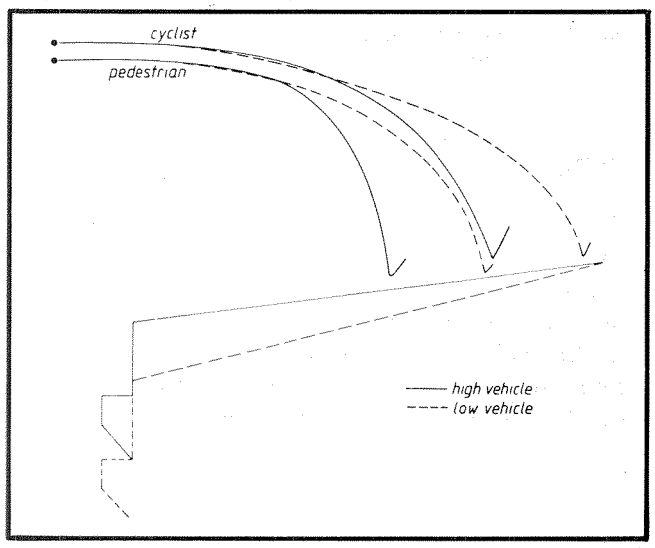

Figure 6. Influence of vehicle front height on head trajectories of pedestrian and cyclist (vehicle speed—30km/h)

In identical test conditions, the maximum head accelerations (and HIC) of the cyclist were always higher than those of the pedestrian. However, maximum chest accelerations of cyclist and pedestrian were almost equal in the tests with the high vehicle front and only slightly higher for the cyclist in the low vehicle tests. Chest SI appears to be equal (30km/h test) or slghtly lower (40km/h) for the cyclist in the tests with the high vehicle front and slightly higher in the low vehicle front tests. Maximum pelvis accelerations were also of the same magnitude in identical tests. The maximum knee and foot accelerations were lower for the cyclist in the low vehicle tests.

Mathematical Simulations

Model Setup

The model to be formulated here represents a pedestrian or cyclist impacted from the side by a vehicle front (Figure 7). Due to the three-dimensional nature of the dummy kinematics observed in some of the tests, simulations will be conducted with the MADYMO 3D version(4). The model can be divided into three separate systems: one for the dummy, one for the bicycle, and one for the vehicle.

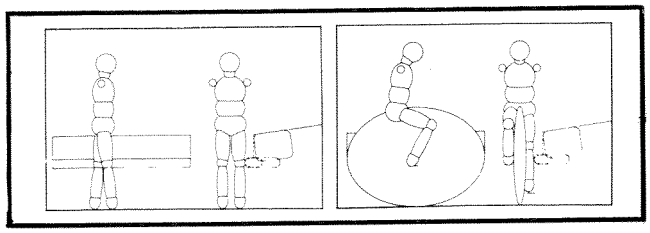

Figure 7. Pedestrian and cyclist mathematical model setup

Dummy Model

The same dummy model will be used to represent the dummy in the pedestrian and cyclist tests, except for the position of the head-neck assembly relative to the torso, since a special neck bracket with parallel interfaces for the connection to head and torso was used in the pedestrian tests. From earlier mathematical and experimental studies, it could be observed that small changes in the initial arm position can have a relatively large effect on the test results. Based on this, it was decided not to incorporate the arms in the mathematical model and to assign the arm mass for 50 percent to the upper torso mass. As a consequence, the dummy model will have nine segments: head, neck, upper torso, central torso, lower torso, and four elements for the legs. The mass distribution will be based on a recommended dataset of the Part 572 dummy prepared for the SAE Human Biomechanics and Simulation Subcommittee based on measurements by three different laboratories(5). Joint characteristics including joint stops, free range of motion, friction, and damping characteristics in this model have also been selected on the basis of measurements or estimations in various laboratories. Ellipsoids are attached to the model segments to describe the outer body geometry. Besides the standard ellipsoid as used in the Part 572 dummy model, two additional ellipsoids were attached to the upper torso to represent the shoulders. One ellipsoid was also connected to the right hip to account for initial contact beween cyclist and the right side of the saddle. The position of the dummy before impact was reconstructed in the model using detailed measurements of a number of dummy segment targets. Figure 7 illustrates the resulting initial model position.

Bicycle Model

Although the bicycle consists of several segments, it was decided to represent the bicycle in the present model by only one element. Mass distribution data for the bicycle, as far as center-of-gravity location and total mass (12.5kg) are concerned, were based on actual measurements, while moments of inertia were estimated. The external geometry of the bicycle is represented by an ellipsoid cylinder and two finite planes to represent the pedals (Figure 7). In addition, a plane is defined to represent the saddle (not shown in Figure 7).

Vehicle Model

The vehicle is represented in the model by one segment. The vehicle mass (i.e., moving barrier + simulated front) was measured (930kg) and assigned to the element. Due to the one-dimensional nature of the vehicle motion in the tests, moments of inertia and center-of-gravity location do not have to be specified accurately. The standard test defined earlier (i.e., 8303/8306) will be used here as the reference simulation. The mathematical representation of the vehicle front is illustrated in Figure 7; two hyperellipsoids are used for the bumper and the grill/hood-edge, respectively, while the hood is represented by a plane.[1] Input for the simulation is the initial velocity of the vehicle while a 0.7g acceleration field is applied to simulate braking.

Contact Interactions

Force-deflection characteristics of the foam used for the vehicle front were determined using a rigid spherical impactor(3). On the basis of these data, model parameters for the dummy-vehicle interactions were determined. Since no local stiffness data were available for the bicycle, model parameters for these contacts were roughly estimated taking into account the gross bicycle deformation during the crash. A coulomb friction coefficient of 0.7 was specified for all contacts with the vehicle and 0.5 for all contacts with bicycle and the bicycle-ground interaction.

[1] The present version of MADYMO 3D graphics does not have an option for hyperellipsoids and, as a consequence, contact surfaces in the vehicle model differ slightly from the approximation used in the graphics program (compare Figures 7 and 8).

Model Validation

Six test conditions from the cyclist-pedestrian test program have been selected for an initial judgment of the model's reliability (C3OH, C3OL, C4OH, P3OH, P3OL, P4OH in Table 2). For the standard test condition specified earlier, i.e., a 30km/h crash with a high vehicle front (C30H and P30H in Table 2), a detailed model verification will be presented here. The other test conditions will be discussed only briefly here. Figure 8 shows a comparison between the cyclist and pedestrian kinematics predicted by the model for this standard test condition. Gross kinematics appear to be very well in agreement with observations from the high-speed films. For instance, the differences in rotational motion between cyclist and pedestrian around the longitudinal body axis is well illustrated by the model. Model predictions for the head impact location on the hood appear to be quite realistic (see Table 4). The pedestrian model results are very close to the range of experimental variability, while the cyclist model shows a slight overestimation for this parameter (8 to 10cm).

Figure 9 shows a comparison between mathematical and experimental acceleration-time histories. Results are presented for the head, chest, pelvis, and left knee of the dummy and, in addition, for the acceleration of the vehicle. A quite good agreement between model predictions and experimental results can be observed, although, in general, the deviations between model and experiments are larger than the deviations between two experiments. One striking difference, for instance, between model and experiment is in the peak dummy accelerations, which show differences up to 50 percent. A sensitivity study showed these deviations are due mainly to the limited accuracy and reliability of the present contact-interaction models. Model input parameters are based on tests with a standard spherical impactor, while in reality the shape of the interacting geometries is much more complicated.

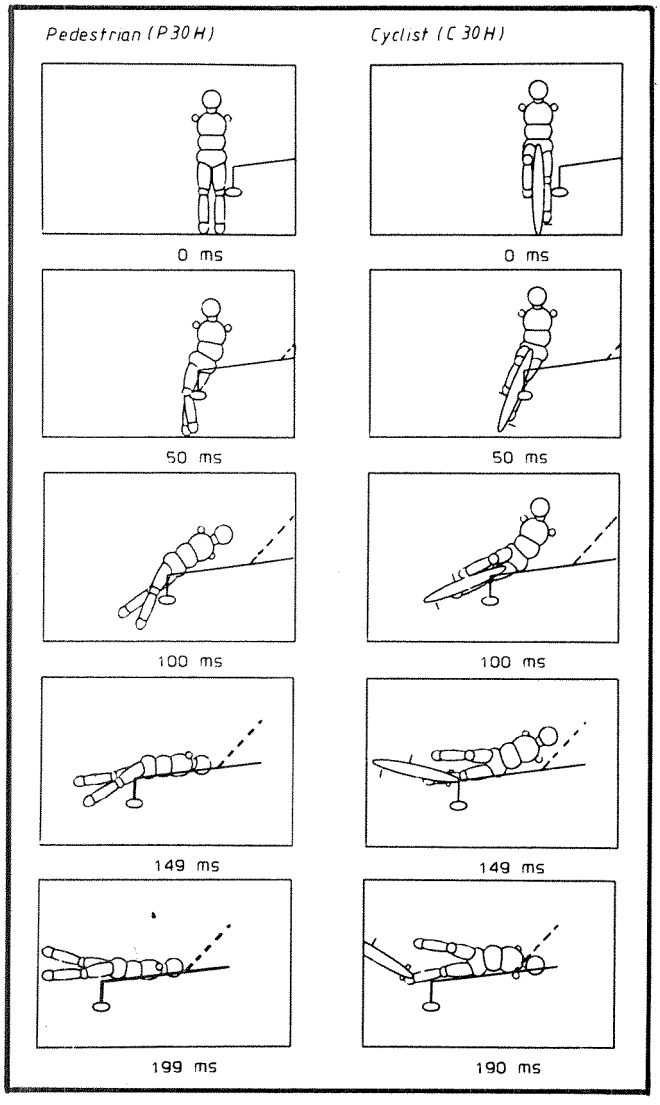

Figure 8. Comparison of kinematics in cyclist (C30H in Tables 2 and 4) and pedestrian (P30H in Tables 2 and 4) mathematical simulation

Table 4. Comparison of head impact location on the hood and the head impact velocity with an imaginary windshield

Test Condition	Head Impact Location on the Hood		Windshield Impact Velocity	
	Model (m)	(Experiment) (m)	Model (m/s)	(Experiment) (m/s)
C30H	1.22	(1.12-1.14)	11.7	(11.1-11.7)
C30L	1.40	(1.45)	15.4	(12.2)
C40H	1.33	(1.24)	16.7	(16.9)
P30H	0.76	(0.77-0.86)	10.5*	(*)
P30L	1.23	(1.12)	15.6	(13.3)
P40H	0.79	(0.84)	18.7*	(*)

* The imaginary windshield is connected to the hood at 1m from the hood-edge so no imaginary windshield impact velocity can be detected in this experiment. For the model, the head impact velocity with the hood is incorporated.

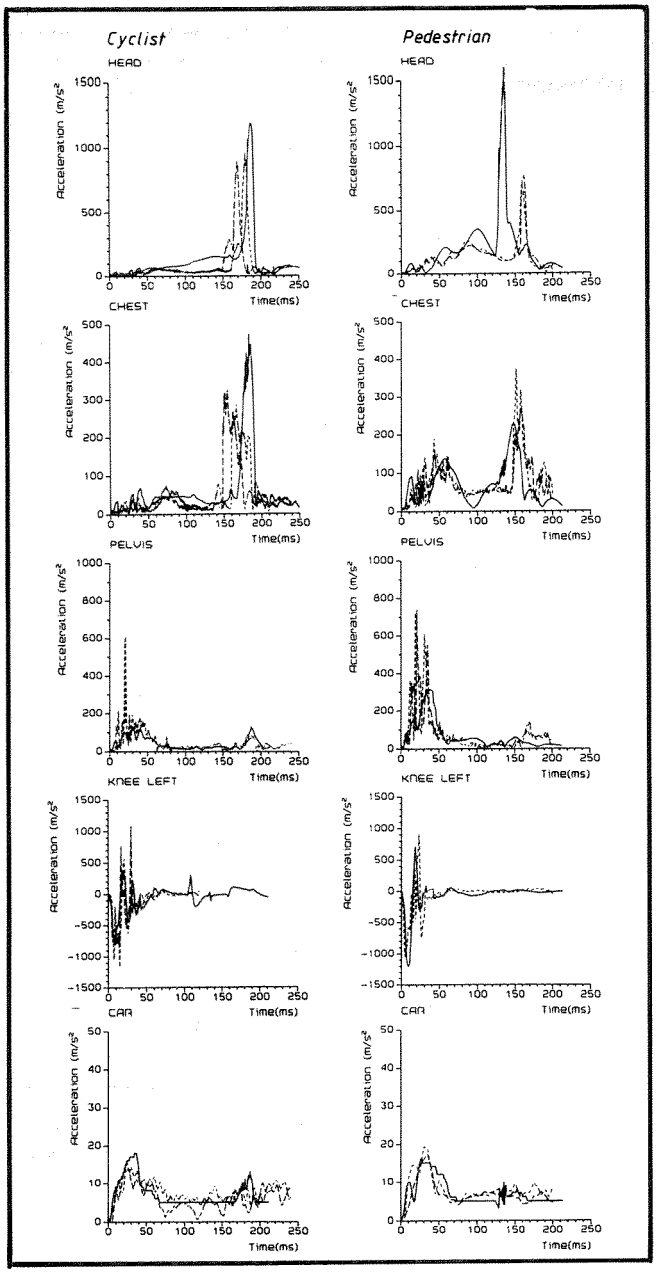

Figure 9. Comparison of acceleration-time histories from cyclist (C30H) and pedestrian (P30H) mathematical simulation (solid line) with the experimental results (dashed line)

Future contact models should account for such geometrical effects.

Deviations between model and experimental accelerations for the other test conditions incorporated in Table 2 are found to be in the same order of magnitude as in the standard test condition. Two parameters that characterize the impact of the head with the hood or windshield are presented here for both the experimental and mathematical simulations (see Table 4):

- The head impact locations on the hood
- The head velocity at the time of contact with the imaginary windshield

It follows that the deviations between model and test results for the head impact location are all less than 0.11m. For the head impact velocity, model predictions for the high vehicle front are very close to the experimental results. For the low vehicle front, they are overestimated by 20 to 25 percent.

Parameter Variations

In addition to the preceding simulations, various calculations were conducted without experimental verification. The reliability of the model is considered to be of such a level that the model results to be presented here are expected to be realistic, at least in a qualitative sense. The following types of simulation will be presented in this paper:

- The influence of an initial velocity of the cyclist
- Variations in bicycle mass
- The behavior of a pedestrian and cyclist in a simulation with a low vehicle front and a 40km/h vehicle velocity

Results of these simulations, together with the validated simulations, are summarized in Table 5. The effective head impact mass in this table is defined as peak head load during head impact, divided by peak head acceleration.

The Influence of the Initial Velocity of a Cyclist

In the cyclist impact tests, the initial velocity of bicycle and cyclist is zero. To study the influence of this velocity, a mathematical simulation has been conducted with an initial velocity for the bicycle-cyclist combination of 15km/h perpendicular to the vehicle velocity. Results for the kinematics in two planes are shown in Figure 10. The most important effect is a shift in head impact location on the hood of 67cm to the lateral side of the vehicle. Another effect is that the dummy model rotates forward around its longitudinal axis, while in the reference simulation (i.e., zero bicycle-cyclist velocity) almost no rotation could be observed. The distance of the head impact location on the hood to the hood edge is hardly affected, namely an increase by only 1cm (Table 5). The effect on other response parameters such as dummy acceleration-time histories appears to be small.

Variations in Bicycle Mass

The cyclist impact tests were conducted with a standard Dutch men's bicycle with a mass of 12.5kg. Two simulations were conducted with a varied bicycle mass. In the first simulation (light bicycle), the mass is decreased by 90 percent; in the second simulation (light-powered two-wheeler), the mass is increased to 5 times the original bike

Table 5. The influence of some parameter variations

Validated Simulations	Head Impact Location on Hood (m)	Head Impact Velocity on Windshield (m/s)	(ms)	Peak Bumper Load (N)	Effective Head Impact Mass (kg)
C30H	1.22	11.7	159	9753	5.2
C30L	1.40	15.4	155	7057	3.4
C40H	1.33	16.7	124	12685	5.2
P30H	0.76	10.5*	125*	8690	5.5
P30L	1.23	15.6	145	7087	4.1
P40H	0.79	18.7*	93*	12725	5.3
Variations					
C40L	1.49	18.2	122	8789	3.6
P40L	1.36	18.1	117	8910	4.1
Light bicycle	1.18	13.6	153	7681	4.7
Light-powered two-wheeler	1.23	8.5	177	24423	4.8
Initial velocity bicycle	1.23	10.8	160	9789	5.7

* Head impact velocity on hood

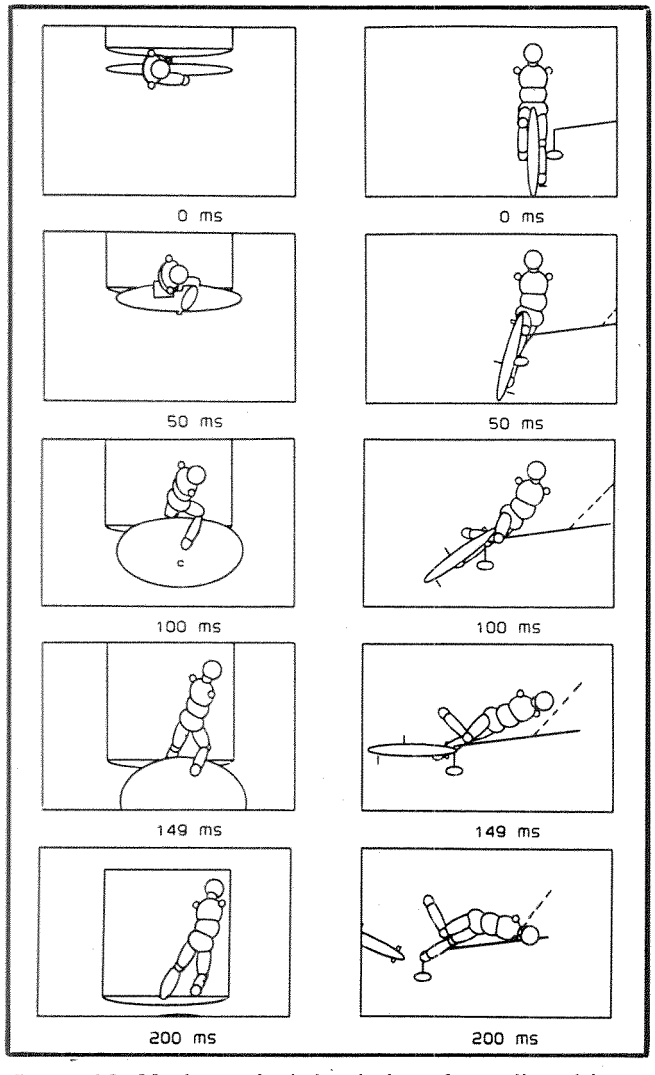

Figure 10. Mathematical simulation of a cyclist with an initial velocity of 15km/h (vehicle speed 30 km/h; high vehicle front)

mass. Results of these simulations, together with the reference simulation, are summarized in Table 5. It follows that the head impact location on the hood is hardly affected by these parameter variations. In case of a light bicycle, the head impact velocity slightly increases, while the bumper load decreases. In case of the light-powered two-wheeler, the opposite can be observed: a decrease in head impact velocity but a much larger bumper load.

The Influence of a Low Front in Combination With a High Vehicle Velocity (40km/h)

In the tests in the experimental verification program, only one test parameter was changed with respect to the standard test conditions (standard = 30km/h and high front). Here the effect of two variations at the same time will be considered, namely, a 40km/h vehicle velocity and a low vehicle front. The effect of this for a pedestrian and cyclist on head impact location, head impact velocity, and peak bumper load is included in Table 5. For both the pedestrian and the cyclist, a strong increase can be observed in the windshield head impact velocity and in the head impact location on the hood relative to the hood edge. The bumper load is not affected much because the effects of speed increase and lower front height compensate each other.

Discussion and Conclusion

Injury prevention research concerned with pedestrian safety has focused mainly on leg and head injuries, since these body areas are most frequently injured in road accidents. Accident analysis studies show for cyclist

accidents a similar trend in the injury distribution over the body. A major objective of the present study was to analyze, in detail, similarities and differences between pedestrian and cyclist accidents. A large number of experimental reconstructions of pedestrian and cyclist impacts have been conducted for this purpose, while additional mathematical simulations were performed to extend the analysis to conditions for which no experimental data were available. These models were formulated for both pedestrian and cyclist impacts. Experimental verification was conducted for three different test conditions, and, in general, very realistic model results were obtained. The experimental and mathematical simulation results offered a good insight in a large number of aspects of this rather complex impact behavior. Some major trends will be summarized in this section.

Figure 11 shows in eight different conditions the head impact location on the hood or windshield, and the corresponding head impact velocity. Results are based on mathematical simulations, since no expermental data were available for some of the test conditions. Incorporation of experimental findings in this figure, however, would not affect the general trends that can be observed:

- If the vehicle impact speed increases, a strong influence on the head impact velocity can be observed while the head impact location is hardly affected (Figure 11a).
- If the pedestrian is replaced by a cyclist, the opposite effect can be seen: a large shift in head impact location, with only a slight change in impact velocity (Figure 11b).
- Replacement of the high front by a low one influences both the head impact location and the head impact velocity (Figure 11c).

From the head acceleration-time histories and the contact load-time histories resulting from the mathematical models, effective head mass values can be determined (see Table 5). Significant differences could be observed between a high and a low vehicle front, while the effective masses for cyclists and pedestrians in similar test conditions are quite close to each other.

The above findings relate to the secondary impact, i.e., the impact with the vehicle hood. The impact with the vehicle front (i.e., primary impact) can be characterized by the peak bumper load, which has been included in Table 5. It follows that the differences in peak bumper load between pedestrian and cyclist impacts are relatively small, in spite of the fact that the cyclist mass distribution relative to the vehicle significantly differs from that of the pedestrian due to the higher body c.g. location and the upward position of the cyclist's right leg. The bicycle mass probably compensates for these differences.

The preceding results indicate important similarities between pedestrian- and cyclist-vehicle impacts for the test conditions evaluated in this study, namely, almost identical bumper impact loads and head impact velocities

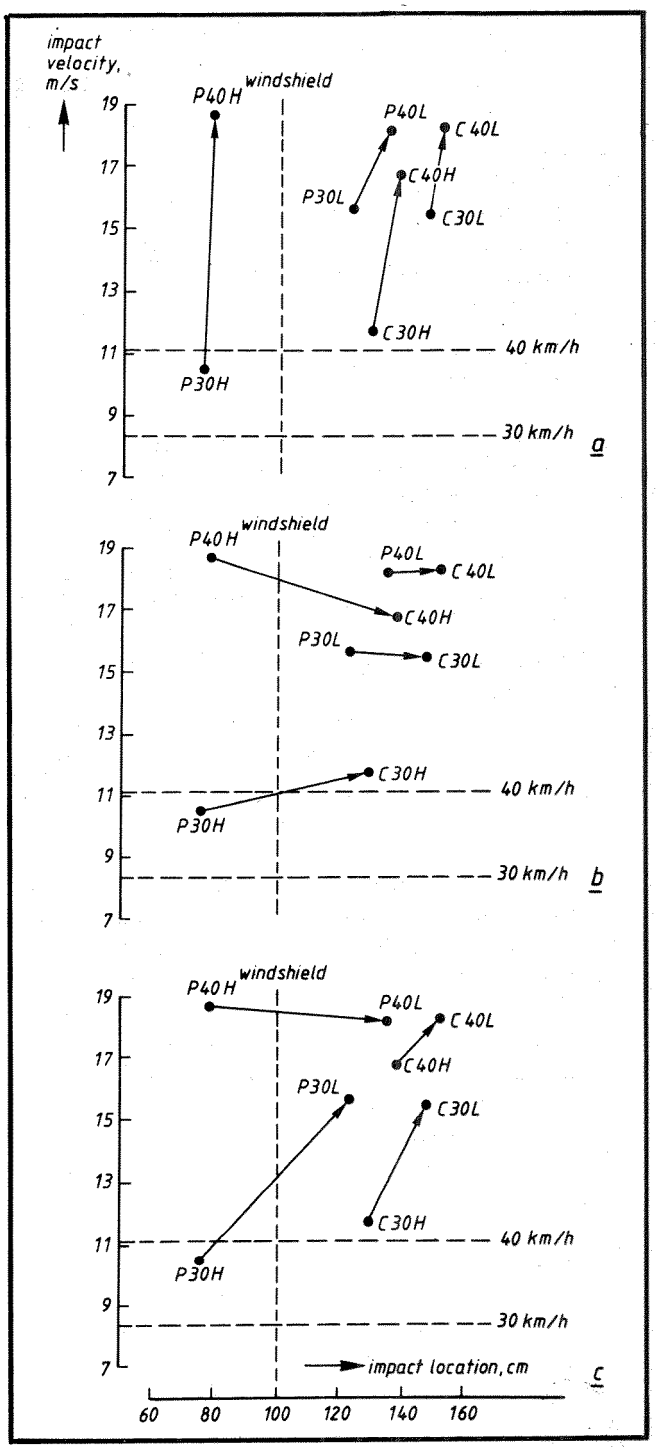

Figure 11. Head impact location and velocity on the hood or windshield from mathematical simulations (influence of vehicle speed (a), pedestrian versus cyclist (b), and vehicle geometry (c))

and only small differences in effective head masses. A major difference is found in the head impact locations and, as a consequence, impact of a cyclist's head with the windshield or even with the roof is much more likely than for a pedestrian. Mathematical simulations showed the effect of an initial cyclist velocity is small, except for the

shift of the head impact location to the lateral side of the vehicle, which could lead eventually to an absence of head/hood contact. This longitudinal and lateral shift of the cyclist's head impact compared with the pedestrian's head impact can also be obtained in a test with a large pedestrian initially impacted more lateral on the car front. Another difference between a moving and non-moving cyclist is the rotation around the longitudinal dummy axis; this rotation is absent in the stationary cyclist. For the moving cyclist, this rotation appears to be close to that observed in the pedestrian simulations.

If impactor tests are selected in future international regulations for the evaluation of vehicle fronts, the above data indicate that similar impactor masses and velocities can be selected to account for cyclist as well as pedestrian safety. However, other impact locations should be selected for the cyclist. The mathematical model results obtained here indicate the capabilities offered by mathematical simulations for specification of the initial conditions for these impactor tests (impact location, velocity, and effective mass). If accident analysis studies or human cadaver tests show that typical bicycle-induced injuries occur that are not observed in pedestrian accidents, special recommendations could be made in this respect.

It should be noted here that the results obtained up to now are mainly based on tests with a (modified) Part 572 dummy, which is not a realistic human substitute for this type of impact. Deficiencies of this dummy are, among other things, the limited flexibility of the shoulder-thorax and knee areas, and the limited instrumentation possibilities. Spine accelerations, for instance, are not well correlated with typical dummy response; they normalize direct rigid or padded impacts on the chest(6). Furthermore, leg injuries cannot be assessed by knee and foot accelerations but should be replaced, for instance, by long bone and knee torques. In this respect, the research program will be extended with human cadaver tests, with special emphasis on integration of cyclist and pedestrian safety.

Acknowledgments

The research program is sponsored by the Dutch Government in the framework of the Dutch National Road Safety Program. The authors wholeheartedly thank E. van Oorschot for conducting the mathematical simulations.

Experimental Research on Pedestrian Protection Using a Mobile Deformable Barrier

L. Maestripieri
Alfa Romeo Auto S.p.A., Safety Laboratory

Abstract

A test device has been built that consists of a mobile deformable barrier with the capacity to simulate different configurations and structural behaviors of various car front ends, using foam shapes of various density and moulding (Figure 1). With this barrier, a series of tests were carried out using a standing adult dummy as a pedestrian. The tests were aimed at generally reviewing and identifying the main factors contributing to an effective reduction in pedestrian injuries. As manufacturers, we have obtained information on how to improve both the structures and shapes of striking cars. In testing, research is not restricted to pedestrian car

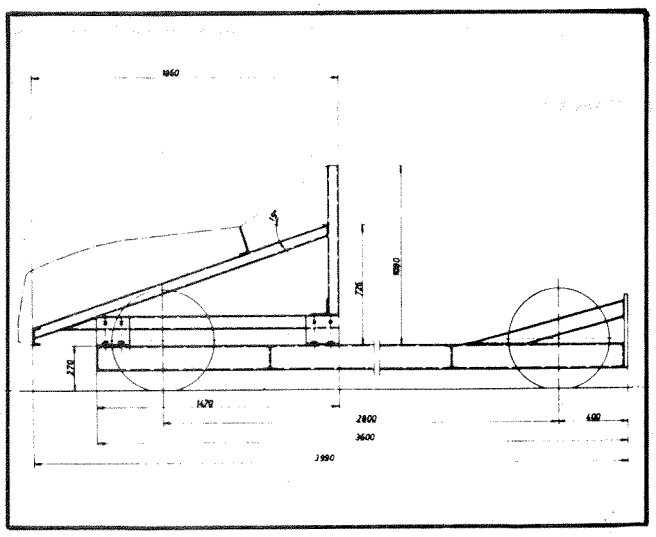

Figure 1. Mobile deformable barrier specifications

contacts but includes pedestrian/ground impacts to identify a possible correlation between car architecture and pedestrian injury levels in impacts against the ground.

Introduction

Vehicle manufacturers have felt a particular need to obtain information as soon as possible on vehicle configuration and structural aspects capable of limiting and reducing injury to pedestrians involved in road accidents. This has pushed the industry to use theoretical as well as experimental research to obtain a maximum amount of valid information and indications for organs in charge of defining future products. In the experimental research field, this need has induced Alfa Romeo to make, in addition to simulation by means of mathematical use of models, a mobile deformable barrier. This barrier has made it possible, during a short period of time and at fairly low cost, to simulate a considerable number of external configurations of vehicles, as well as structural solutions, with the purpose of obtaining a series of chosen elements for the designers before final experimentation takes place with definitive prototypes. To date this has usually been carried out with complete vehicles.

Description of the Equipment

The low cost and speedy achievement aspects have led us to define a simplified equipment solution. It consists essentially of a platform-truck with four braking wheels without suspension. A further framework can be mounted on the platform-truck, which supports the various configurations or mock-ups of previously chosen vehicle fronts (see Figure 1). Both vertical and transverse adjustments of the mock-ups are clearly possible. The global mass of the barrier can be varied starting from a minimum weight of 700kg.

For the deformable part, which simulates the front configuration of the vehicles, we chose polyurethane foam shapes after having considered various alternative material solutions (honeycomb, simplified steel structures, etc.). This foam shape offers the following advantages:

- Possibility of making practically any external configuration in a short time and with simple processes (cutting with a belt saw or a heated steel wire)
- Good homogeneity and constancy by the force/deformation (F/D) characteristics
- Ease in varying the F/D characteristics themselves
- Moderate constancy and repeatability of the physical characteristics of the product
- Low cost, approximately \$50/m3 (machined product)
- Easy traceableness on the national market

Characterization of the Deformable Barrier

When passing to the characterization of both the external configuration and the structure of the deformable part of the barrier, bearing in mind that improving vehicles to reduce injury to pedestrians involves both structural and configuration aspects, it was thought opportune to seek significant and optimal design values in the first phase, privileging only the external front configuration of the vehicle. This has been done bearing in mind a preestablished and constant determined structural characterization that appeared to be optimal and consistent with present mass-produced production possibilities.

Influencing Factors Linked With the External Configuration

Consistent with the abundant and in-depth bibliography available, it is possible to individuate and catalogue, within the global collision phenomenon, three distinct contact phases for the pedestrian; the first two are linked with pedestrian/vehicle contacts, whereas the third involves the successive pedestrian/ground contact.

During the first phase, usually defined as primary contact, the zones and parts of the pedestrian body involved are the legs and pelvis, whereas the vehicle bumpers and front structures are involved. The principal factors, linked with the vehicle configuration, that influence this first contact, are—

- Contour of the bumpers
- Height of the bumpers
- Height of the engine bonnet
- Bumpers/bonnet tangent angle

During the second contact of the pedestrian/vehicle, the involved parts of the pedestrian body are the pelvis, thorax, and head; the vehicle parts are the bonnet/mudguard zone and, according to speed, the windscreen and surrounding structures.

The following principal influence factors, linked with the vehicle configuration, should be mentioned:

- Curve of the pointed low V-shaped engine bonnets and the pontoon shapes
- Length of the bonnet where the initial positioning of the windscreen is particularly important
- Friction characteristic on the surface of the bonnet, which particularly influences the W.A.D. (Wrap Around Distance)

For the third and last phase regarding the pedestrian/ground contact, particular indications do not appear from studies and works already carried out, which demonstrate that a certain aspect of the vehicle particularly influences same. We have, nevertheless, also considered this phase of the phenomenon in the hope that significant data would emerge due to the particular simplification and schematization obtainable in the configuration of our deformable barrier.

Basic Prechosen Configurations

Because of the substantial number of influencing factors linked with the configuration alone, we soon realized the need to circumscribe the number of variables examined with the precise purpose of not increasing greatly the number of necessary tests.

In carrying out a first indicative inquiry into the influence of the front external configuration of the vehicle during a pedestrian collision, we have chosen three basic configurations (see Figure 2), of which (A) and (C) represent the two extremes of the shape. (A) is a low, rounded contour; (C) is a squared (pontoon) contour; and (B) is, instead, an intermediate configuration that approaches the average contours presently used on our vehicles.

Consistent with a need to limit a part of the influencing factors, the three configurations present identical solutions for some fundamental parameters, such as—

- Contour of bumpers
- Height of the bumpers from the ground, kept at a value of about 350mm
- Tangent angle of the bumpers—the beginning of the bonnet, kept constant at 80°

The common preestablished values for the above parameters reflect, in their values, optimization indications traceable in the many relative studies.

In short, only the height of the beginning of the bonnet and the characteristics of same have been introduced as influencing factors linked with the configuration and kept differentiated among the three configurations.

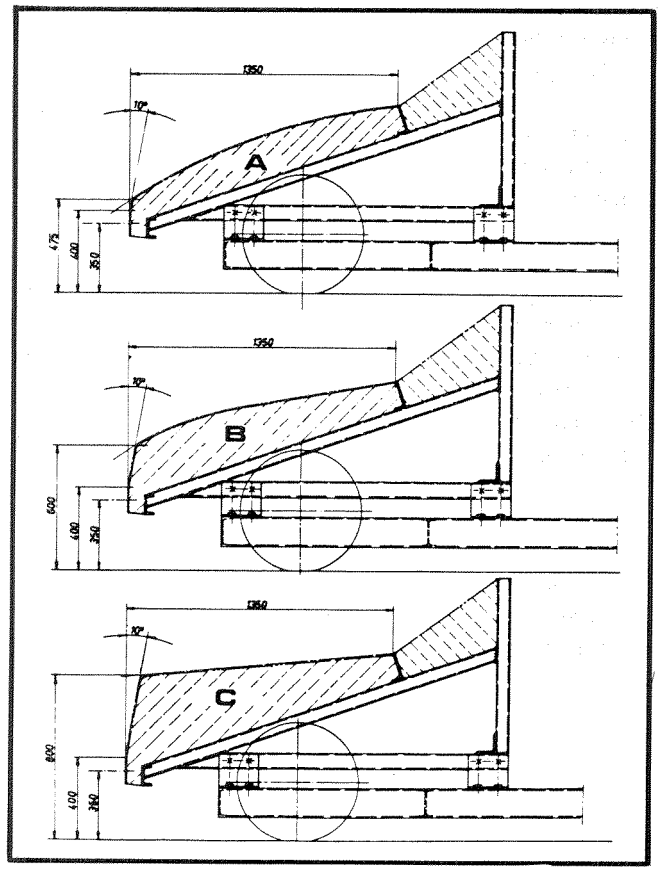

Figure 2. Different PU foam shapes

It was decided to obtain a bonnet contour length to guarantee that the pedestrian's head comes in contact with the bonnet structure, even at a speed of approximately 40km/h, to avoid, for the time being, dealing with the ulterior problem of the head coming in contact with the windscreen.

Structural Characterization

Our decision to begin an inquiry, limited only to the possible influence that the external configuration may have, forced us to choose and define a very precise structural definition to maintain constant behavior on the part of the various configurations and during various repeated tests. Such a configuration has been simulated with elevated-thickness polyurethane elements, taking care to verify by means of static and dynamic calibration tests a constant and homogenous behavior in all contour zones.

Tests for Defining the Structural Characteristics

The preliminary tests for defining and characterizing the materials to be used in the global collision tests have been chosen from those that help us establish a good

correlation between replacement materials and the front parts of mass-produced vehicles made of steel sheets.

In light of this, we have adopted both a simple static test, carried out by compressing samples of the material under examination with a spheric head (ø 165mm) to obtain some F/D values, and a dynamic test, using the head of the pedestrian dummy destined for the tests, opportunely equipped with accelerometers and dropped onto an analogous sample from a height that varies according to the speed adopted. In this latter test, the data available for analyses are represented by the acceleration values and the HIC. To obtain reference values with these two types of tests, we have also carried out a series of trials on the front parts of our vehicles presently manufactured in the zones foreseeably involved in pedestrian/car collisions (see Figures 3, 4, 5, and 6).

This type of inquiry and, in particular, that carried out by means of the test alone, unfortunately has revealed how the constructive solutions adopted at the present time and relating to certain front zones of the car do not permit acceptable results in contacts at a certain speed,

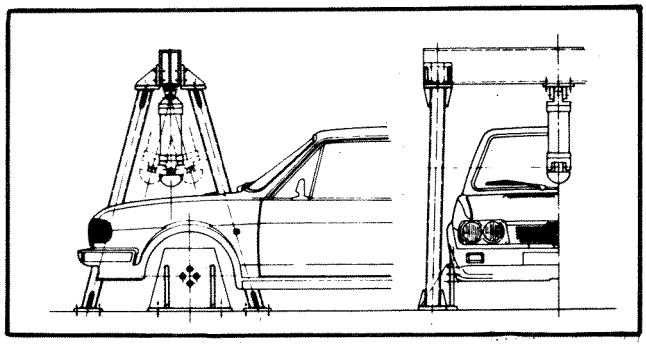

Figure 3. Equipment used for static body F/D characteristics

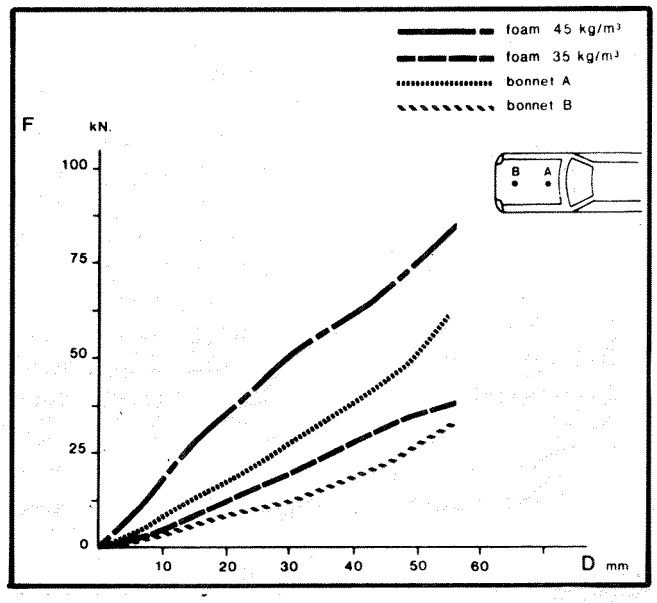

Figure 4. Various static F/D characteristics

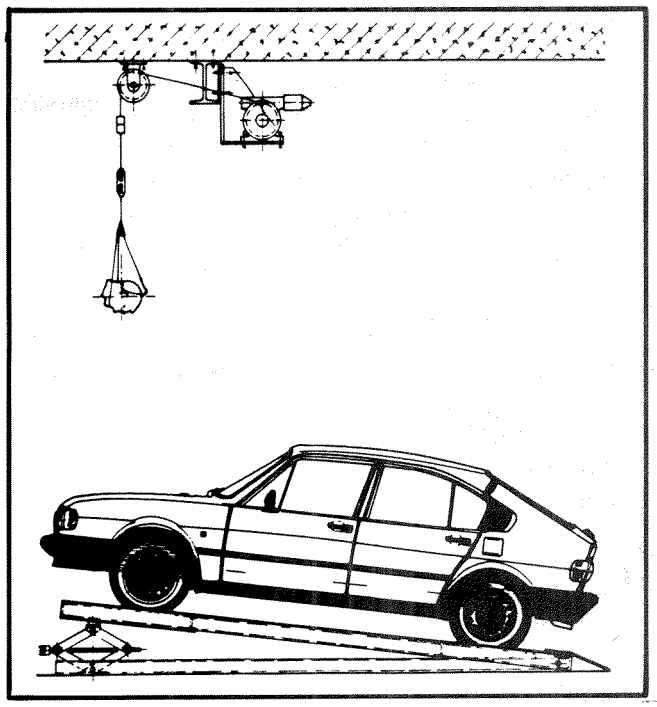

Figure 5. Equipment used for head drop tests

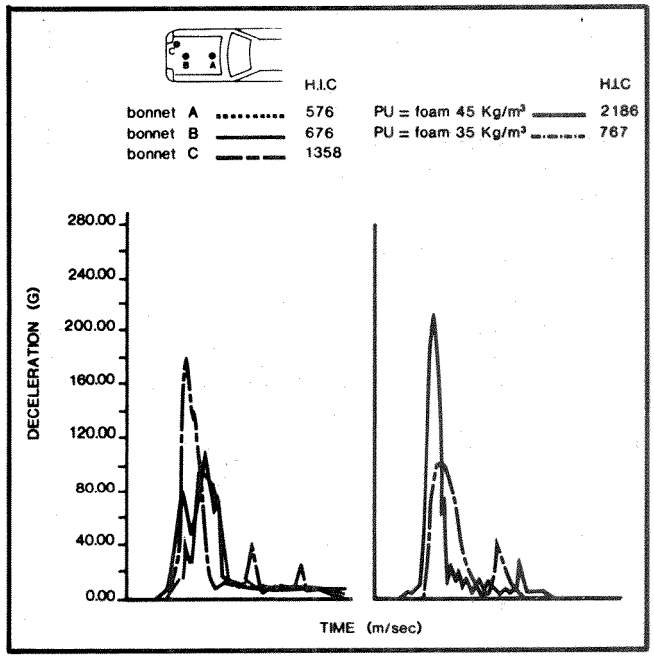

Figure 6. HIC and head acceleration values for different bonnet points and PU foams

when compared with presently accepted biomechanics criteria (see Figure 6). Nevertheless, these experimental data demonstrate that the structures presently used in relation to fairly vast engine bonnet and vehicle front zones seem to have 600 to 800 HIC values at a speed of about 30km/h and are therefore acceptable because these HIC values, obtained with the test alone, must definitely be considered more critical when compared with data

obtained from the same zones hit by complete dummies at the same speed and, therefore, by a greater mass.

Bearing in mind these latter data, it was decided to adopt as a structural reference characteristic, in the correlation sought between foam shapes and real vehicles, that characteristic obtained in the engine bonnet central zones. It was thought that such structural behavior could really be adopted and extended to the whole zone involved in the pedestrian/vehicle contact, at the same time guaranteeing good fulfillment of and respect for all other functions of the front part of a vehicle and fully consistent with production knowledge and techniques presently used when mass-producing vehicles.

Having defined as structural reference behavior that of the engine bonnet structure, we then passed to the selection of the polyurethane foams by means of the static and dynamic tests adopted, correlating F/D and HIC values.

The mechanical characteristics of the foam shapes are easily modified both by acting on the density and by making holes of variable diameters. The inquiry carried out regarding the various samples and using exclusively density variations has enabled us to individuate a 35kg/m3 density value. For both the F/D and maximum acceleration values as well as the HIC values obtained, 600 to 800 to be very similar to the behavior of the engine bonnet metallic structure (see Figure 6).

Experimentation

Barrier Test Speed

In defining and choosing the speed at which to carry out the tests, the results of the available statistical data have been borne in mind, i.e., that 50 percent of the accidents produce grave injuries to pedestrians at a speed of less than 35km/h, whereas the percentage of grave injury increases to 90 percent at speeds around 50km/h.

Since we are also interested in the influence of speed, together with the influencing factors linked with the configuration, we have chosen some test speed levels on the colliding barrier above and below 35km/h. Such chosen levels were 30 and 40km/h. The barrier begins braking at the first moment of collision with a 0.7 ± 1g deceleration.

Pedestrian Involved in the Accident

The 572-50P Pedestrian Dummy Model has been used simulate the pedestrian involved in the accident, equipped with the following instrumentation:

- Head: three right-angled accelerometers at the center of gravity (Fh = 1,000Hz)
- Thorax: three right-angled accelerometers (Fh = 180Hz)
- Pelvis: three right-angled accelerometers (Fh = 180Hz)
- Leg involved: one accelerometer in the knee and one accelerometer in the ankle (positioned on opposite side to the impact)

To reduce the influence of the pedestrian dummy's when the head is hit, a 60° angulation of the dummy's axial body plan with the direction of the impact has been adopted.

Experimental Tests

A total of 24 tests has been carried out with the three configurations (A, B, and C) previously chosen (see Figure 2), 12 at 40km/h, submitting each foam element to two tests in two symmetrical zones in relation to the central line; this was possible due to the constancy of the section and the good homogeneity of the material. In this way, four tests have been carried out with each configuration at 30km/h and four at 40km/h (see Photos 1, 2, and 3). At the end of each test and with regard to all contours, some tests have been carried out to check the characteristics of the foam shapes when only the head fell at 30km/h (see Photo 4).

Analysis of the Results

When analyzing the results (see tables in Figures 7 and 8), we thought it opportune to analyze the values obtained by each individual part of the dummy (head, pelvis, etc.) during the two phases, which can be traditionally distinguished as—

(a) Pedestrian/vehicle impact phase during its two primary and secondary contacts
(b) Pedestrian/ground impact phase

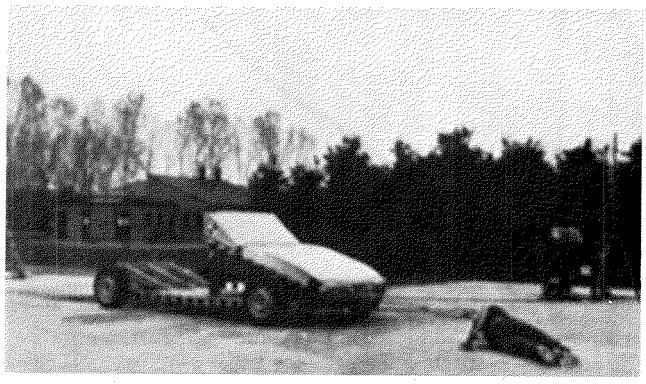

Photo 1.

Photo 2.

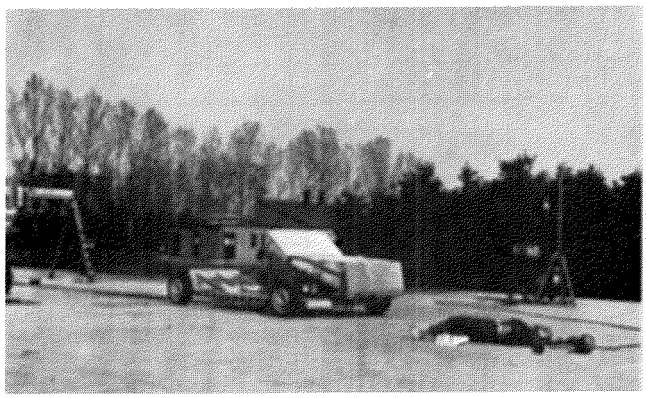

Photo 3.

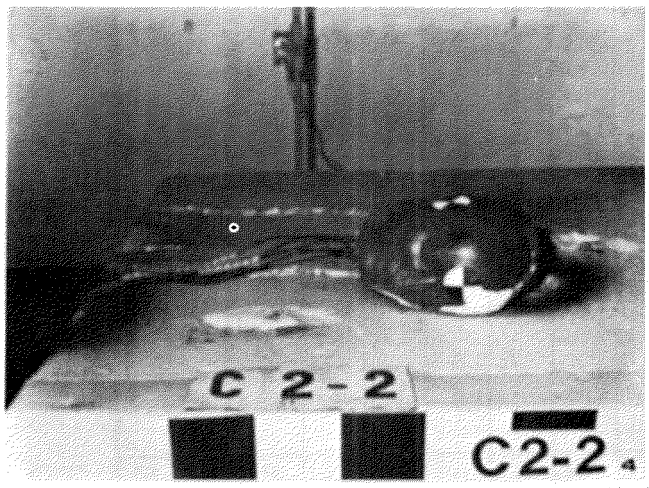

Photo 4.

Ankle (A Max)

Pedestrian/Vehicle Contact

This part of the dummy pedestrian in contact with the part of the contours and which had intentionally been defined as constant for the three types (A), (B), and (C) (H = 350, constant bumper section, 80° bumpers and bonnet angle) has supplied acceleration values which have been kept moderately constant at all speeds, increasing consistently with the increase in same.

It should be noted how these values, obtained with a 35km/m3 foam shape uniformly adopted in all its contours, must be considered slightly elevated on an average if compared with those obtained during analogous tests regarding a real Alfa Sud-type vehicle (see Figure 9).

Pedestrian/Ground Contact

This contains values that are aleatory and independent of the contour (Figure 9).

Knee (A Max)

Pedestrian/Vehicle Contact

The fact that all contours were made uniform, both with regard to the bumper height and the angle (bumper/bonnet tangent), brings about constancy of values in the three configurations with a moderate increase that can be appreciated only by passing from 30 to 40km/h (Figure 10).

Pedestrian/Ground Contact

These values are also aleatory and independent of the contour (Figure 10).

Pelvis (A Max)

Pedestrian/Vehicle Contact

This part of the pedestrian is involved differently according to the deformable barrier configurations, which present different heights from the beginning of the engine bonnet and a different bonnet curve. From data gathered during the tests, it is, in fact, possible to individuate an increase in accelerations consistent with the increase in the engine bonnet height itself.

An analogous increase is also traceable when the impact speed is increased (Figure 11).

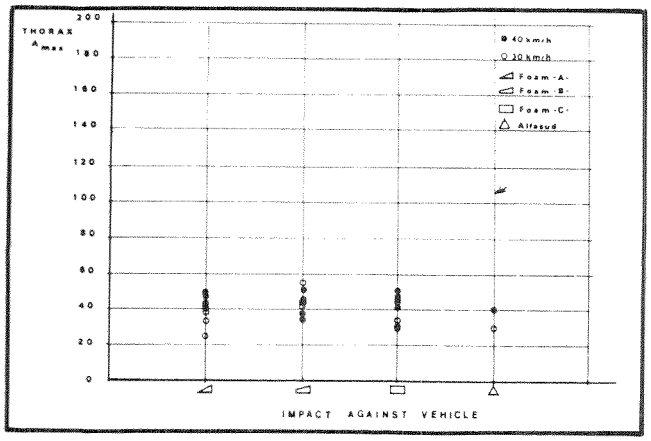
Pedestrian/Ground Contact

These values are aleatory and independent of the type of contour and the speed (Figure 11).

Thorax (A Max)

Pedestrian/Vehicle Contact

The acceleration values obtained show a certain insensitivity toward the barrier configuration variation as well toward the collision speed variation (Figure 12).



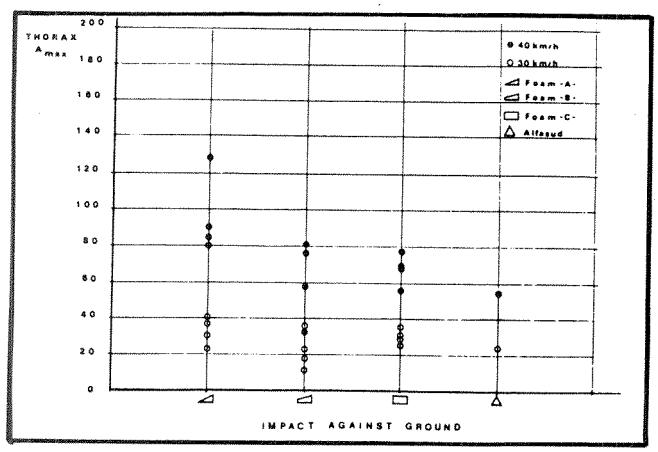


Figure 12. Thorax A Max for different shapes

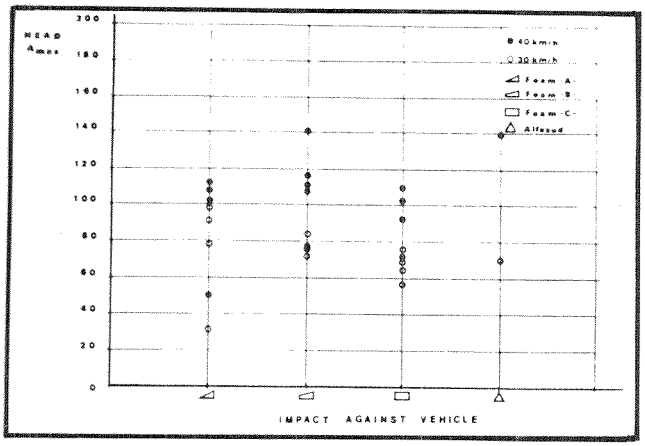

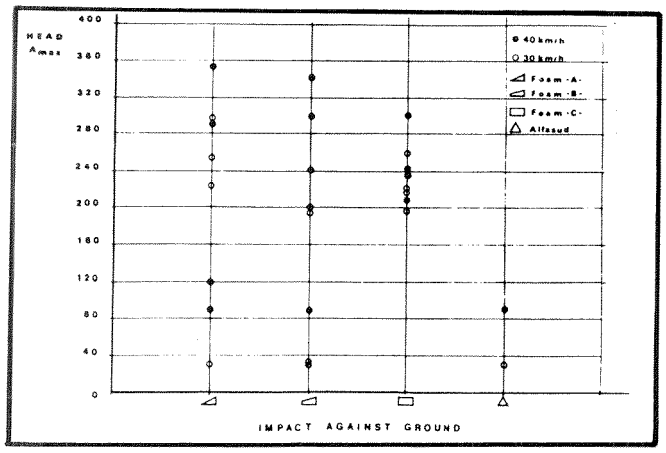

Figure 13. Head A Max for different shapes

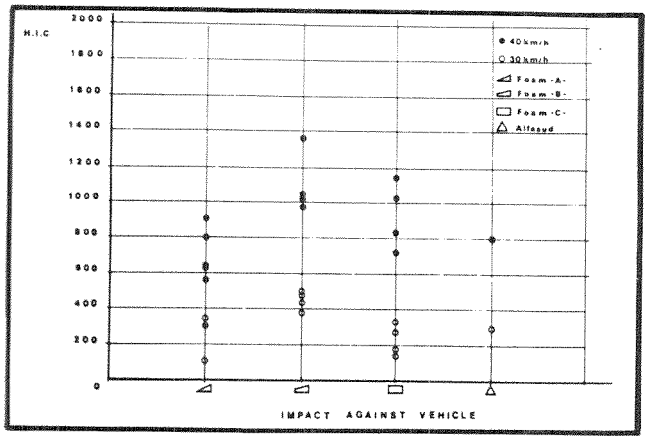

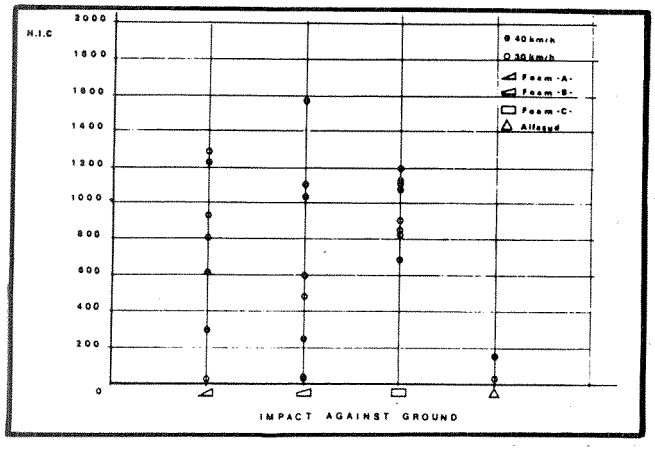

Figure 14. HIC for different shapes

Pedestrian/Ground Contact

Though a certain dispersion of data and the usual independence from the type of contour occurs, it is possible to individuate a certain increase in average value in accordance with the impact speed increase and, consistently, the speed with which the dummy's body hits the ground (see Figure 12).

Head (A Max, HIC)

Pedestrian/Vehicle Contact

This part of the pedestrian behaves differently in the case of the two speed values:

- During the 30km/h tests, the speed of the head and, consistently, the maximum acceleration

HIC seem to decrease when the bonnet is higher, provided a considerable dispersion of contour values is accepted due to a different way in which the arm rests on the contours.

- During the 40km/h tests, the differences are less noticeable and tend, however, to disappear, the lowered (A) contour on an average due to a greater possibility of the arm resting on it before impact with the dummy's head (Figures 13 and 14).

Pedestrian/Ground Contact

Also in the case of the head, it is not possible to individuate the degree to which the gravity of injuries depends on the vehicle's configuration. As in the case of other body parts, there is a certain tendency toward an average increase in gravity when the speed increases (Figures 13 and 14).

General Considerations

Considerations Regarding the Various Configurations

We have intentionally destined the first series of tests for research into the eventual influence of the external configuration alone in relation to injuries suffered by pedestrians involved in collisions.

If we carry out a reconstruction action regarding injuries suffered by various parts of the pedestrian's body, it is possible to individuate a series of information that reconfirms many of the conclusions reached by other researchers.

In fact, as far as injuries to the head are concerned, the lowered type (A) and (B) external configurations seem to induce impact speeds that are slightly greater on average and, consequently, of greater stress in relation to more squared-off (C) type solutions within a collision speed band that is relatively low. The increase in the latter, on the other hand, seems to lead to a certain leveling out among the various solutions, even if much higher levels of injury can be traced.

With regard to all other parts of the pedestrian's body, the stress seems to increase when passing from the lowered (A) type configuration to those of the squared-off (C) type.

Nevertheless, when limiting the slight global prevalence of the (A) type contours, some aspects linked with general modern vehicle architecture should be pointed out.

In fact, if we examine the W.A.D. (Wrap Around Distance) and the L.O.I. (Location of Impact) in Figures 7, 8, 15, and 16, it becomes evident that the head impact zone is always further away from the tangent surface and

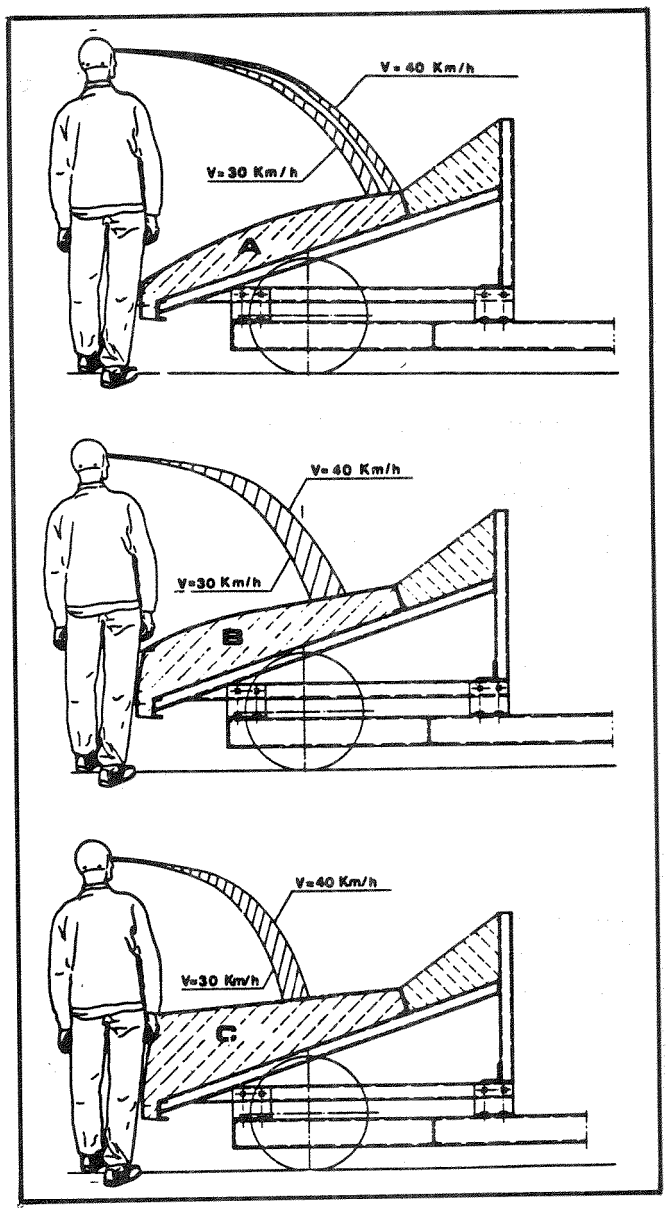

Figure 15. Movement of head relative to various shapes

nearer to the bumpers, both under the influence of speed as well as type of contour. At 40km/h, L.O.I. values vary from about 800mm for the (C) profile to more than 1,300mm for the (A) type contour.

Such a characteristic on the part of the lowered (A) contours means that, whenever you want to limit the contact between the head and the windscreen zone, a bonnet length (Lw) of around 1,400mm must necessarily be foreseen—and a value acceptable only in the case of vehicles in the superior or sports segments (see Figure 17).

In the case of vehicles in the medium-small segments, if you want to keep the Lw/Lt (total length) ratio at an approximate acceptable value of about 0.30m, a need clearly arises for more squared-off type (C) contours, which require lower L.O.I. values.

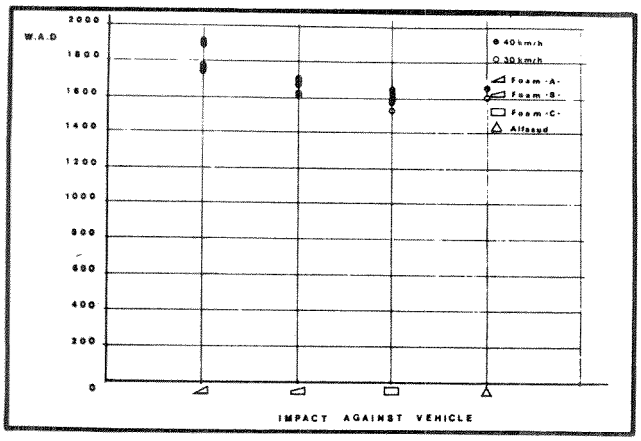

Figure 16. W.A.D. (wrap around distance) and L.O.I. (location of impact) for different shapes

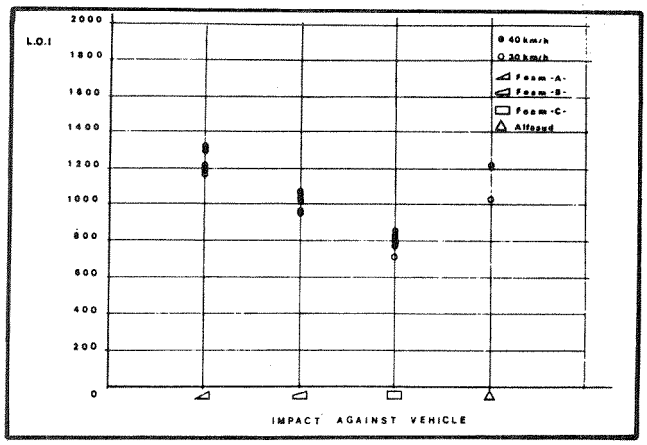
Structural Considerations

As already mentioned, this series of tests was intended mainly to review and confirm the optimal design characteristics for the front external configurations of the vehicles in view of improving the eventual pedestrian/colliding vehicle contact.

The behavior of the 35kg/m3 polyurethane foam shapes as structural elements simulating the real structures has proved satisfactory, easily repeatable, and homogenous. This can be reconfirmed by the final calibration tests carried out by the test alone at 30km/h, which presented HIC values ranging from 650 to 800 for the various foam shapes points (see Photo 4).

As far as the optimal characteristics of the structures are concerned, the fact that a type of structure similar to of the engine bonnet has been adopted for all the



configurations demonstrated some limits linked with the greater speed.

In particular, the data obtained during the 40km/h tests (see the table in Figure 7) demonstrate that, even in the absence of contact of the head with the windscreen zone, no guarantees exist sufficient for obtaining acceptable head injury values.

Conclusion

We have carried out a simplified means of experimental research to obtain the greatest amount of information and data to forward to those in charge of defining and designing our vehicles, encouraging them to install therein all that is presently available to reduce injuries suffered by pedestrians involved in collisions with vehicles.

The first series of experimental tests has been aimed mainly at an inquiry into the most suitable configuration for new vehicles. The performance and fundamental characteristics we have sought in the equipment have been the capacity to rapidly assume the desired configuration with certain structural simulations, all at costs and times that justify its alternative use in place of real structures. The series of experimental tests carried out, in addition to demonstrating the good homogeneity and structural constancy qualities of the polyurethane foam shapes, has supplied a series of indications consistently in line with many conclusions offered by studies already carried out in this specific research area.

In fact, from the point of view of the optimal configuration to be assigned to the front parts of a vehicle, carrying out a global evaluation of the injuries suffered by the pedestrian involved, it would seem that slight preference should be given, in substance, to the lowered type (A) contours or the intermediate (B) type contours, bearing in mind, however, the considerable bonnet length necessary for reducing the possibility of the head hitting the windscreen zone.

Among the ulterior research themes set at the beginning of this experimental cycle, there was also the eventual

individuation of a possible correlation between vehicle architecture and pedestrian injury levels during the final impact-with-the-ground phase. The dispersion of the values in the traced data, consistent with other bibliographical data available, seems to make this final collision phase rather aleatory. The only consistent aspect traceable is a certain general tendency to increase injuries to all parts of the body when the speed increases.

As far as suggestions connected with the choice of suitable structures are concerned, it should be pointed out that the generalized adoption of structures, however good and feasible they may be, such as those regarding the engine bonnet, does not guarantee adequate protection at speeds of around 40km/h. Future use of a simplified piece of equipment, such as the deformable barrier, will undoubtedly be of great help in rapid definition of the structural characteristics to be achieved and suitable for future vehicles.

The really important problem will clearly be that of achieving these new structurally optimized solutions for reducing injury to pedestrians, bearing in mind the surrounding design and production limits existing.

Research Concentrated on an Experimental Method for Protecting Pedestrians

Abstract

This paper describes a test procedure in which a dummy and a sled impact tester are used to simulate vehicle-pedestrian accidents for the purpose of investigating pedestrian protection. In the series of tests conducted, the bumper height, hood-edge height, bumper lead, front-end compliance of the vehicle, impact velocity, and other factors were varied in an effort to clarify to what extent modifications to the vehicle front end would contribute to enhanced pedestrian protection.

Preliminary test findings obtained with this test procedure are also presented regarding the effects of the front-end shape of the vehicle and the stance of the dummy at the moment of impact.

Introduction

There has been a substantial increase in motor vehicle ownership in Japan since 1970. Yet the number of pedestrians killed in traffic accidents dropped significantly during the second half of the 1970's after having peaked in 1970 (Figure 1). In recent years, the number of fatalities has remained at virtually the same level, and the current figure is actually less than half the 1970 level.

A comparison of pedestrian fatalities by age group shows that children under 6 and elderly people over 70 make up a large proportion of the total number. Recently, the number of fatalities among children under 6 has dropped greatly(1,2).

Various factors can be cited for this rapid decrease in pedestrian fatalities in Japan, including an improved traffic environment, more extensive traffic safety education, and protective modifications[1] made to motor vehicles. In particular, improvements made to the traffic environment and to traffic safety education programs are presumed to have contributed greatly to the reduction in pedestrian fatalities.

To investigate to what extent modifications made to the shape and compliance of the vehicle front end would contribute to pedestrian protection, a study was conducted to find a suitable test procedure for simulating vehicle-pedestrian accidents. This paper presents the results of

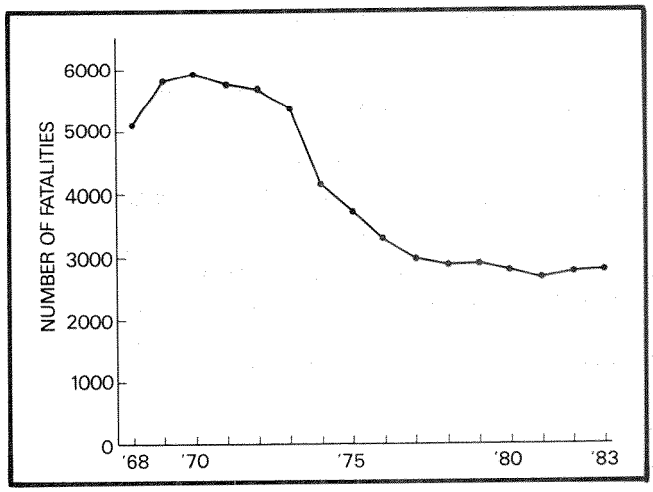

Figure 1. Change in number of pedestrian fatalities

1 An example of a vehicle modification is the addition of side bars to large trucks prevent people from being dragged under the wheels when the vehicle makes a turn.

that study, together with preliminary test findings obtained with the test procedure that was devised.

Test Procedure Study

The following objectives were set for the test procedure simulating vehicle-pedestrian accidents using a dummy and a sled impact tester(3,4):

- It must be possible to evaluate the primary impact characteristics at the moment of impact between the dummy's legs and the vehicle front end as well as the secondary impact characteristics at the moment of impact between the dummy's head and the top of the hood. Tertiary impact characteristics at the moment the dummy strikes the ground are excluded from the analysis.
- It must be possible to vary such factors as the shape and compliance of the vehicle front end and impact velocity to examine their respective influence on pedestrian protection.

Test Buck Simulating Vehicle Front End and Dummies Used

Test Buck Simulating Vehicle Front End

A test buck used to simulate the shape of a vehicle front end was installed on a sled as illustrated in Figure 2. This test buck was utilized in place of actual vehicles in investigating the influence of the shape and compliance of the front end. The buck was designed so that the

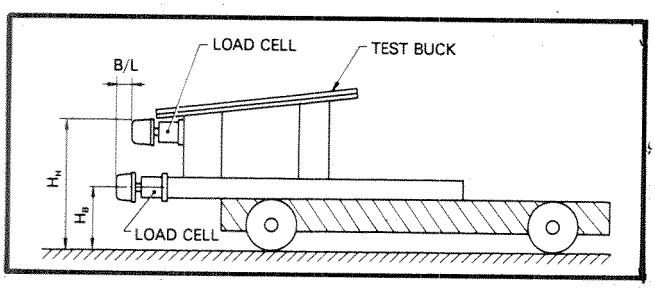

Figure 2. Test buck configuration simulating shape of vehicle front end

bumper height (H_B), hood-edge height (H_H), and bumper lead (B/L) as well as the compliance of the bumper and hood edge could be varied as desired. Load cells were installed where the bumper and hood edge were attached to measure the force input to the bumper and hood edge at the moment of impact between the dummy's legs and the vehicle front end.

Dummies Used

A Hybrid II 50P dummy made by the Alderson Co. was used as the adult dummy in a frontal stance impact, and a Hybrid II 50P dummy manufactured by the Humanoid Co. was used in a lateral stance impact. The rubber neck attachment of the Alderson-made dummy was replaced so the dummy's head would be in a perpendicular condition. A Humanoid-made Hybrid II 6C dummy representing a 6-year-old child was used as the child dummy.

Preliminary Study

Items Measured

Impact Forces of Bumper and Hood Edge—The load cells illustrated in Figure 2 were adopted to measure the forces input to the bumper and hood edge at the moment of impact between the dummy and the vehicle front end. These measurements were used to determine the impact forces sustained by the dummy's legs and pelvis.

Head Impact Velocity—A high-speed camera was employed to photograph the behavior of the dummy's head. The head impact velocity at the moment of impact between the dummy's head and the top of the hood was found by analyzing the photographs. As illustrated in Figure 3, the head impact velocity was divided into the horizontal component V_Y and the vertical component V_H and the maximum vertical velocity V_{HM} and vertical velocity V_{HO} were found.

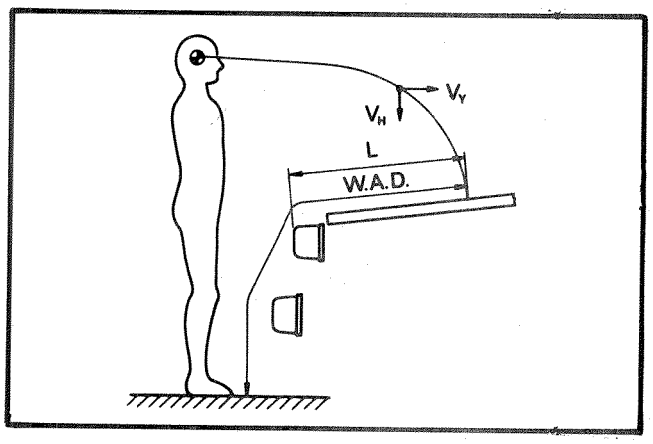

Figure 3. Head impact point

Head Impact Point—The point of impact between the dummy's head and the top of the hood was also found by analyzing the photographs taken with the high-speed camera. The point where the dummy's head struck the hood was indicated by using the Wrap Around Distance (W.A.D.) and the distance from the edge of the hood.

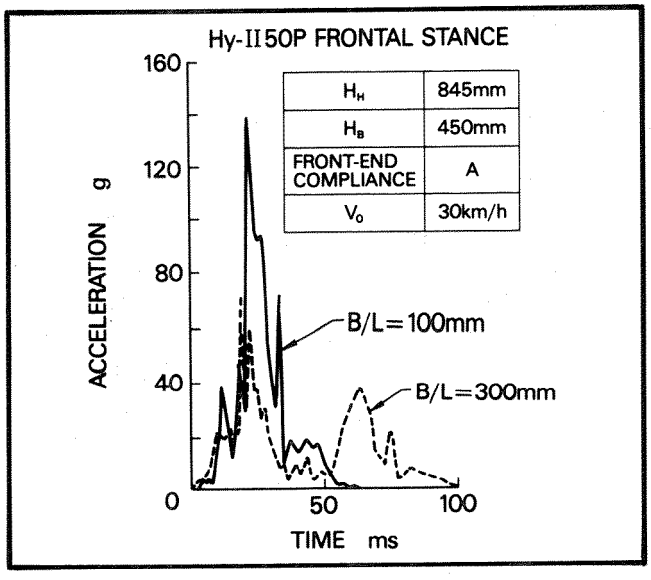
Acceleration (g) Waveforms—

- Head g Waveform—In the case of the Hybrid II dummy, acceleration is generated on the dummy's head both at the moment of impact between the

bumper and the knees and at the time of impact between the hood edge and the thighs. The time of impact between the dummy's legs and the vehicle front end differs greatly from the time of impact between the dummy's head and the top of the hood. Consequently, the acceleration on the dummy's head can be accurately measured when the dummy's head strikes the hood.

However, since the stiffness of the test buck used in this study was higher than that of an actual hood, the acceleration generated on the dummy's head was larger than what would be true for a production vehicle. Therefore, the head g waveform was treated simply as reference data.

- Pelvis g Waveform—The impact between the bumper and the knees generates acceleration on the dummy's pelvis, similar to the situation for the dummy's head. When there is a large bumper lead of 300mm, the impact between the hood edge and the thighs produces a g waveform with two peaks (Figure 4). However, when the bumper lead is 100mm, the two peaks overlap and the acceleration generated by the impact between the hood edge and the thighs cannot be measured accurately.



Note: Front-end compliance A represents a semi-hard urethane foam (density of 0.1 g/cm^3) to which a urethane fascia is attached.

Figure 4. Resultant pelvis acceleration

- Knee g Waveform—The waveform for the acceleration generated on the dummy's knees by the impact between the bumper and the knees shows a certain correlation with the impact force of the bumper. Thus it can be regarded as one index for comparing the severity of an impact.

In this study, the primary impact characteristics were evaluated on the basis of the impact forces of the bumper and hard edge and the secondary impact characteristics on the basis of the head impact velocity and head impact point.

Dummy Release Timing

To improve test accuracy and repeatability, the dummy's posture must be uniform at the moment of impact. Changes in the dummy's posture following release were investigated by analyzing photographs taken with a high-speed camera. The results indicated that the dummy retained its posture for about 200ms following release and that it was necessary to keep the force suspending the dummy constant. Thus, in each test, dummy release timing was set so impact would occur within 200ms following release of the dummy. Further, a load cell was employed to keep the force suspending the dummy constant.

Measures To Prevent Dummy Knee Damage

Results of experimental tests indicated that the knees and shoulders of the current Hybrid II dummy suffered damage even at an impact velocity of 20km/h. To prevent such damage, the adult dummy was made with steel clavicles, and the femur link rod was designed to allow shape changes (Figure 5). The shape of the link rod yielded before the kneecap was damaged, and the link rods were replaced after every test.

The same type of flexible femur link rod was adopted for the child dummy, and, in addition, the kneecap was modified.

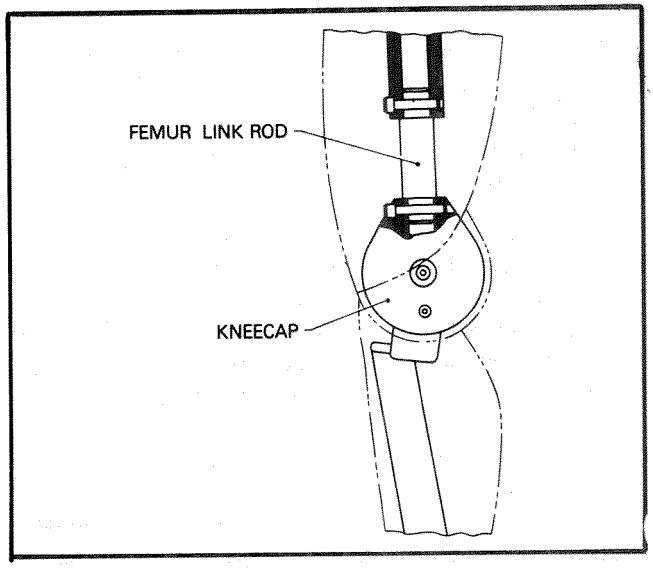


Figure 5. Leg profile of Hybrid II pedestrian dummy

Effects of Ground Friction Coefficient

The effects of the ground friction coefficient on impact characteristics at the moments of impact between the dummy's legs and the vehicle front end and between the dummy's head and the top of the hood were investigated to determine at what value the ground friction coefficient should be set during the tests.

Tests were conducted under the conditions given in Figure 6, and the results obtained are shown in Figures 7 and 8. Because the number of tests was limited and there was considerable variability among the data, no definite conclusions can be drawn. However, it would appear there is no clear-cut difference in bumper impact force, hood-edge impact force, and head impact point (W.A.D.) for various ground friction coefficients.

As far as the head impact velocity is concerned, there was only one test result. Considering the possibility of variability in the data, nothing definite can be concluded.

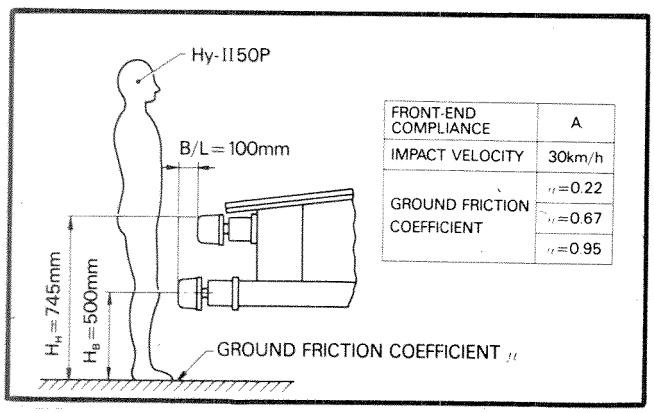

Figure 6. Test conditions

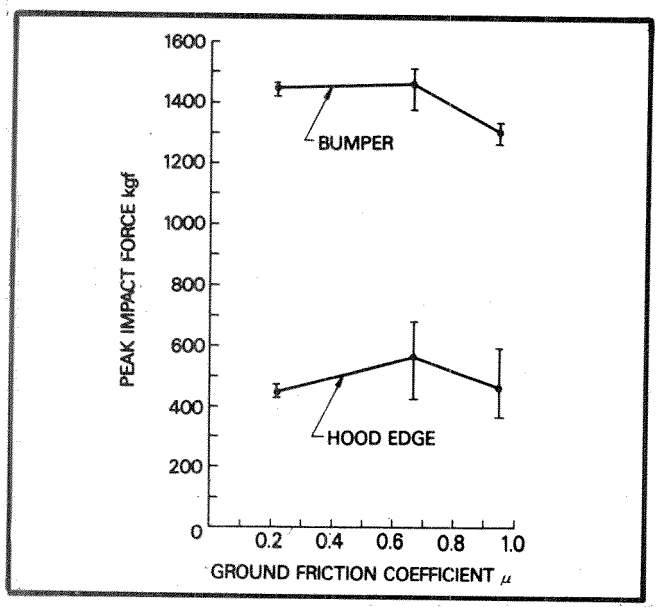

Figure 7. The effects of ground friction coefficient on peak impact forces of bumper and hood edge

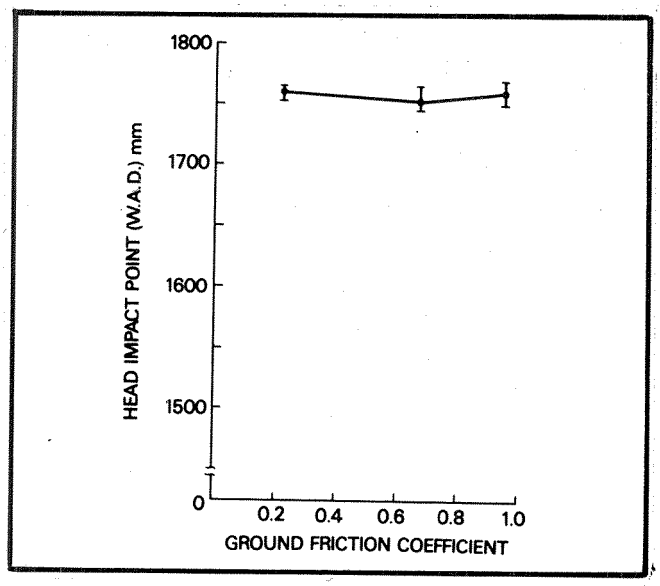

Figure 8. The effects of ground friction coefficient on head impact point (W.A.D.)

Based on the foregoing results, it was decided to conduct the tests with the ground friction coefficient set at a constant μ = 0.67, which is close to the actual value. Additional studies need to determine whether the effects of the ground friction coefficient can be accurately grasped with just the evaluation index used in this work.

Effects of Dummy's Femur Joint Torque

Tests were conducted under the conditions shown in Table 1 to investigate the effects of the dummy's femur joint torque on the impact characteristics and dummy's behavior at the moment of impact between the dummy's legs and the vehicle front end. In these tests, the dummy's femur joint torque was varied between 1 and 2g.

The test results are presented in Figures 9, 10, and 11. There is a great deal of variability in the data, and no definite conclusions can be drawn. However, it would appear there is no appreciable difference even when the femur joint torque is increased to 2g.

Table 1. Test conditions

Hood Edge Height (H_H)	780mm
Bumper Height (H_B)	450mm
Bumper Lead (B/L)	100mm
Front-End Compliance	A
Impact Velocity (V_o)	30km/h
Dummy	Hy-II 50P
Dummy Stance	Frontal

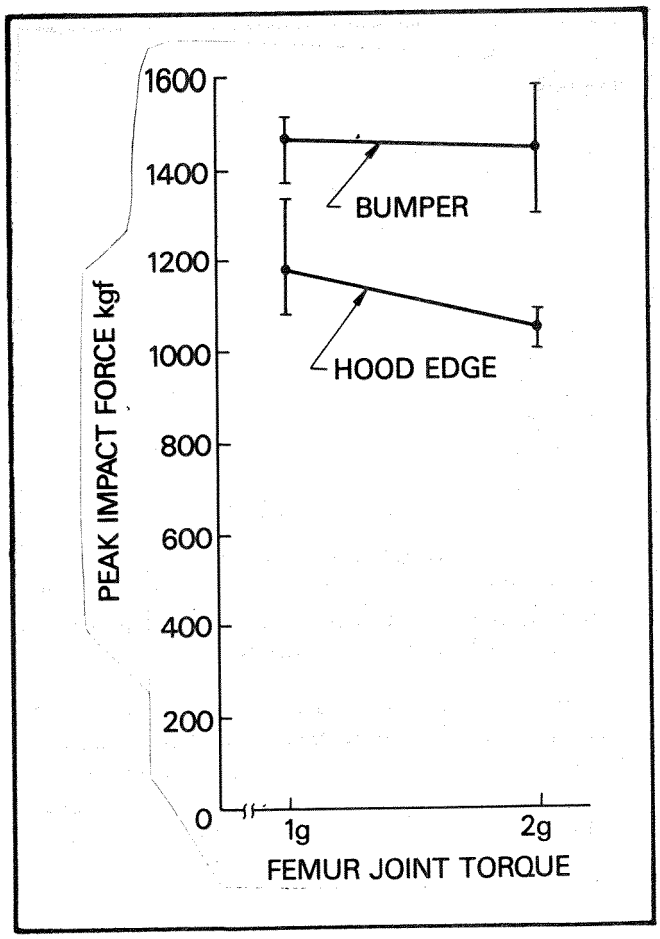

Figure 9. The relationship between dummy femur joint torque and peak impact forces of bumper and hood edge

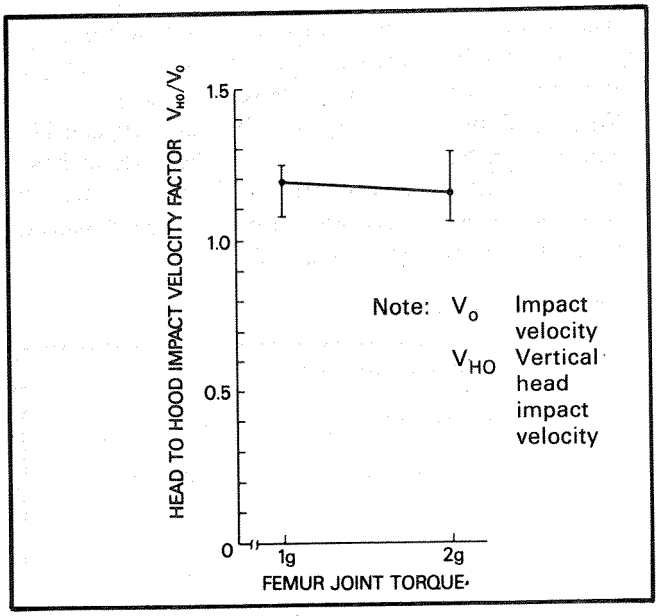

Figure 10. The relationship between dummy femur joint torque and head-to-hood impact velocity

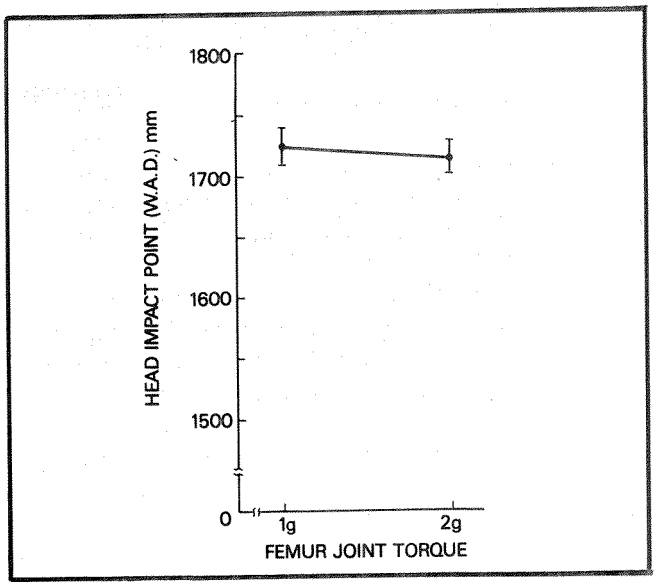

Figure 11. The relationship between dummy femur joint torque and head impact point

Based on these results, it was decided to set the femur joint torque at 1.5g, which would make it easier to keep the dummy's posture uniform during testing.

Summary of the Test Procedure

A diagram illustrating the specific configuration of the dummy and test apparatus used to simulate vehicle-pedestrian accidents is shown in Figure 12. The various elements are: (A) dummy, (B) dummy release mechanism, (C) load cell for measuring the force suspending the dummy, (D) sled, (E) test buck simulating the front end of a vehicle, (F) load cell for measuring the force input to the hood edge, and (G) load cell for measuring the force input to the bumper.

The prominent features of this test apparatus are as follows:

- The factors noted below can be varied in a simulated impact between a pedestrian and the vehicle front end.

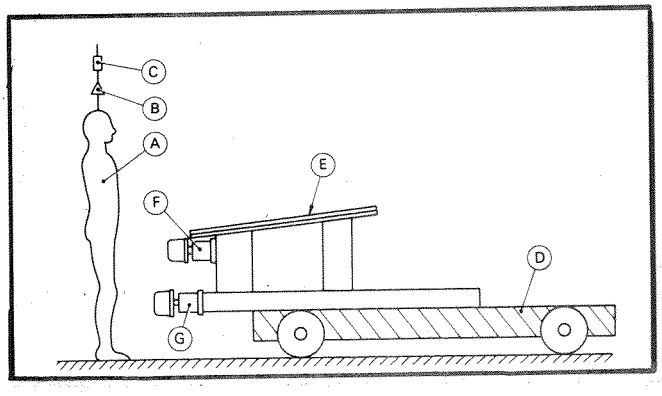

Figure 12. Test apparatus for simulating vehicle-pedestrian accidents

— Impact velocity between pedestrian and vehicle front end
— Front-end shape (bumper height, hood-edge height, bumper lead, hood slant)
— Front-end compliance (compliance of bumper and of hood edge)
— Dummy stance at time of impact (lateral stance, frontal stance, and oblique stance impacts)
— Dummy size (adult or child dummy)

- The dummy knee has been modified to prevent damage to the kneecap.

The following items were measured during the tests:

- Measurements were made of the bumper impact force and the hood-edge impact force to determine the impact forces applied to the legs and pelvis at the moment of primary impact.
- The dummy's behavior at the time of secondary impact was photographed using a high-speed camera. The head impact velocity and impact point were then found by analyzing the photographs.
- Measurements were made of the acceleration generated on the dummy's head, thorax, pelvis, and knees.

In this series of tests, the primary impact characteristics were evaluated on the basis of the bumper impact force and the hood-edge impact force and the secondary impact characteristics on the basis of the head impact velocity and impact point.

The following preset values were employed:

- The dummy's femur joint torque is set at a constant 1.5g.
- The ground friction coefficient is set at a constant 0.67.
- The apparatus can be set so impact occurs at all impact velocities within 200ms following dummy release.

Test Results

Using the test procedure described in the previous section, a fundamental study was done on the following items:

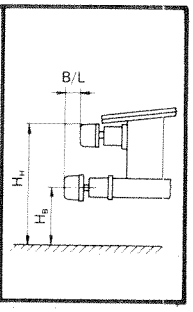
- Effects of the front-end shape of the vehicle
- Effects of the dummy's stance at the moment of impact
- Effective mass of the legs in tests using dummies

The Effects of the Front-end Shape of the Vehicle

Four types of front-end shapes were assumed (Table 2) to investigate what effects the shape of the vehicle front end has on pedestrian protection with respect to a pedestrian's legs and head. Preliminary tests were conducted with an adult dummy in a frontal stance and at an impact velocity of 30km/h.

Table 2. Front end specifications

Item / Type	H_B	H_H	B/L	Front End Compliance
A	350mm	695mm	100mm	A
B	↑	795mm	↑	↑
C	450mm	695mm	↑	↑
D	↑	795mm	↑	↑



Bumper Impact Force

The relationship between the shape of the front end and the bumper impact force is illustrated in Figure 13. The peak bumper impact force tends to be larger at a bumper height of 350mm than at a height of 450mm. Moreover, the peak bumper impact force does not appear to change significantly when the hood-edge height is varied from 695 to 795mm, although a definite conclusion cannot be drawn on the basis of these tests alone.

In other papers, it has been reported that a lower bumper height tends to mitigate injury to a pedestrian's lower limbs, a finding contrary to the results obtained in these tests. This suggests there are certain aspects about lower limb protection that cannot be evaluated with just

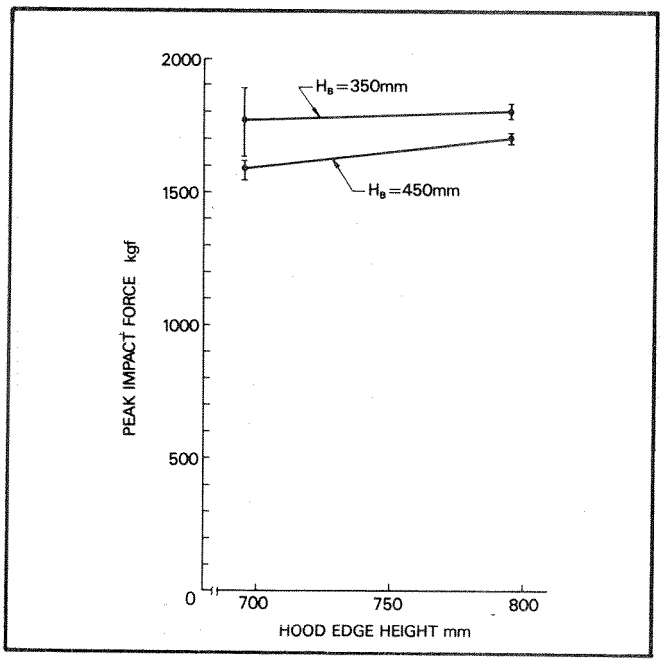


Figure 13. The relationship between front-end shape and bumper impact force

the criteria of the peak bumper impact force and the acceleration generated on the dummy's legs(5,6,7).

Hood-edge Impact Force

The relationship between the shape of the front end and the impact force of the hood edge is illustrated in Figure 14. In this series of tests, the peak impact force of the hood edge was smaller than the peak bumper impact force. The peak impact force of the hood edge tends to increase in proportion to increasing hood-edge height and is higher with a lower bumper height. On the whole, the peak impact force of the hood edge seems to be more strongly influenced by the shape of the front end than the peak bumper impact force.

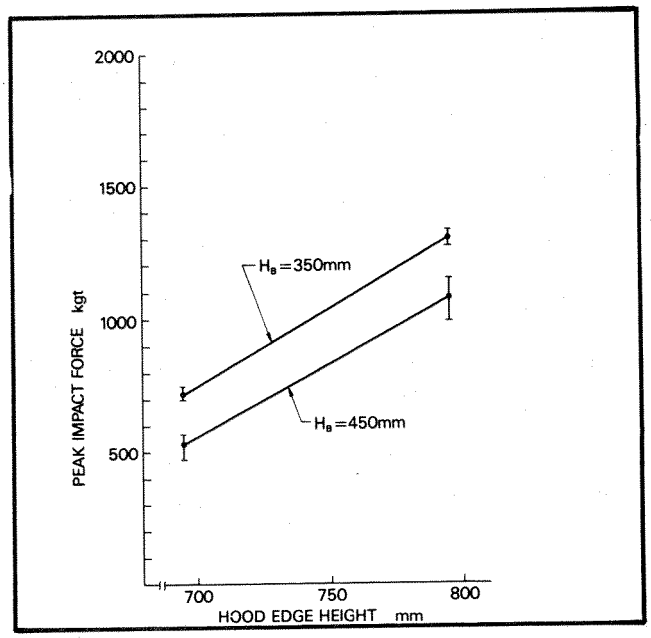

Figure 14. The relationship between front-end shape and impact force of hood edge

Head Impact Velocity

The relationship between the shape of the front end and the head impact velocity is illustrated in Figure 15. The head impact velocity shows different tendencies depending on the bumper height. With a bumper height of 350mm, the head impact velocity tends to increase as the hood-edge height increases.

With a bumper height of 450mm, the head impact velocity tends to decrease slightly as the hood-edge height increases. These results suggest that the head impact velocity changes in a complex fashion depending on the shape of the front end. Thus more detailed studies are needed to elucidate the factors involved.

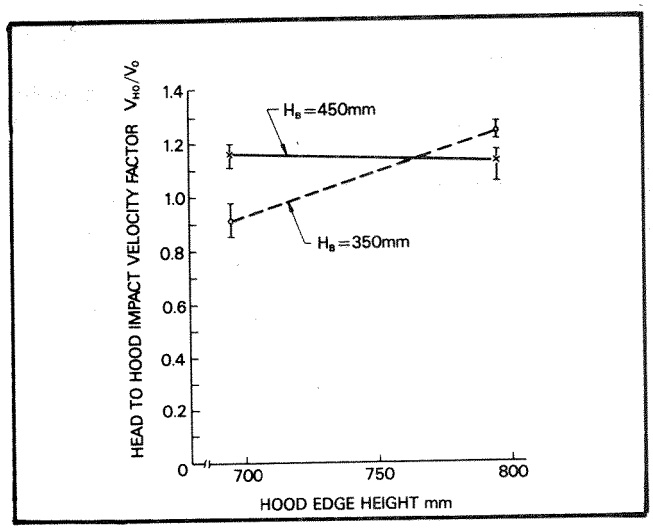

Figure 15. The relationship between front-end shape and head impact velocity

Head Impact Point

The relationship between the shape of the front end and the head impact point is shown in Figures 16a and 16b. In Figure 16a, the head impact point is expressed in terms of W.A.D. and in Figure 16b in terms of the distance (L) from the front of the hood edge. Both W.A.D. and L tend to become smaller as the height of the hood edge increases. Although the change in W.A.D. is less than 50mm, L shows a change of more than 100mm (Figure 16b), which suggests it is strongly influenced by the hood-edge height. The same tendencies are also observed for various bumper heights.

Results obtained in these tests show good correlation with the findings reported by other researchers with

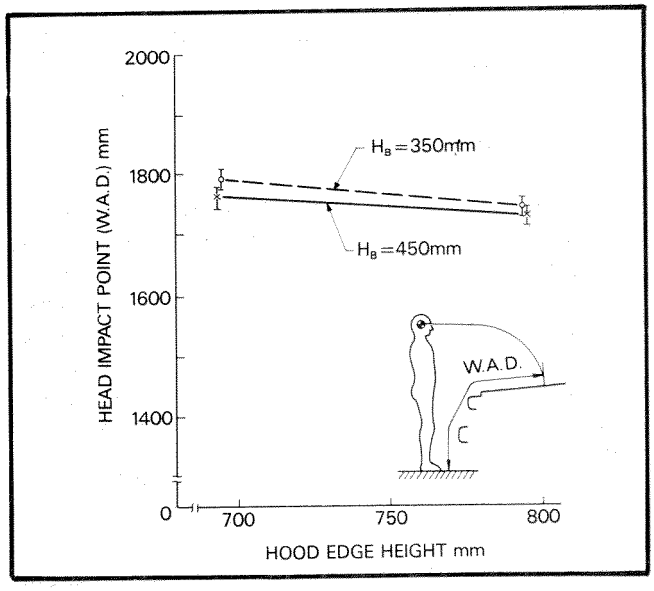

Figure 16a. The relationship between front-end shape and head impact point (W.A.D.)

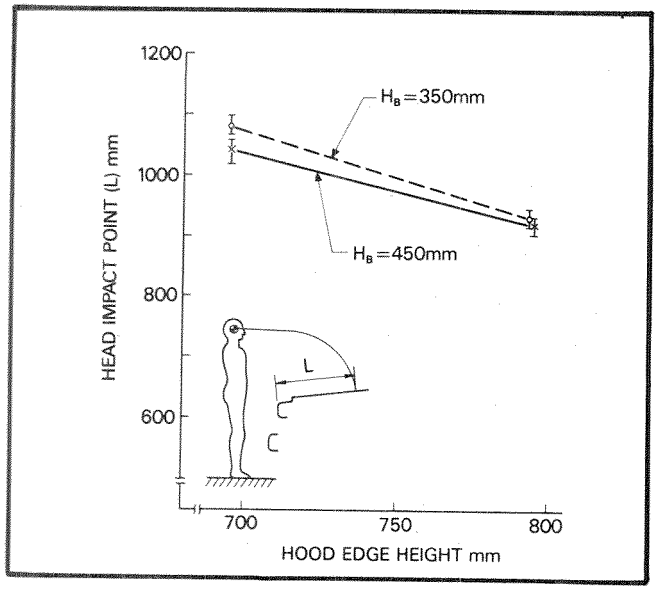

Figure 16b. The relationship between front-end shape and head impact point (L)

respect to tendencies for the peak impact force of the hood edge to increase and the head impact point to shift forward as the hood-edge height increases(8,9,10). As was noted, the head impact velocity shows opposite tendencies depending on the bumper height. Few detailed analyses have been reported regarding this point, and it is difficult to affirm whether this result is valid or not. However, since this factor has an important bearing on pedestrian protection, more detailed investigations should be done in the future.

It has been seen that the hood-edge impact force, head impact velocity, and head impact point undergo complex changes by simply varying the front-end shape as was done in these tests. Therefore, comprehensive investigations should be undertaken to clarify what effects the front-end shape and compliance, impact velocity, and other factors have on pedestrian protection.

Dummy Stance at the Moment of Impact

Preliminary tests were conducted using an adult dummy, an impact velocity of 30km/h, and the front-end specifications listed in Table 3 to investigate possible differences between frontal and lateral stance impacts. Particular attention was focused on the variation that occurred in the impact forces of the bumper and hood edge at the moment of primary impact and in the head impact velocity and impact point at the time of secondary impact.

Impact Forces of Bumper and Hood Edge

The relationship between dummy stance and the impact forces of the bumper and hood edge is shown in Figure 17.

Table 3. Front end specifications

Hood Edge Height	(H_H)	845mm
Bumper Height	(H_B)	450mm
Bumper Lead	(B/L)	100mm
Front-End Compliance		A

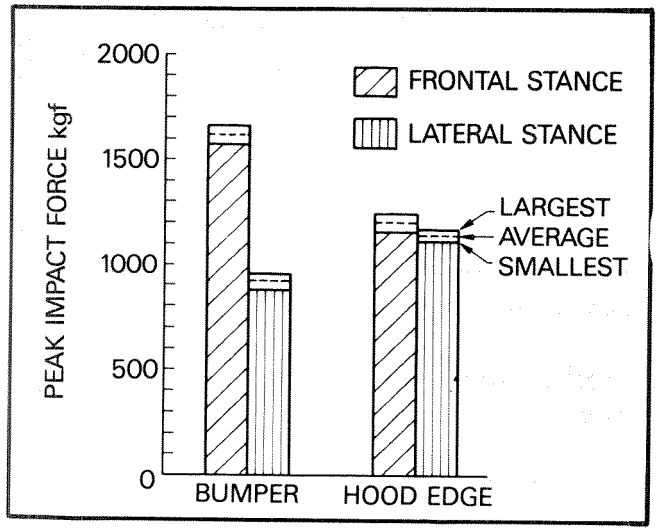

Figure 17. The relationship between dummy stance at moment of impact and impact forces of bumper and hood edge

The bumper impact force is smaller in a lateral stance impact than in a frontal stance impact. The impact force of the hood edge is virtually the same in both types of impacts. One reason for the difference in bumper impact force between the frontal stance impact and the lateral stance impact can be found in the difference in bumper impact force waveforms. As illustrated in Figure 18, the impact force waveform of a frontal stance impact has one peak, whereas that of a lateral stance impact has two peaks.

Head Impact Velocity and Impact Point

The dummy's head inevitably strikes the top of the hood in a frontal stance impact. However, in a lateral stance impact, the dummy's head is not likely to strike the top of the hood because its shoulder or arm strikes the hood first. For this reason, a comparison of the head impact velocity and impact point at the moment of secondary impact could not be made between the frontal stance and lateral stance impacts.

Dummies used to simulate pedestrians should be improved to incorporate the features of side impact dummies when used to test lateral impact.

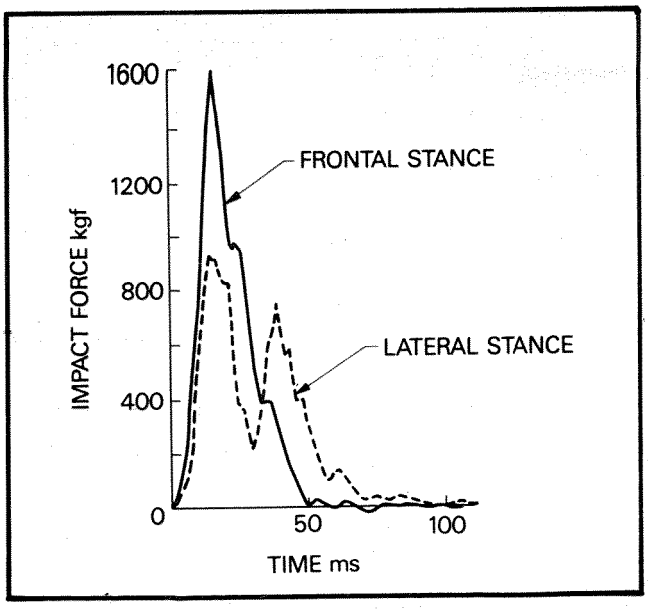

Figure 18. Bumper impact force as a function of time

Effective Mass of the Legs in Tests Using Dummies

In tests in which adult dummies were used, the effective mass applied on the bumper and that applied on the hood edge at the moment of impact were estimated.

Effective Mass Applied on the Bumpers

The effective mass applied on the bumper at the moment of impact was estimated at 6.7kgf from the bumper impact force obtained in a lateral stance impact using the front-end specifications listed in Table 4. This result is approximately double the figure of 3.2kgf given in (3) for cadavers. However, a precise comparison cannot be made because the test conditions were different.

Table 4. Front end specifications

Hood Edge Height	(H_H)	845mm
Bumper Height	(H_B)	450mm
Bumper Lead	(B/L)	100mm
Front-End Compliance		A

Effective Mass Applied on the Hood Edge

The effective mass applied on the hood edge was estimated from the impact force of the hood edge in the same manner as for the effective mass applied on the bumper. The results are given in Table 5.

The effective mass applied on the hood edge is little affected by the dummy stance, but it changes greatly according to the bumper height and the hood-edge height. The values for the effective mass applied on the hood edge in these tests in which dummies were used compare favorably with the findings given in (11) for the effective mass applied on the hood edge in tests using cadavers.

In summary, the effective mass applied on the hood edge in these tests using dummies was close to that of the cadaver tests, but the effective mass applied on the bumper was approximately twice the value reported for the latter. It is assumed that the reason for this difference is that the bumper impact force in the dummy tests was larger than the bumper impact force in the cadaver tests.

Conclusion

This study on a test procedure for investigating pedestrian protection by using dummies has brought out the following results:

- The ground friction coefficient did not have a significant effect on the bumper impact force, hood-edge impact force, or the head impact point within a friction coefficient range of 0.22 to 0.95.
- The dummy's femur joint torque did not have a significant effect on the bumper impact force, hood-edge impact force, head impact velocity, or head impact point within a torque range of 1 to 2g.
- To assure a uniform dummy posture at the moment of impact, the force suspending the dummy must be constant and the impact must take place within 200ms following dummy release.

Table 5. Effective mass applied on hood edge

Dummy Stance / Item	Frontal Stance		Lateral Stance	
Hood Edge Height ($H_H$mm)	745	845	745	845
Bumper Height ($H_B$mm)	450	450	500	450
Bumper Lead (B/L mm)	100	100	100	100
Effective Mass (kgf)	5.8	10.4	5.1	13.8

The results of this study suggest that the following points are the main issues remaining to be resolved with respect to the test procedure for investigating pedestrian protection by utilizing dummies.

- A dummy should be developed that is designed exclusively for use in pedestrian tests. Such a dummy would help to overcome the following problems with the Hybrid II dummy:
  - In lateral stance tests, the head of the Hybrid II dummy is not likely to strike the top of the hood.
  - The impact between the bumper and the dummy's knees also generates acceleration on the dummy's pelvis, which overlaps with the acceleration generated by the impact between the hood edge and the dummy's thighs. As a result, accurate measurements cannot always be made of just the acceleration generated by the impact between the hood edge and the dummy's thighs.
- A new evaluation method should be studied and devised because the characteristics of the impact between the pedestrian's lower limbs and the bumper cannot be fully evaluated with only the criteria of the bumper impact force and the acceleration generated on the dummy's knees.

The primary and secondary impact characteristics tend to change in complex ways by simply varying the shape of the front end. This result was brought out in preliminary tests that were conducted with the test procedure for examining pedestrian protection and in which various front-end shapes were used. However, since the number and types of tests were limited, this conclusion is not regarded as definitive. In future work, therefore, a comprehensive analysis should be done to determine what effects the front-end shape and compliance, impact velocity, and other factors have on pedestrian leg and head protection.

Abstract

In pedestrian accidents, the many differences that occur in the impact location and size of pedestrians and design of vehicles produce wide variations in the severity and location of the resulting injuries.

To obtain a better understanding of the mechanisms influencing the variability of these injuries, B.L. Cars PLC and the Transport and Road Research Laboratory have conducted a collaborative project using highly developed computer simulation techniques(1), matched to experimental test results, to study the relationship of vehicle shape and stiffness with the resulting forces and accelerations acting on pedestrian dummies.

Changes to the spoiler, bumper, and bonnet leading edge for simulated impacts to adult pedestrians at a speed of 40km/h show the following results:

1. A low front profile concentrates most of its input energy well below the centre of gravity of an adult, inducing high angular rotation onto the bonnet resulting in high head impact velocities.
2. Increasing the height of the bonnet leading edge increases the energy it absorbs resulting in higher accelerations to the regions of the adult and child that it contacts, but this is combined with reduced head impact velocities.
3. In a 40km/h impact, the energy absorbed by the bumper or bumper plus spoiler is generally between 1,000 and 1,200J.

   A bumper mounted at 450mm above the causes high bending moments and shear forces adult knees. If the bumper stiffness is above 3kN, child pelvic accelerations may also be high.

   Lowering the bumper reduces the risk to the adult knee and child pelvis. Introducing a suitable spoiler (air dam) reduces the risk of adult knee and lower leg injury and gives the most satisfactory conditions, providing the bumper component of the bumper/spoiler stiffness is approximately 3kN.
4. The input energy of the bonnet edge and grille varies widely with respect to its location, increasing as the bumper lead decreases or as the bonnet leading edge height increases.

   For adult impact at 40km/h, energy input values for the bonnet front ranged from 150J for a low bonnet with a bumper lead of 150mm, increasing to 1,700J for an 850mm-high vertical front profile and reducing to 600J for a high profile and 350mm lead. For some car profiles, a stiffness of 7kN, typical of some current small cars, produces high child pelvic accelerations and high adult femur bending moments. Reducing the stiffness to 5kN gives acceptable child pelvic accelerations and reduces the magnitude of leg bending moment by about 20 percent.
5. Within the range of shapes studied, the adult head impact velocity may be reduced by up to 40 percent of the worst case by increasing the bonnet height from 600 to 850mm. It may also be reduced by 30 percent by reducing the bumper lead from 350mm to zero, but only for a medium-height bonnet. Extreme values of head impact velocity range from 40 percent above car impact velocity to 25 percent below.

   For the child, head impact velocities are more consistently just below car impact speed, reducing by 60 percent for a high vertical front profile.
6. The most significant changes noted in the simulations of different dummy sizes are that head impact velocity increases in magnitude and the location of head impact point moves further rearward with increasing dummy height.

   The severity of pelvic acceleration is increased as the pedestrian's height is reduced because the bonnet leading edge strikes closer to the pelvis.
7. The relationships determined in these studies have been utilised to give guidelines for modifying a small saloon car to give improved pedestrian protection(2).

Introduction

In pedestrian accidents, the many differences that occur in the impact location and design of vehicles and the size of pedestrians produce wide variations in the severity and location of the resulting injuries.

To obtain a better understanding of the mechanisms influencing the variability of these injuries, B.L. Cars PLC and the Transport and Road Research Laboratory have conducted a collaborative project using computer simulation techniques matched to full-scale dummy impact tests to study the relationship of vehicle shape and stiffness with the resulting forces and accelerations acting on pedestrian dummies.

This paper summarizes the results of this work and gives examples of simulations that represent changes to the spoiler (air dam) bumper and bonnet for adult and 6-year-old child pedestrians at impact speeds of 40km/h.

Only the impact between the pedestrian and the vehicle is considered because this is the most predictable period and is claimed to be more injury-producing(3) than the final stage when the pedestrian falls to the ground. In the simulations, the model of the adult leg is based on modified dummy legs having lateral compliance at the knee and increased adduction at the hip joint.

Computer Simulation

The computer model used was developed by B.L. Cars from the Calspan Corporation 3D Crash Victims Simulation Program version (CVS 111 version 20).

This development(4) has been extensively validated and includes improved vehicle-to-dummy contact models.

Forces and torques may be output for any joint in the geometric reference system of a segment as seen at any point within that segment. The data are also output in the same reference system as the vehicle, which with vehicle panel contact data allows an investigation of segment bending moments.

Dummy Model

The simulation model of the pedestrian is based on a dummy of Ogle design representing a 50th percentile adult male, 1.76m tall, and a 6-year-old child, 1.19m tall.

The simulation of the child dummy depicted standard, current joint movements and torques. The adult embodied modifications that were fitted to the Ogle dummy at the hip and knee to give a more realistic performance. These dummies have been used in representative tests to check the accuracy of the simulations discussed in this paper. The hip joint of the leg on the impacted side only was modified to increase the maximum possible angle of adduction to 28° with a corresponding reduction in adduction.

With the leg on the nonimpacted side unmodified, both legs are able to swing up to 25° in the direction of impact.

Both the knee joints were modified to allow lateral rotation in either direction, with friction pads added to give an adjustable but constant level of friction torque. With this arrangement, the severity of the impact to the knee is a function of the amount of lateral angular rotation that occurs. The acceptance level is judged to be 6° of rotation, with the friction torque set at 200Nm, representing the onset of an injury of severity AIS 3(4).

Simulated Impact Conditions

Since the simulations are based on the characteristics of a dummy, the majority of the posture conditions chosen are those that have been shown by full-scale tests to compensate most successfully for the limitations in the performance of a dummy and yet represent a typical car-pedestrian accident.

Pedestrian

The pretest condition simulates a pedestrian in a walking stance with the right leg backward and the left leg forward. Both legs are straight and the full body weight evenly distributed between the two legs. Impact is to the right-hand side at an angle of 30° forward of truly sideways.

This stance gives a near lateral impact to the lower limbs that represents typical accident conditions and improves the probability of head-to-vehicle contact, without the shoulder striking in such a manner that it gives an unrealistically high level of protection to the head.

Two different postures were also simulated. In one case, the dummy was represented as having all its weight on the struck leg; in the second case, the dummy was struck squarely on the side.

Vehicle

Most simulations represent a 40km/h impact on the centreline of the car. This speed is considered to be the maximum at which pedestrian protection could be practically achieved. One additional case is simulated at 32km/h to study the influence of speed.

The vehicle is represented as having a fixed suspension with the brakes applied at the instant of impact to simulate a deceleration of 0.7g.

Vehicle Simulation

Vehicle Components

The vehicle front is modelled by using six flat planes or groups of planes, which is the minimum number required to represent the important shapes and features for pedestrian impact. The planes are given idealised stiffness functions that are initially based on those for current production vehicles.

The panels are shown in Figure 1 and represent the under-bumper region, bumper, grille, bonnet leading edge, bonnet top, and windscreen. The dimensions of the car shapes that are simulated are given in Table 1.

To increase the amount of information gained from each run of the program, three bonnet lengths are modelled simultaneously, each having the same leading and trailing edge heights. Associated with each bonnet length is a group of three windscreens that are given negligible stiffnesses. This allows the head impact velocity

with the windscreen to be determined for nine different locations of windscreen.

Two forms of leading edge are examined, one approximating to a square edge and the second to a radiused front.

When a radiused front is simulated, a slightly more complex model is used (Figure 1). The three panels used to model the curvature operate in a dependent manner, and, for each body segment, only the panel with the greatest contact is assumed to generate a reactive force at any instant.

The leading edge vertical plane, panel 4, is utilised to supplement the lower panel of the rounded front to give the increased stiffness often present in this location.

Stiffness Characteristics

The planes are given idealised stiffness functions, which are shown in Figure 2 and Table 2, and describe forces that are normal to the vehicle panels. All reach a force plateau at which there is no limit of deflection and no allowance made for the stiffness of understructure

* Dual phase leading edge

(engine, etc.). By this means, necessary material crush depths can be assessed for each condition. The maximum stiffnesses used are based on values determined by dynamic impact tests on current small production cars.

For the round front, the stiffness of the leading edge vertical plane is utilised to supplement the lower panel of the rounded front to give the increased stiffness often present in this location.

Results

The impact loadings and responses calculated for the pedestrians in the simulated tests are shown in the appendix.

In these results, the location of head impact is the distance behind the bumper front face that the path of the centre of gravity of the head intersects the bonnet top or windscreen 2A, as appropriate.

The head impact velocity is the average of the head velocities, normal to each of the three windscreens that form the most forward group of three windscreens.

Pelvic and thoracic accelerations are the peak calculated values while the pedestrian is struck by the front or bonnet of the car.

Knee lateral angular rotation is given for two phases of the impact. Phase A spans the first part of the impact up to the instant the bumper forces start to reduce. These angles will, therefore, give an indication of the influence of the bumper and spoiler on knee bending forces.

Phase B gives the total angular displacement of the knee. The difference between the values of phases A and B is the influence of the cantilevering of the femur around the bonnet leading edge, causing a loading across the knee to accelerate the lower leg.

If the femur were to fracture from the action of these forces, the loading across the knee would be relieved. In these simulations, the femur is not programmed to fracture.

Knee shear force is the maximum value across the joint of the impacted leg. Leg bending moments are calculated for the instant when the applied forces are a maximum on the upper and lower legs, respectively.

For the adult, the upper leg bending moments derive from contact with the bonnet leading edge and the lower leg moments from either bumper or spoiler contact. For the child, the upper leg moments derive from bumper contacts and the lower leg from striking the spoiler.

Comments on Results

In general, all features of the shape of a vehicle combine to influence the characteristics of an impact, but the following broad trends could be attributed to respective vehicle components for the cases studied. The influence on the overall kinematics has already been reported(4).

Adult Pedestrian (Impact Speed 40km/h)

Bumper Stiffness

Bumper stiffnesses of 4, 6, and 8kN were simulated at a height of 450mm, and the resulting lower leg and knee forces are compared in Table 3.

Table 3. Adult lower leg and knee forces with respect to bumper stiffness

Run No.	Bumper Stiffness kN	Lower Leg Bending Moment Nm	Lateral Knee Angle Degrees	Knee Shear Force kN
I15	4	390	6.8	1.5
I16	6	478	6.9	2.1
I14	8	560	6.8	2.7

The results show that lower leg bending moment and knee shear forces both increase with bumper stiffness: a 100 percent increase in stiffness giving a 43 percent increase in leg bending moment and an 80 percent increase in knee shear force.

The angle of lateral displacement of the knee is constant because its magnitude is related to the total rotational energy input resulting from torque loadings, and the energy required to accelerate a leg to a given velocity is approximately constant.

Bumper Height and Spoiler

Three heights of bumper were simulated, centred at 250, 350, and 450mm above the ground. These are compared in Table 4 with cases that include spoilers mounted at 262.5mm above the ground.

In selected cases for this comparison, the bumper was the only part of the car simulated so that its effect could be isolated.

For the cases shown, lower leg bending moments are approximately constant except for a high value resulting from the narrow 30mm deep bumper at 450mm and low values from the more compliant bumper plus spoiler combinations. Both the shear forces and the lateral angular displacements of the knee reduce with lower bumper heights and reduced bumper-to-spoiler lead.

Bonnet Leading Edge

The position of the bonnet leading edge directly influences pelvic accelerations and upper leg bending moments and also affects the location and severity of subsequent impacts of the head to the car.

Pelvic Accelerations—Pelvic accelerations vary with respect to bonnet leading edge height and bumper-to-bonnet lead (see Table 5).

The accelerations range from 18 to 64g and increase in magnitude with increased bonnet height and also with reduced bumper lead.

Table 5. Adult pelvic accelerations relative to bonnet leading edge location

Bumper to Bonnet Lead mm	Pelvic Accelerations g for Bonnet Leading Edge Heights mm		
	600	720	850
0	24	43	63
150	18	34	64
250	—	30	54
350	—	21	52

Upper Leg Bending Moment—For the leg arrangement simulated, the upper leg bending moments (see Table 6) were a maximum for impacts to the midsection of the upper leg and were associated with bonnet leading edge heights of 720 and 750mm. The 600mm- and 850mm-high bonnets struck near the ends of the upper leg and the adjacent hip joint and friction-loaded knee joints limited the magnitude of the bending moments generated.

Table 6. Adult upper leg bending moments relative to bonnet leading edge location and stiffness

Bumper to Bonnet Lead mm	Upper Leg Bending Moments Nm for Bonnet Leading Edge Heights mm		
	600	720	850
0	397	581	226
150	307	495	218
250	—	451 (388)	202
350	—	303 (241)	276

Location and Velocity of Head Impact—The location of the bonnet leading edge influences both the position and the velocity of head impact. The location of head impact may affect its severity. For example, an impact to traditionally soft bonnet top will probably cause less injury than an impact to a rigid scuttle or windscreen frame. Table 7 shows that the head impact point ranges from 0.84 to 1.4m behind the bumper and moves further rearward as the height of the bonnet is reduced and also as the bumper-to-bonnet lead is increased.

Table 7. Distance of adult head impact point from bumper, relative to location of bonnet leading edge

Bumper to Bonnet Lead mm	Distance of Head Impact Point Behind Bumper m for Bonnet Leading Edge Height mm		
	600	720	850
0	1.33	1.15	0.84
150	1.4	1.25	1.05
250	—	1.4	1.25
350	—	1.4	1.35

With a bumper height of 450mm, the velocity of head impact (see Table 8) ranges from 73 to 142 percent of car impact speed. It increases as the height of the bonnet is reduced and also for a medium height bonnet as bumper-to-bonnet lead increases.

Table 8. Impact velocity of adult head with forward windscreen group relative to location of bonnet leading edge

Bumper to Bonnet Lead mm	Head Impact Velocity m/s for Bonnet Leading Edge Height mm		
	600	720	850
0	13.3	9.75	8.3
150	14.3	11.4	8.1
250		13.0 [13.9]	8.5
350		14.2 [15.8]	9.1 [10.0]

Note: Velocities shown generally relate to bumper height of 450mm without spoiler. Numbers in brackets refer to bumper combined with spoiler.

These velocities are increased by approximately 10 percent with the inclusion of a spoiler, which effectively lowers the height of leg contact.

Energy Distribution

The energy absorbed by the front panels is shown in Table 9 for cases having a 450mm-high bumper with no spoiler. The total energy absorbed by all the front panels, the bonnet leading edge, the grille, the bumper, and the bumper panels is shown together with the energy absorbed by the bumper and bumper under-panels only.

The total energy absorbed increases significantly with increased bonnet height and less significantly with reduced bumper lead. The energy absorbed by the bumper ranges between 970 and 1,170J for all configurations except for zero bumper lead where values range from 280 to 500J.

The results shown in the appendix indicate that, for the shapes studied, the energy absorbed by a bumper plus spoiler is approximately the same as that absorbed by a 450mm-high bumper without spoiler.

Changes to Dummy and to the Impact Speed

In nearly all the simulations, the impact speed and the characteristics of the dummy are held constant. In Table 10, the results of changes to these characteristics are compared with those from a run with the standard dummy arrangement described in an earlier section.

The variations studied are for a 5th percentile female and a 95th percentile male of 1.53 and 1.85m height, respectively; a test at the standard dummy arrangement, but with all the weight on the impacted leg; an impact with the dummy turned so it is struck squarely on the side; and, finally, a simulation of a 32km/h impact with the dummy again simulated as described previously.

Some significant differences are noted in these runs. The head strikes nearer the front and at a lower velocity for the 5th percentile female, and this is coupled with higher pelvic accelerations. A more rearward head impact occurs at a higher velocity for the 95th percentile male, and there is a reduced head velocity for the side-impacted case. Accelerations were not significantly reduced for the 32km/h run because, with a constant crush force stiffness characteristic for each panel, the contact forces generated were the same for both velocities.

Child Pedestrian (Impact Speed 40km/h)

Bumper Height and Spoiler

Bumpers were simulated at heights of 350 and 450mm, and their influence on forces to child legs is compared in Table 11 with cases that include spoilers mounted 262mm above the ground.

The combination of spoiler and 450mm bumper gives low leg bending moments of approximately 150Nm and low knee shear forces of 0.5kN. Removal of the spoiler increases the shear force to 0.9kN, and lowering the

I 2	450	50	4.5	157	152	153	.52	62

bumper to 350mm raises the upper leg and knee bending moments and the knee shear force.

Bending moments have been calculated only where direct contact occurs, and consequently no values are given for the lower leg in cases where spoilers have been omitted.

Bumper/Bonnet Leading Edge

For the child, the location of the bonnet leading edge directly influences thoracic accelerations and the subsequent impacts of the head to car. It also interacts with the bumper to affect pelvic accelerations.

Pelvic Accelerations—In these simulations, the magnitude of child pelvic accelerations is influenced primarily by the stiffness of the car front, particularly the and also by the height of the bonnet.

The effect of stiffness is shown in Table 12, in which the pelvic accelerations given, ranging from 52 to 99g, are the averages for all the shapes studied.

Table 13 shows that the effect of changes in shape is less pronounced. The only direct pelvic impact with the

Table 12. Average child pelvic acceleration with respect to the bumper and bonnet edge stiffness

Front Structural Stiffness kN			Pelvic Acceleration. Averaged for All Car Shapes (g)	
Bumper Plus Bonnet kN	Bumper kN	Bonnet Edge kN	Average	Standard Deviations

8	3	5	69	12
11	4	7	99	23

Table 13. Child pelvic accelerations relative to location of bonnet leading edge

Bumper to Bonnet Lead (mm)	Pelvic Acceleration (g) for Bonnet Leading Edge Height mm		
	600	720	850
150	73	115	107
250	—	95	95
350	—	100	100

bonnet leading edge resulted in the highest acceleration of 115g; for the lowest acceleration of 73g, the bonnet edge struck below the pelvis.

In other cases, pelvic impact was essentially to the softer front grille.

In these cases, the effect of car shape was partly masked because a level force plateau was used to describe the stiffness function and the maximum force was reached in each run.

Thoracic Accelerations—Thoracic acceleration is most affected by car shape and structural stiffness, and results are shown in Table 14. The 150mm bumper lead clearly demonstrates the influence of shape. With the lower 600 and 720mm bonnets, the leading edge strikes below the thorax giving low thoracic acceleration of 50g. Conversely, for the 850mm bonnet, direct leading edge to thorax contact occurs giving a higher acceleration of 85g.

For increased bumper-to-bonnet leads, the thoracic acceleration increased for the 720mm high bonnet and decreased for the 850mm bonnet.

Table 14. Child thoracic acceleration relative to location and stiffness of bonnet lead edge of 7kN, but with values in brackets for 5kN stiffness

Bumper to Bonnet Lead (mm)	Thoracic Accelerations (g) for Bonnet Leading Edge Heights (mm)		
	600	720	850
150	50	47	85
250	—	56 (37)	68
350	—	59 (34)	59 (45)

Reduction of leading edge stiffness from 7 to 5kN gave corresponding reductions in accelerations ranging from 21 to 42 percent.

Location and Velocity of Head Impact—The location of the bonnet edge also influences the location and velocity of head impact for the child. Generally the location of head impact was between 300 and 800mm behind the front face of the bumper with impact being more rearward with reducing bonnet height.

The head impact velocities given in Table 15 are generally in the range of 8.5 to 10.5m/s, but values of 4.0 to 6.5m/s occur with the 850mm-high bonnet and more vertical front. The velocity of the head striking the bonnet top is significantly influenced in the simulations and tests by neck flexure.

Table 15. Child head impact velocity relative to location of bonnet leading edge

Bumper to Bonnet Lead (mm)	Head Impact Velocity m/s for Bonnet Leading Edge Heights (mm)		
	600	720	850
150	10.3	10.2	4.0
250	—	9.7	6.5
350	—	10.4	8.6

Conclusion

This study of the influence of car shape and stiffness on the protection offered to pedestrians in an accident is based on the presumption from previous studies that the highly developed mathematical model used gives a good simulation of the characteristics of a car-to-pedestrian impact.

It has been extensively validated by comparison with selected dummy impact tests and includes improved vehicle-to-dummy contact models and the output of additional joint force data allowing the evaluation of segment bending moments.

The adult dummy simulation has improved hip and

knee joint flexure to give more realistic bumper and bonnet leading edge contacts.

1. The studies show the following general relationship between vehicle design and the resulting severity of impact to pedestrians at speeds of 40km/h:
   - A low-front profile concentrates most of its input energy well below the centre of gravity of an adult, inducing higher angular rotation onto the bonnet resulting in high head impact velocities. Distribution of energy input is closer to the centre of gravity of the simulated child, resulting in lower head impact velocities.
   - A medium-height profile results in similar energy inputs at the bumper but increased energy input at the bonnet leading edge giving higher accelerations to the regions of the child and adult contacted by the leading edge, but this is combined with lower head impact velocities.
   - A high profile further increases the energy input of the bonnet edge, giving increased accelerations to the adult pelvis and child thorax, but gives a further reduction in head impact velocity.
2. Changes to individual components give the following trends. Specific values relate only to the size of pedestrians that are simulated: a 50th percentile adult male and a 6-year-old child.
   - Bumper—A bumper mounted at 450mm causes excessive lateral bending to the adult knee but low loadings to a child knee. Lowering the bumper improved conditions for the adult but gave increased loading to the child knee and femur. The introduction of a suitable spoiler with the 450mm bumper gave improvement to both adult and child.

     If a leg bending tolerance value of 200Nm is assumed(4), then adult lateral knee bending is excessive from a bumper mounted at 450mm and having a stiffness of 4kN. Lowering the bumper to 350mm or introducing a spoiler giving total bumper/spoiler stiffness of up to 6.5kN gave acceptable conditions.

     For the child, the 450mm-high bumper influences pelvic acceleration, and a simulated stiffness of 4kN is associated with pelvic accelerations of about 100g. Lowering the bumper to 350mm reduces these accelerations to 65g.

     A bumper/spoiler combination gives acceptable values for both child leg and pelvis providing the stiffness of the bumper component is 3kN or less.

     When struck by an adult, a bumper or bumper plus spoiler absorbs between 1,000 and 1,200J of energy when the bumper lead is 150mm or more. In the cases with zero bumper lead, only 280 to 500J are absorbed.

     When assessing the safety of a bumper/spoiler combination, the spoiler may reduce the bending and shear forces across the knee, but it will not give adequate protection when added to a bumper that is so hard it causes crushing injuries.
   - Bonnet Leading Edge—The input energy of the bonnet edge and grille varies widely with respect to its location, increasing as the bonnet is raised or as the bumper lead decreases. Energy input values range from 150J for a low bonnet with a bumper lead of 150mm, increasing to 1,700J for a high vertical profile and reducing to 600J for a high profile and 350mm bumper lead.

     Child pelvic accelerations and bending moments on the adult upper leg are too high in nearly all cases when the leading edge stiffness is 7kN. Reducing the stiffness to 5kN gives acceptable values for the child pelvis and reduces the magnitude of leg bending moments by about 20 percent. The stiffness of the leading edge of some current small cars is about 7kN.
   - Bonnet Top Impact—The location of head impact is between 0.3 and 0.8m behind the bumper for the child and from 0.4 to 1.4m behind the bumper for the adult. Within the range of shapes studied, the adult head impact velocity may be reduced by up to 40 percent of the worst case by increasing the bonnet height from 600 to 850mm.

     It may also be reduced by 30 percent by reducing the bumper lead from 350mm to zero, but only for a medium-height bonnet. Extreme values of head impact velocity range from 40 percent above car impact velocity to 25 percent below. For the child, head impact velocities are more consistently just below car impact speed, reducing by 60 percent for a high vertical front profile.
3. Dummy characteristics. The most significant changes in responses noted in the simulations of different dummy sizes are that head impact velocity increases in magnitude and the location of head impact point moves further rearward with increasing dummy height.

   The bonnet leading edge strikes closer to the pelvis of the 5th percentile female giving higher pelvic accelerations than for a taller dummy.

   Changes to the standing arrangement of the dummy do not produce major changes in the

impact conditions. Striking on the side at right angles gives a 15 percent reduction in head impact velocity, but changing the weight distribution from evenly spread over two feet to all the weight on the impacted leg causes no notable change.

4. The relationships determined in these studies have been utilised to give guidelines for modifying a small saloon car to give improved pedestrian protection(5).

Abstract

As part of an ongoing NHTSA/Battelle/Calspan research program, 16 experimental vehicle-to-pedestrian impacts at 25mph are being performed using the Calspan sled facility. The instrumented vehicle test buck represents a vehicle front end that can be equipped with either an unmodified hard production-type bumper or a modified compliant pedestrian-compatible bumper. The instrumented pedestrian surrogates are unembalmed whole body anatomic specimens. The test matrix involves carefully paired subjects for comparison of the modified and unmodified configurations. Individual results are reported regarding pedestrian kinematics, measured forces and accelerations, physiological trauma incurred, and estimates of associated impairment, as well as an overall evaluation of injury-mitigating potential of the bumper system modifications.

Background

Each year, thousands of pedestrians are struck by motor vehicles. Data from the National Highway Traffic Safety Administration (NHTSA) Fatal Accident Reporting System (FARS) and Pedestrian Injury Causation Study (PICS) indicate that an excess of 135,000 pedestrians are injured annually. Approximately 72 percent of these pedestrian accidents involve passenger cars, and 74 percent of these passenger car accidents involve impact with the front structure of the vehicle. Translated into numbers, approximately 73,000 pedestrians are struck by the front structures of passenger cars annually. Ninety-one percent of these accidents occur at or below 20mph. Most of the accidents at these velocities are not fatal; however, many people suffer serious and often permanent impairment, especially to the lower extremities due to knee contact with the bumper and pelvic contact with the hood leading edge areas of the vehicle. Through the use of statistical techniques, NHTSA has predicted that over 140,000 pedestrians will be struck in 1994 with a total number of projected fatalities of 8,700(1). Assuming the same percentage of passenger car frontal impacts, approximately 77,000 pedestrians will be injured in 1994 if the design of passenger car front structures remains essentially unchanged. The purpose of the study discussed in this paper is the evaluation of injury reduction benefits achieved when the lower extremities of pedestrian victims are struck by a front bumper that is more compliant than those currently produced.

In January 1981, NHTSA published a notice proposing a new safety standard applicable to passenger cars that would require modification of front structures to reduce knee injuries sustained by pedestrians when struck by a vehicle. Since 1974, Battelle's Columbus Laboratories have been performing research on trauma-producing and trauma-mitigating mechanisms in pedestrian impacts by vehicles. This research utilized both instrumented Anthropomorphic Test Devices (ATD) and human cadavers(2-7) in support of this proposed safety standard. From 1974 through 1977, these impact experiments using human cadavers were performed at the Transportation Research Center (TRC) of Ohio. Since 1982, research using human cadavers and ATD's has been performed at the Calspan Advanced Technology Center (ATC). During the past year, Calspan has conducted eight pedestrian experiments using fresh, unembalmed cadaver subjects to evaluate the effects of production and modified bumper impacts.

Bumper Design

Early Battelle experiments resulted in the selection of a 1978 Pontiac LeMans as a representative test vehicle. All subsequent testing performed at Calspan has used the LeMans as the impacting vehicle. The results of these Battelle tests indicated that a bumper that limited the acceleration to less than 100g when impacted with a 7 lb mass (i.e., a representative knee mass) at 20mph would result in significant reductions to lower extremity injuries in pedestrian accidents. The proposed regulation has specified a bumper design that demonstrates a 90g acceleration level when impacted at 20mph with the 7 lb mass to achieve the maximum benefit to pedestrian accident victims. To accomplish the desired impact conditions of not over 90g, Battelle and NHTSA selected an open-cell polyurethane foam material. This particular energy-absorbing foam used in the bumper modification has a density of 4.8 lb/ft^3 and a modulus at 50 percent strain of 16 lb/in^2. This foam was cut into several layers and stacked into the C section of the LeMans bumper after the face plate had been removed. Figure 1 is a drawing of the foam insert indicating the size and shape. The corresponding acceleration (deceleration) time history

of a 20mph impact with the 7 lb impactor is presented in Figure 2. Also included in Figure 2 is the acceleration-time history of a similar impact at a velocity of 25mph. It should be noted that, in addition to satisfying the knee acceleration criteria just discussed, the design criteria for the modified LeMans bumper included a need to (1) satisfy the then existing 5mph no-damage performance requirement, and (2) stay within the space envelope provided by the production vehicle.

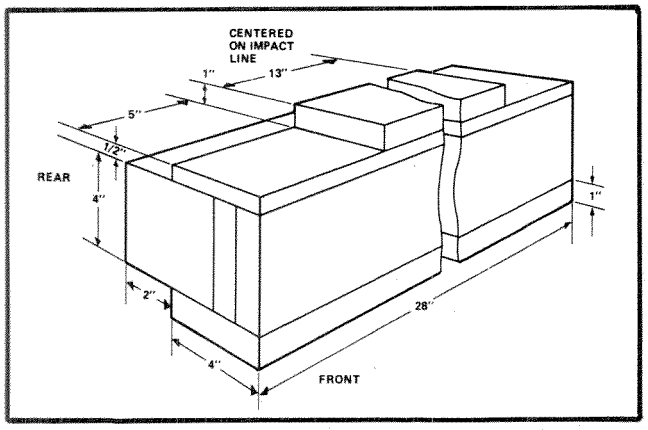

Figure 1. Foam bumper configuration

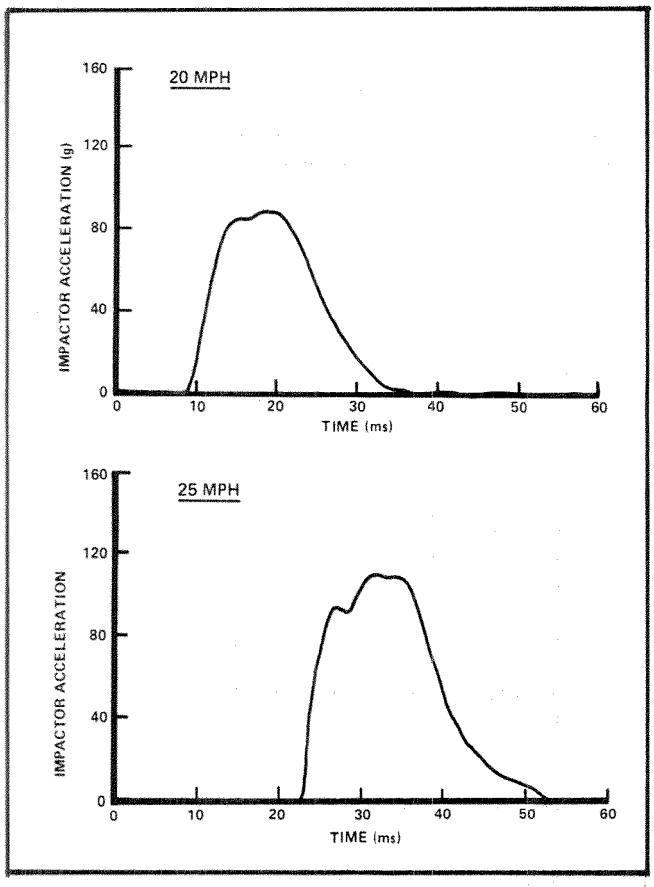

Figure 2. Seven lb impactor acceleration versus time history

Load cell balance systems were designed into the structure of the LeMans test buck at the bumper and hood leading edge (HLE) locations to record the longitudinal impact forces imparted to the knee and hip regions of the test subjects. The expression hood leading edge is used for convenience. The load cell balance at this location measures the forces applied to the forwardmost portion of the upper fascia and grille work of the vehicle. This area is approximately 6in in front of the forwardmost edge of the hood.

Cadaver Selection

Cadavers used in this research program were supplied by the Department of Anatomical Sciences of the State University of New York at Buffalo (SUNYAB). The subjects had been willed to the university for use in scientific research. A personal interview with the next of kin was conducted by representatives of Calspan and SUNYAB. During this interview, the objectives and techniques of the program were explained briefly and an informed consent release document for use of the body was signed and witnessed. After the experiment, the subject was returned to SUNYAB for disposition according to the willing document. Strict adherence to NHTSA Order 700-4 was observed in all instances.

Pretest full body x-rays were taken, and the femur x-rays were used to determine a Percent Cortical Area (PCA) measurement. This PCA was used to assess the acceptability of the subject with respect to bone quality. All accepted subjects were within one sigma of the average normal PCA as defined by Garn(8), and extended by Calspan(9). One subject was rejected during this study due to an obvious osteoporotic condition. Cadavers that had been confined to bed for more than 1 week's duration prior to death were also determined to be not acceptable. Cadaver anthropometry is presented in Table 1, and the averaged PCA values of the femurs are displayed in Figure 3. Human cadavers are referred to as Calman XX during this study. Calman is a generic form used by Calspan to designate a cadaver. The number is a serial number that provides a means of reference while maintaining anonymity of the donor.

To assess the benefit received from impact with the modified (MOD) bumper versus the production (PROD) bumper, an attempt was made to match the cadavers as closely as possible. The parameters used for matching cadavers are presented in Table 2. Table 3 indicates the modified versus production matched experiments selected for comparison. This table presents matched experiments wherein the sex remains constant, and age, height, and weight are displayed according to the degree of parameter match based on the criteria of Table 2. Comparison numbers 1 through 4 show the highest degree of parameter match. A good match for Calman 24 in age (46yr) and

8	24	27	(Mod/Prod)	Poor (46/63)	Match (M/M)	Excellent (70/71)	Poor (132/194)

height/weight ratio (70in, 132 lb) was not found among the male subjects available for this program. Comparisons 7 and 8 show excellent matches in height between Calman 24 and both Calman 23 and 27, but poor matches in age and only good-to-poor matches in weight.

Test Procedures

When a suitable cadaver subject was selected and instrumented, the impact test was performed. Whole body x-rays were exposed and examined by a radiologist, a full autopsy examination was performed by a forensic pathologist, and the lower extremities were dissected. The results of these examinations were sent to Dr. John D. States at the Department of Orthopedics of the University of Rochester for evaluation of potential temporary and permanent impairment.

Equipment and Setup

All pedestrian impact experiments were performed using the Calspan 12in HYGE sled facility as a velocity generator for the 1978 Pontiac LeMans sled buck supplied by Battelle. Some structural modifications to the sled buck were required to insure compatibility with the Calspan sled facility since it had originally been fabricated for experiments performed on the larger TRC of Ohio sled. A photograph of the experimental setup is shown in Figure 4.

Each pedestrian subject was positioned in a walking posture with the struck leg placed 18in to the right of the centerline of the vehicle (midway between the center and outside edge of the bumper) with a minimum of 50 percent of the body weight on the struck leg. This percentage increases to approximately 80 percent between the time the pedestrian support quick release mechanism is triggered and initial impact. The subject was standing on a load cell platform to monitor this weight distribution. The struck side arm was secured behind the subject's back to preclude arm contact with the hood leading edge, and the subject was tethered to the sled buck to preclude secondary contact with the ground. A quick release mechanism attached to the body harness was electronically fired at a predetermined time in the testing sequence, allowing the subject to be freestanding at the time of contact.

Contact occurred at a velocity of 25mph with the sled brakes set to simulate a 3/4g braking deceleration. The impact velocity of 25mph was chosen to demonstrate the residual benefits of a higher velocity impact using the 20mph pedestrian-compatible bumper design according to the specifications of the Notice of Proposed Rule Making(1).

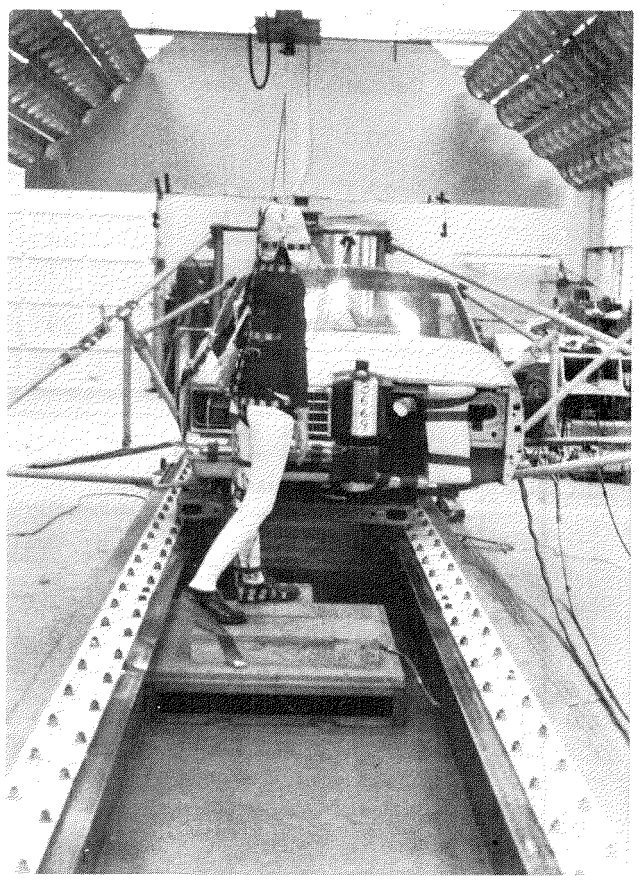

Figure 4. Experimental setup

A strobe-flash unit was mounted in the field of view of the cameras to indicate initial contact between the bumper and the subject's legs. Six high-speed cameras were used to document the impact tests. They included a full view of the event from the center of the sled track and an overhead view from off-board cameras. The four on-board cameras provided the rear view of the struck extremity, front view of the whole body, front view of the upper body, and upper body view through the windshield.

Subject Instrumentation

The human cadavers selected for use in this program were stored under refrigeration from the date of death until the morning of the test. The subjects were unembalmed with the exception of selective light embalming of the prevertebral muscles bilaterally done on Calman 27 and 28. This light embalming was to help stabilize the head/neck complex since no external cervical support was used.

The cadavers were clothed in tight-fitting, stretch, long underwear. Accelerometers were attached in the following locations:

Head	9-accelerometer head mount, angular accelerometer, triaxial mouth mount
Sternum	Upper Anterior-Posterior (A-P), Lower A-P
Ribs	#4 Medial-Lateral (M-L), #8 A-P, bilaterally
Thoracic Vertebrae	Triaxial mounts at T-1, T-12
Sacrum	S-2 triaxial
Knee	External triaxial
Ankle	External triaxial

The angular head accelerometer was attached to the 9-accelerometer head mount. The head and mouth mounts were attached to the subjects, and stereotaxic measurements were taken using a Kapf sterotaxic unit modified for a human head. Several dummy tests were conducted with full cadaver instrumentation to check out the system prior to any cadaver impact tests.

Experimental Results

Although electronic data were recorded for the head and thoracic regions of all subjects, only lower extremity data are presented in this paper. Table 4 contains a data summary of the peak accelerations on the struck knee and pelvis (sacrum) and load measurements from the vehicle bumper and hood leading edge for each test.

It is observed from Table 4 that the accelerations experienced by the struck knees are significantly lowered when the subject is impacted with the modified bumper as compared to impacts with the production bumper. Likewise, the peak longitudinal forces measured by the bumper load cell balance are also significantly lower (approximately one-third of the production bumper values). Figures 5 and 6 display comparative data from one of the matched experiments (Calman 20 and 23)

Figures 7 and 8 illustrate pelvic resultant acceleration and hood leading edge load data measured during a matched experiment (Calman 21 and 22). The resultant accelerations and hood leading edge loads are close in both magnitude and profile. These data indicate there is no significant effect in the pelvis/hood leading edge contact as a result of bumper design.

The averaged peak data from all modified and production impacts are displayed in Figure 9. This figure shows a significant decrease in knee accelerations and bumper

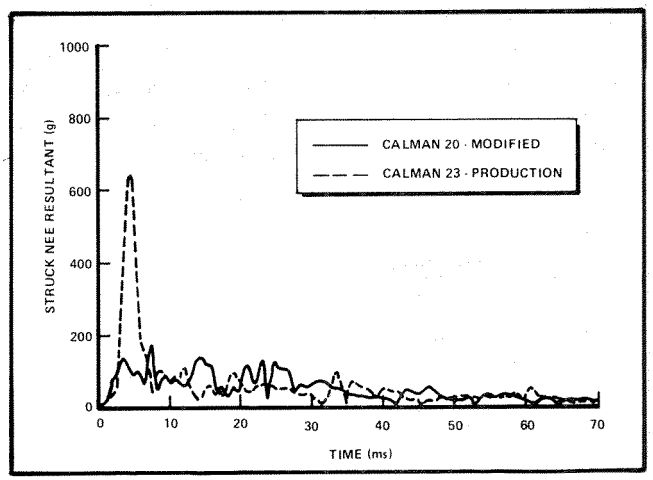

Figure 5. Knee acceleration time versus time—modified and production bumper comparison

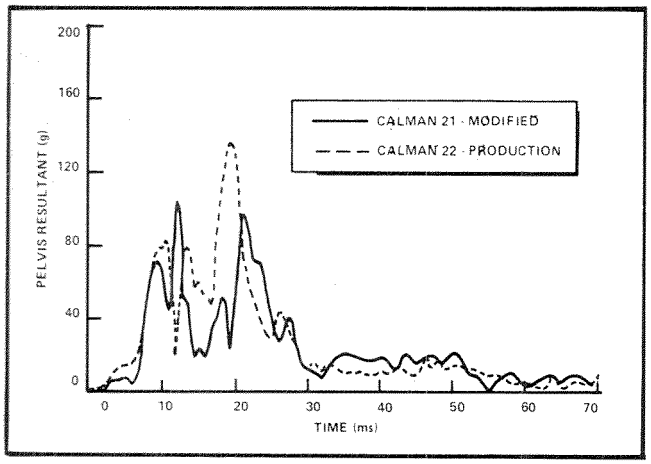

Figure 7. Pelvis acceleration versus time—modified and production bumper comparison

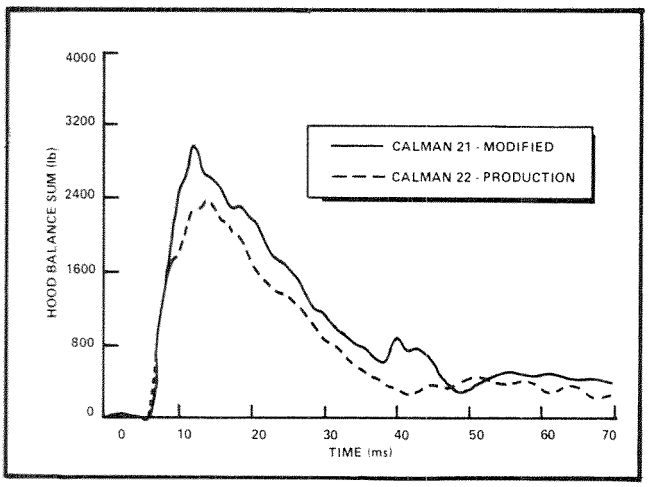

Figure 8. Hood leading edge load versus time—modified and production bumper comparison

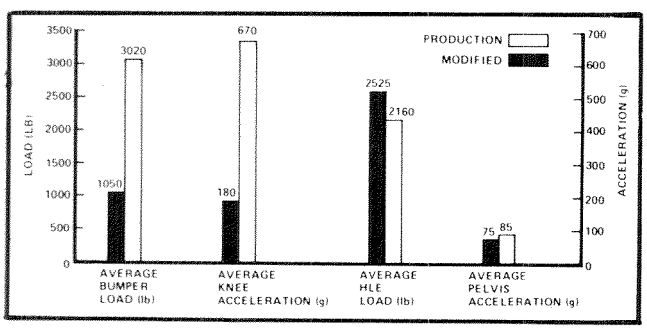

Figure 9. Average load acceleration data

loads as a result of bumper modification. Pelvis resultant accelerations and hood leading edge loads are close in magnitude; however, the average of the modified bumper hood leading edge loads is slightly higher (approximately 15 percent). This may be due to the different kinematic responses of the cadavers to impact using the modified and production bumpers. The modified bumper crushes over a 15 to 20ms timespan from time of contact with the pedestrian knee. The pedestrian is still in a standing position when his pelvic area is struck by the hood leading edge (about 10ms after knee contact). Impact with the rigid production bumper forces the pedestrian's lower extremities upward on contact, and the pelvic area contacts the hood leading edge when the subject's feet are lifted off the ground, thus causing a possible difference in the contact velocity and/or the effective mass of the hip at the time of impact with the hood leading edge.

The test that was performed using Calman 26 requires some discussion, due to two apparent data anomalies. The first is the resultant acceleration of the struck knee at approximately 22ms. During this experiment, the right knee (shielded) was contacted by the left knee (struck), thereby subjecting the left knee to increased loading as compared to the other subjects impacted by the modified bumper. This additional contact can be seen in the acceleration versus time history presented in Figure 10.

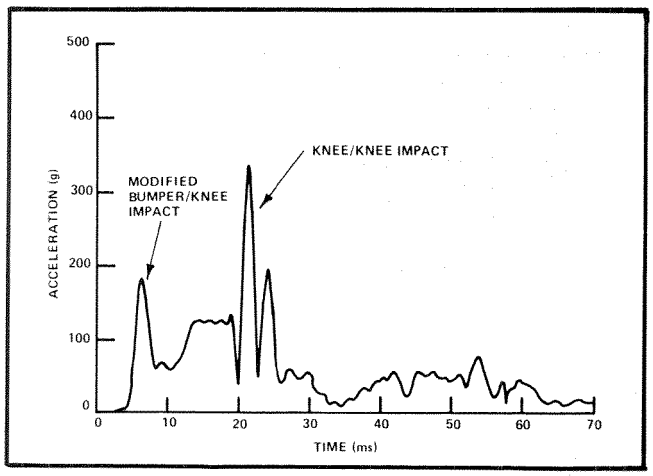

Figure 10. Calman 26 struck knee acceleration

The initial acceleration of approximately 175g at 6 to 7ms is typical of accelerations and times of the other modified bumper-struck knees. However, the second (and larger—335g) peak acceleration at approximately 22ms is not typical. Furthermore, the major contribution to the resultant acceleration value was from the X (A-P) direction, indicating that the struck knee had been turned somewhat prior to contacting the right knee. Second, the original hood leading edge load that was reported was 4,774 lb. This value is considerably higher than the other loads reported both for modified and production bumper combinations. Upon reevaluation of the load cell balance data, it was noted the inboard load cell (toward the center of the vehicle) was recording a load that was essentially a factor of two higher than the seven other inboard load cell recordings from all other impact tests, while the outboard load cell output was consistent with the other seven tests. It is believed that a shunt calibration resistor

of one-half the correct value was inadvertently installed in the load cell circuit for this test and that the sum of the hood leading edge load cells should be 2,998 as shown in Table 4.

Clinical Results

As stated earlier, an attempt was made to match, as closely as possible, the subjects used in the modified and production bumper tests. This effort was undertaken to assure that, within a reasonable range of age, stature, and weight, the outcome of the experiments would not be biased toward one or the other of the systems. Therefore, based on the criteria of Table 2 and holding the sex of the subjects as a match, comparisons of the clinical results are presented below. Tables 5 and 6 present a description of the injuries to the struck knees, as determined by a complete dissection, for the modified and production bumper impacts, respectively. The injuries to the struck knee of Calman 26, as noted in Table 5, are more severe than the injuries sustained by any of the other cadavers struck by the modified bumper. It is believed these injuries were due to contact between the right (shielded) knee and the left (struck) knee as previously described in Experimental Results. Table 7 displays comparisons of the knee injuries for modified and production bumper impacts in the format of the test matrix of the matched Calman experiments presented in Table 3. Note that comparison numbers 1 through 4 are the highest level matches that could be obtained for the maximum number of parameters. Comparison numbers 5 through 8 are presented for completeness even though the degree of parameter match is less than in comparison numbers 1 through 4.

The clinical results for injuries to the hip and thigh for both the hood leading edge/modified bumper and the hood leading edge/production bumper impacts are presented in Table 8.

Table 5. Injuries to struck knee—modified bumper impacts

Table 6. Injuries to the struck knee—production bumper impacts

Calman	Knee Injuries
22	Anterior cruciate ligament avulsed; posterior cruciate ligament partially avulsed; medial collateral ligament avulsed; popliteal vein ruptured
23	Anterior and posterior cruciate ligaments avulsed; superficial and deep fibers of medial collateral ligament avulsed; rupture of medial portion of knee capsule, deep fascia of knee joint and semimembranosus muscle
27	Posterior cruciate ligament avulsed from femur; posteromedial side of joint capsule ruptured; medial collateral ligament avulsed from femur
28	Tibia fractured in 2 places; complete fracture of fibula; medial collateral ligament laceration; cartilage and bone fracture of medial condyle

Clinical Evaluation

A clinical evaluation was performed(10) for each test based on the results obtained from the post-test x-rays and the complete knee and hip dissections as noted in the previous section, Clinical Results. For purposes of continuity (from previous work) and consistency (minimization of cadaver variability), the clinical results were treated as though the trauma reported had been determined on a 50-year-old person of the same sex as that of the subject cadaver. In the sections on Experimental Results and Clinical Results, information was presented only with regard to the struck leg (only the struck leg was instrumented) and hips. Both legs and hips were dissected. The clinical evaluations presented in this section include both knees as well as both hips.

Temporary impairment was defined as impairment lasting up to 365 days. The clinical evaluations of temporary impairment (in days) for the knees and lower extremities are presented in Table 9. This table includes an estimate of the requirement for surgery in treatment of the injury in the last column. It should be noted the requirement for surgery includes, but is not limited to, surgical reduction of fractures, avulsions, etc.

Table 10 presents the clinical evaluation of each subject for residual (over 1 year) and long-term (over 5 years) impairment. The same body areas and categories are addressed in Table 10 as were addressed in Table 9, with the addition of a sensory category. Calman 22 suffered a lacerated common peroneal nerve in the unstruck leg. Since this was the only sensory injury observed for any of the subjects, the category was not included in Table 9. Also included in these tables are the average days at the four levels of impairment for each category, for the

modified and production bumpers, the reduction in days attributable to the bumper modification (Table 9), the average level of residual and long-term impairment for each category, for the modified and production bumpers, and the reduction attributed to the bumper modification (Table 10). The results of the clinical evaluations for the knees, as presented in Table 9, are graphically displayed in Figure 11 and that information for the lower extremities is presented in Figure 12. The reduction in the average severity level for residual and long-term knee impairment, as listed in Table 10, is displayed in Figure 13.

The two body areas reported in these tables are knees and lower extremities. The lower extremities include the hip and everything below the hip. Therefore, the temporary impairment days for the knees and lower extremities are not always the same for the level of impairment for each category, nor for the total number of days in each category. The categories used for clinical

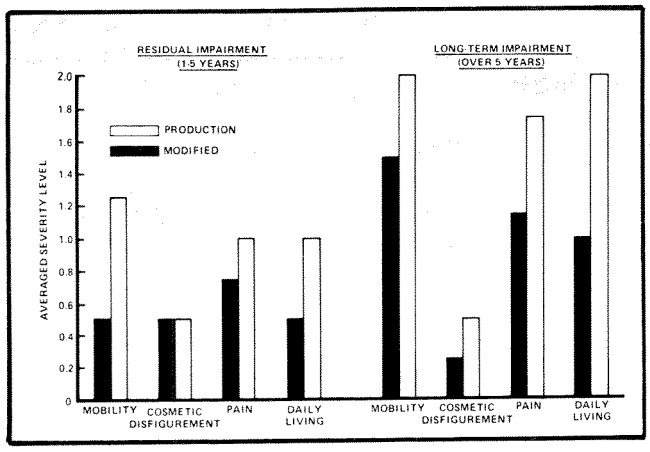

Figure 13. Reduction in average residual and long-term impairment severity levels due to bumper modification

evaluations were: Mobility, Cosmetic Disfigurement, Pain, and Daily Living. The levels (1 through 4) of each category are defined by the following guidelines:

Mobility

1. Impaired mobility with intact functional ability.
2. Impaired mobility with mildly abnormal function. Partially dependent on mechanical assistance. Unable to lift reasonable size objects. Needs crutches, walker, etc.
3. Severely impaired mobility with abnormal function. Dependent on mechanical assistance and wheelchair, occasionally needs attendant.
4. Entirely dependent on attendant or otherwise confined to bed.

Cosmetic Disfigurement

1. Mild—normally covered, amenable to cosmetic cover-up. Readily covered orthosis.
2. Moderate—can be effectively covered by cosmetics and/or forces a change in dress habits. May require orthosis but does not require prosthesis.
3. Severe—prosthesis or cover-up required.
4. Severe—readily observable, not amenable to cosmetic, prosthetic, or clothing cover-up.

Sensory

1. Slight—10 to 25 percent loss to special senses or limbs.
2. Moderate—26 to 50 percent loss to special senses or limbs.
3. Severe—greater than 50 percent loss to special senses or limbs.
4. Maximum—total loss to special senses or limbs.

Pain

1. Normal function with no or occasional nonnarcotic drugs and/or other noninvasive therapy.
2. Normal function only with the use of nonnarcotic drugs and/or other noninvasive therapy.
3. Can function normally only with narcotic drugs and/or invasive therapy.
4. Cannot function normally even with narcotic drugs and/or invasive therapy.

Daily Living

1. Inability to do some nonessential activities.
2. Inability to do most nonessential and/or some essential activities.
3. Partially dependent on assistance for essential functions.
4. Totally dependent on assistance for most activities and functions.

Concluding Remarks and Future Work

This effort has demonstrated a benefit to the struck knees of these pedestrian cadaver subjects at impact velocities of 25mph. This velocity is 5mph above the velocity specified in the NHTSA-proposed safety standard. The results of eight sled tests, four using the Pontiac LeMans production bumper and four using the bumper configuration modified to comply with the specifications of NHTSA's proposed safety standard, showed significant decreases in the days of temporary impairment of the lower extremities, particularly the knees, which can be expected from pedestrian accidents. Decreases in the severity levels of residual (1 to 5yr) and long-term (over 5yr) impairment was also demonstrated.

During this part of the program, the injuries observed in the hip and thigh areas of all subjects, regardless of the bumper design, were similar in severity level. These injuries were caused by contact with the hood leading edge of the 1978 Pontiac LeMans. NHTSA has conducted a study that indicates the frontal geometry of the Pontiac LeMans used for this program is not representative of post-1982 vehicles. Results of this study show that the location of the hood leading edge of more current vehicles is approximately 2in rearward and 4in lower than the LeMans hood leading edge.

Analytical modeling was performed that duplicated the results generated during the LeMans pedestrian impact experiments. Once the model was validated by reproducing these results, the effects of contemporary vehicle front geometry were examined. This was accomplished by maintaining the current production bumper characteristics in the model while changing the vehicle geometry to simulate a contemporary vehicle.

Results predicted that peak forces applied to the leg were identical to the baseline LeMans results, but the maximum hood leading edge forces were significantly lower. When the modified bumper characteristics were incorporated into the model with the new front end geometry, a drop in the peak bumper force and a corresponding increase in the peak hood leading edge force were noted (as was seen in the LeMans modified bumper experiments). This predicted peak hood leading

edge force, while being equal to the LeMans/production bumper hood leading edge force, was less than the force of the LeMans/modified bumper configuration. This indicates the contemporary hood design is less injurious to a pedestrian than the LeMans.

Based on the results of this study, it is planned that a sled buck will be fabricated using a representative contemporary vehicle. A similar 90g modified bumper will be developed and installed. Four cadaver impacts are planned with this modified bumper configuration. A determination will then be made, based on the level of injury associated with hood leading edge contact during these four tests, whether the remaining impacts will be performed using the contemporary front end/production bumper or (if the injury level is unacceptable) a contemporary vehicle with the modified bumper and a modified hood leading edge.

Abstract

In a previous experimental study, a comparison was made between a 1978 Pontiac LeMans car front with a standard bumper and the same front with a more compliant bumper developed by the National Highway Traffic Safety Administration (NHTSA). The tests were made with the two car front and bumper systems mounted at the normal bumper level 45cm and with a lower front configuration with the bumper level 32.5cm above the ground. The experimental biological model system developed at Chalmers University of Technology for detailed kinetic analysis of car front to leg impact sequences was used for this comparison. The tests were carried out at 30 to 32km/h impact speed. A significant difference was found only between the standard bumper in the higher position and the compliant bumper in the lower position.

A still more compliant bumper than that used in the previous test series was produced by NHTSA and tested with the front and bumper system in the normal position 45cm above the ground. Ten impacts to the biological model were made at 32km/h with loaded and unloaded specimens, and five impacts were made at 20km/h with unloaded specimens.

Damage to the knee was seen, including fractures of the knee condyles, in two tests with the loaded specimens. Knee ligament tears were observed in all the tests, indicating the importance of the inertia of the lower leg and foot when the impacts occur at knee level. The modified, more compliant bumper in this test series caused equally serious damage to the knee as did the slightly stiffer bumper in the previous series.

Introduction

In the research program for improved pedestrian safety, NHTSA has developed a compliant bumper system for pedestrian protection(1). One prototype of this bumper system was tested previously at the Department of Traffic Safety, Chalmers University of Technology(2). An experimental model system, developed for detailed kinetic analysis of car front-leg impact sequences, has been used for this purpose(3). In the first test series, 20 human leg specimens were struck with a 1978 Pontiac LeMans car front using the standard rigid and a compliant bumper system. Collisions were made with a normal front configuration with the bumper structure impacting at the 45cm level and a 12.5cm lower front configuration with these structures impacting at the 32.5cm level. The impact velocity was 30 to 32km/h. Serious leg damage was noted with both front configurations and bumper types. The compliant bumper impacting at the 32.5cm level caused less serious damage than the rigid one impacting at the 45cm level. This bumper also seemed to cause less serious damage than the more rigid one at both the 45 and 32.5cm levels, but the difference was not statistically significant.

To try to reduce the risk of injuries to the lower extremity in impacts at the 45cm level, a modified, even more compliant bumper system was developed by NHTSA and tested in the same way as in the previous study.

Scope

The purpose of this study was to investigate the protective effect of the modified, more compliant bumper system developed by NHTSA. The tests were carried out at the 45cm impact level and comparison made with the rigid bumper and the less compliant bumper investigated in the earlier test series.

Method and Material

The experimental setup and the test procedure have been described earlier(3,4,5). The simulated car front was the same as in the previous series with the rigid and the moderately compliant bumper(2) (Figures 1 and 2). In the actual series, all tests were made with the car front mounted in such a way that the middle of the bumper was at the 45cm level. This bumper level was kept during the impact, and the test cart was not braked until 120 to 140ms after impact.

The material properties of the deformable polyurethane block of the compliant bumper and the flexible plastic cover were the same in the two series.

The force-deflexion relationship of the three bumper types was measured statically by pressing a 60mm iron tube at right angles against the impact area with and without the plastic cover (Figure 3).

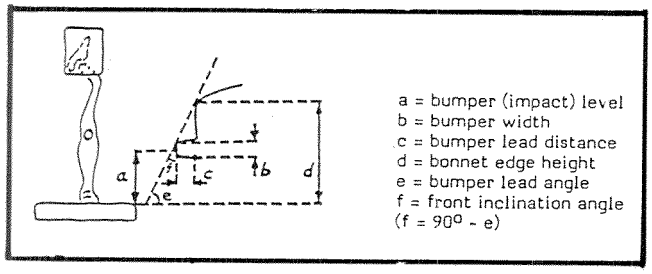

Figure 1. The experimental setup

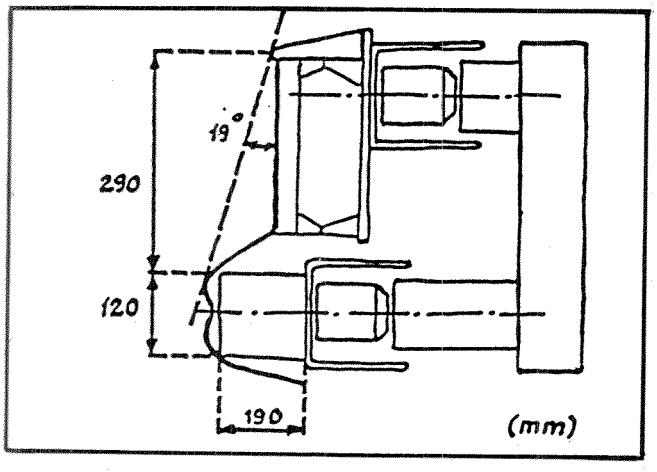

Figure 2. Section of the impact zone

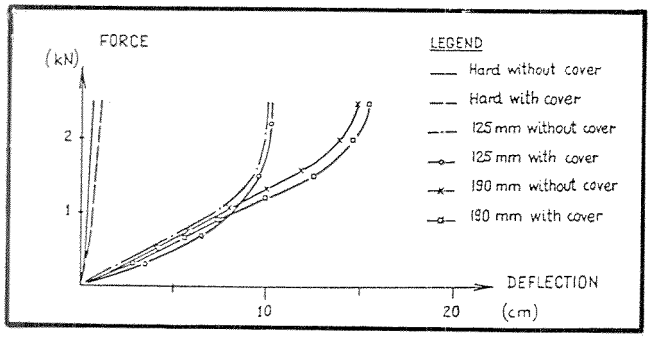

Figure 3. The force-deflexion relationship of the three bumper types with and without the plastic cover (static test)

Unembalmed human leg specimens with the hip joint included were used. These originated from individuals 63 to 87 years of age without skeletal abnormalities. Each specimen was radiographed, and the stability of the knee joint was measured before the test. The bone mineral content was not measured in this series since equipment for this was not available at the time.

The specimen was kept in a standing posture with the foot covered by a shoe on a foot plate before the impact with the toes turned 15° toward the car front from a pure lateral impact. It was balanced with the knee extended and struck on its anterolateral aspect. A simulated, 50kg body mass was connected to the iliac bone. This mass consisted of two equal metal blocks connected with steel wires and separated by plastic foam. The specimen and the body mass were supported by stabilizing cords released by the test cart just before impact.

Five tests were made at 32km/h with the full load (50kg) on the specimen. Five tests were made at the same velocity with the specimen unloaded, i.e., with the body mass supported by cords and the specimen hanging with the foot just above the foot plate. Another five tests at 20 to 21km/h impact velocity were made with the specimen unloaded in the same way.

The impact sequence was covered by high-speed cinematography. Accelerometers were strapped on the specimen opposite the impact side at the ankle, the impact level, and the knee. The impact forces were recorded from two horizontal force transducers in the bumper and two in the bonnet. All channel classes signals were stored on magnetic tape (filters used).

The specimens were radiographed after the test, and the knee stability was measured as in the previous study(2). A complete dissection was made after the test. The severity of the damage to the specimen was classified according to the ADS system, similar to the AIS system for living human bodies.

Results

Fifteen tests were made in this series. All experiments provided a complete set of data. The specimen data are shown in Table 1, the kinetic data in Table 2, and the damage in Table 3.

Damage to the Specimen

Knee damage was noted in all experiments. There was no damage in other parts of the specimens. The knee damage included fractures of the tibial condyles and stretch or rupture of the ligaments and the knee capsule. Fractures of the tibial condyle were noted in two of five experiments with loaded specimens at 32km/h. One of these was an intraarticular fracture (No. 4). There was also a complete rupture of at least one of the knee ligaments in the fractured specimens. At this velocity, the fact that the leg was loaded by a simulated body mass did not seem to influence the damage to the collateral or cruciate ligaments. Complete (ADS = 3) or almost complete (ADS = 3-) ruptures were noted in two or more of these ligaments or in the capsule in all tests with loaded specimens at 32km/h. The same type of ligament damage was noted in four of five tests with unloaded specimens at this velocity. In the fifth test, there was only a partial rupture (ADS = 2) of the medial collateral ligament. The specimen in that case was from the youngest individual (63yr) in the series. At the lower speed (20km/h), the ligament damages were complete in two and partial in three of the five tests.

* Some play was noted in the accelerometer mounting.

The medial collateral ligament was damaged in all tests. The ligament was completely ruptured in nine tests at 32km/h and in two tests at 20km/h. In nine cases, there was a complete rupture of the ligament at the femoral attachment point with a bone fragment in five and without a bone fragment in four cases. In two cases, there was a complete rupture of the superficial part of the ligament quite near the tibial attachment point. The deeper part of the ligament and the capsule were completely ruptured in one and partially ruptured in the other (No. 11) of these cases.

One or both of the cruciate ligaments were completely or almost completely ruptured in seven of ten experiments at 32km/h. Complete ruptures of the cruciate ligaments were not seen at 20km/h. However, almost complete and partial ruptures of the cruciates were noted in two experiments at this lower velocity. The cruciates were ruptured at the femural attachments in all except two cases.

[1] M = the medial collateral ligament; A = the anterior cruciate ligament; P = the posterior cruciate ligament; C = the capsule of the knee (A - behind the ADS number indicates that there was slightly less severe damage than the number itself defines).

[2] e = hyperextension increment; v = (vargus+) algus bending increment (20° flexion); r = inward + outward lower leg rotation increment (20° flexion); s = sagittal translation increment (20° flexion); KAI == e+v+r = the total Knee Angular Instability increment.

Impact Forces

The time histories of the bumper forces were similar for the loaded and unloaded specimens at 32km/h (Figures 4a, 4b, and 4c). The peak force varied between 2.5 and 3.1kN. The force pulses were somewhat broader for the unloaded specimens (Figure 4b). This probably corresponds to the somewhat higher specimen weights in these tests (Table 1). The force pulses were somewhat more extended at the lower velocity (Figure 4c), and the peak forces were about 2.0kN in these tests. The velocity (Figure 4c) and the peak forces were about 2.0kN in these tests. The bonnet edge peak forces were low (less than 3kN in all cases) and approximately the same in tests with loaded and unloaded specimens at 32km/h (Figures 5a, 5b, and 5c).

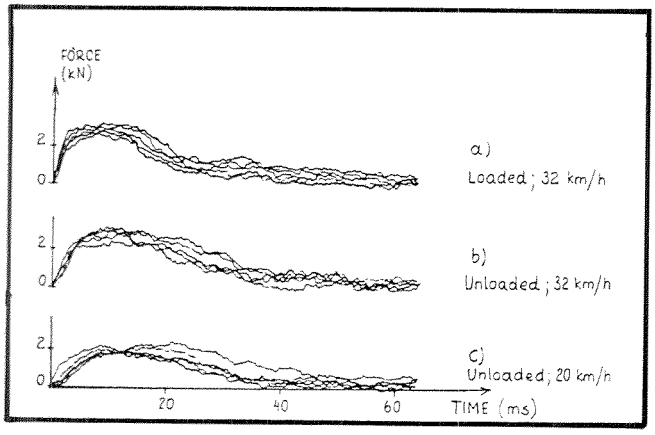

Figure 4. Time histories of bumper forces for (a) loaded and (b) unloaded specimens at 32km/h for (c) unloaded specimens at 20km/h impact velocity

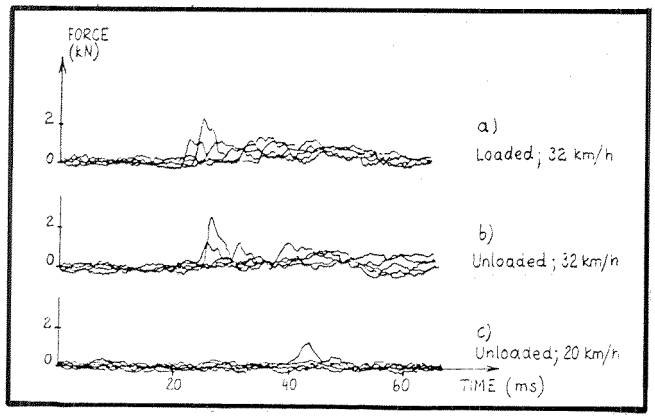

Figure 5. Time histories of bonnet edge forces for (a) loaded and (b) unloaded specimens at 32km/h and for (c) unloaded specimens at 20km/h impact velocity

Accelerations

The magnitude of the accelerations of the leg specimens with loaded and unloaded specimens was the same (Table 2). At 32km/h, the accelerations at the knee level and at the impact level varied between 50 and 100g in both test configurations. The accelerations at the ankle joint varied between 20 and 50g. The accelerations of the leg specimens in impact test with the less compliant bumper at the 45cm level in the previous series(2) were almost the same as in this series.

Discussion

According to the results of this and the previous studies(2,3,4,5), the risk of injuries to the ankle joint, the lower leg, the femur, and the hip joint seems to be low at or below 32km/h if the bumper strikes 45cm above the ground level. No damage was noted in these parts of the specimens in this series, and isolated damage was noted in only a few cases the previous series with the rigid and the less compliant bumper at the 45cm level(2). There may be a higher risk of moderate (ADS = 2) damage to the ankle joint with the rigid bumper at the 45cm impact level due to the somewhat greater accelerations in these cases. Two such damages were noted in five tests in the previous series with that bumper(2). No damage has been noted in the ankle joints in 15 tests with the two compliant bumpers. The bumper type does not seem to influence the risk of damage to the other parts of the specimens except for the knee if the bumper strikes at the 45cm level.

On the other hand, there is a high risk of injury to the knee joint if the bumper strikes at this level. There was a high incidence of serious (ADS = 3) knee damage in this test series as in the previous one with the two bumper types at the 45cm level(2). In this series with the modified, more compliant bumper, serious (ADS = 3) knee damage was noted in all tests with loaded specimens and in four of five tests with unloaded specimens at 32km/h. The type of damage and the ADS damage severity was the same as in the previous series with the less compliant bumper at the 45cm level.

The vertical load on the specimen does not seem to influence the ADS damage severity significantly. However, the load may influence the type of damage. Fractures of the tibial condyle were noted only if the specimens were loaded with the body weight. This type of damage was also noted in the previous series with loaded specimens(2). There is quite a high risk of such a "bumper fracture" if the pedestrian is struck when walking because the vertical load on the knee exceeds the static body weight during approximately 50 percent of the walking cycle(6,7).

The inertia of the lower leg and foot is probably the most important injury-causing factor if the bumper strikes at the 45cm level at 32km/h. This injury mechanism explains the high incidence of ligament damage in this and the previous series for 45cm bumper level. The injury-producing effect of the inertia exists even at 20km/h. Serious ligament damage (ADS = 3) was noted in two collisions at this lower velocity. The damage was moderate (ADS = 2) in the other three tests.

The knee ligaments are very vulnerable to impact forces near the knee if the leg is struck on its fronto-lateral aspect 10 to 20° from a pure lateral impact.

The degree of damage to the knee joint was estimated by the Knee Angular Instability Increment (KAI) and the sagittal translation increment (s) (Table 3). There seems to be a limit between isolated serious (ADS = 3) and combined serious damage to the cruciate and collateral ligaments for a KAI-value approximately equal to 40°. A complete rupture of the medial collateral ligament corresponds to a valgus instability increment exceeding 10°. A sagittal translation increment exceeding 0.3cm seems to be associated with a rupture of the anterior cruciate ligament. In test number 15, the two cruciates were ruptured macroscopically in 70 percent of the cross-section area. However, the instability parameters indicate a considerable elongation of the rest of the ligament tissue corresponding to serious knee ligament damage in that case.

The risk of knee ligament damage appears to be the same for the two compliant bumpers for a 45cm impact level. This might be explained by the force-deflexion relationship of the two bumpers(Figure 3). This relationship does not differ significantly below 70mm compression. The 70mm compression corresponds to a bumper force equal to 1kN in a static test. This is approximately the ultimate tensile strength of the medial collateral ligament(8,9). Thus, theoretically the more compliant bumper will cause a ligament injury of the knee as easily as the less compliant one. There might even be a higher risk of knee ligament injuries with the 19cm more compliant bumper as the front inclination is less steep in this case and might give less support against the femur and thus less protection against knee bending during the impact compared to the 12cm less compliant bumper (Figure 2). On the other hand, there might be less risk for injuries due to direct impact forces with the modified, more compliant bumper according to these deformation characteristics. However, dynamic deformation tests should be made to clarify this.

In all tests with this biomechanical leg impact model, the test cart was accelerated to reach a constant speed before the collision and did not brake during impact. Furthermore, the bumper impact level was equal to the static bumper level. In some real accidents, the car front may pitch down due to braking before the impact. The less compliant bumper tested in the previous series(2) was investigated at the 45cm impact level as well as the 32.5cm level. The risk of serious (ADS = 3) damage seemed to be

lower with the compliant bumper at the 32.5cm level compared with the ordinary rigid one. However, the number of tests was small, and the difference was not statistically significant. According to the results of our earlier test series(3,4,5), the risk of serious lower leg and knee injuries is reduced significantly if the bumper impacts at the mid-tibia level. The risk of lower leg fractures is further reduced with a compliant bumper impacting at the mid-tibia level. However, there may be a risk of such fractures even if the impact force is low if the leg is loaded with the body weight during impact(4).

Conclusion

If the injury mechanisms and tolerance levels can be assumed to be the same for living people as for the specimens, the following conclusions can be drawn from these experiments:

- The risk of serious (AIS = 3) knee ligament injuries is at its maximum for a bumper impact at the knee level.
- At 32km/h, serious (AIS = 3) knee ligament injuries will be caused practically always if the leg is struck at the knee level on its anterolateral side with an extended knee.
- For a bumper impact at the knee level at 20km/h, the risk of serious (AIS = 3) knee ligament injuries is reduced but it cannot be neglected.
- The inertia of the lower leg and foot is the most important injury-producing factor for a bumper impact at the knee level.
- Compared to the rigid bumper, the less compliant and the modified, more compliant bumpers tested in these series do not reduce the risk of serious (AIS = 3) knee ligament injuries if the bumper strikes at the 45cm level.
- The primary, less compliant bumper and the modified, more compliant bumper will cause injuries of equal severity if the bumpers strike at the 45cm level.
- The less compliant and the modified, more compliant bumper will both probably reduce the risk of serious injuries to the lower leg and ankle joint compared to the rigid bumper.

Simplified Test Recommendations for Pedestrian Protection

J. Harris
Transport and Road Research Laboratory, Department of Transport, Crowthorne, United Kingdom

Abstract

Pedestrian accidents are a serious problem in many countries, and some form of vehicle design recommendations to improve pedestrian protection are urgently required.

Research has shown that in an accident the severity of injury is influenced mainly by impact speed, shape of the car, stiffness of the car components struck by the pedestrian, and the stature and strength of the pedestrian (young or old, frail or strong). A measure of the importance of these variables has now been demonstrated, but limitations, in the performance of dummies and gaps in existing knowledge, particularly a human tolerance, have also been identified. These limitations reduce the precision with which car design requirements for pedestrian safety may be specified. Obtaining further information and proving a test dummy to overcome these limitations may be a lengthy process.

Sufficient information is available to allow generalised recommendations to be compiled that could be used as guidelines until more precise requirements may be determined.

This paper proposes a set of simple guidelines for the depth and stiffness of protection to be built into the various components of the car front, which are determined by the shape chosen for the front profile. Meeting these guidelines should insure a good level of protection but, although necessary, they may not be entirely sufficient, and further experience may eventually suggest some fine tuning of the proposals.

This paper shows that for the areas of a car that are important for pedestrian safety (bumper, bonnet leading edge, and bonnet top), the protection requirements may vary considerably according to the overall shape of the front of the car.

It can be shown that the major safe characteristics of these areas may be isolated and examined (with due regard to the overall shape of the car) to assess their potential for causing injury.

Methods of testing each of these areas are being proposed and performance criteria are suggested, which are based on a maximum safe impact speed of 40km/h and an acceptable injury level of severity of AIS 2.

These test criteria are—

- Bumper—Assessed by impact test using a 10kg legform. The maximum recommended impact force is adjusted with respect to the height aboveground and the vertical depth of the bumper.
- Bonnet Leading Edge—Assessed by an impact test using a 16kg hipform. The impact velocity is adjusted with respect to the height of the bonnet edge and the bumper-to-bonnet lead. The recommended maximum impact force is 5kN.
- Bonnet Top—Assessed by a conventional headform impact test using adult and child headforms. The impact velocity is adjusted with respect to the height of the bonnet edge, the bumper-to-bonnet lead, and also the location of the impact point.

It is suggested that these performance criteria may be used as the basis of recommendations for the pedestrian safety performance of cars and used as preliminary guidelines before final recommendations are made for regulatory tests.

These proposals formed the basis of the U.K. contribution to the EEVC ad hoc group on pedestrian protection.

Basis of Recommendations

Accident investigations and tests simulating accidents(1) have shown the regions of a car that most frequently cause injury are the bumper, the leading edge of the bonnet and wing, and the top of the bonnet, wing, and windscreen frame. Some measure of protection may be built into each of these areas, but the appropriate stiffness characteristic will depend on the overall shape of the front of the vehicle, the designed maximum safe impact speed, and the severity of injury considered to be acceptable.

In these proposals, the aim is to give a high probability that the severity of injuries from contacting these areas of a car will be limited to AIS 2 or less, for accidents at speeds up to 40km/h.

These levels have been chosen to reduce the risk of permanent disability, particularly to the legs, and because at least 30 percent of fatalities are reported to occur from accidents at speeds of 40km/h or less(1).

The stiffness recommendations and design performances are derived from the results of a series of computer simulations(2) studying the influence of vehicle shape and stiffness on the severity of an impact to a pedestrian.

These investigations showed clearly that in an accident all features of the shape of the front part of a car interact to influence the severity of an impact, but the following broad trends could be clearly identified for the bumper and bonnet leading edge and also for head impact to the bonnet top and surrounding structures.

Bumper and Spoiler

Current bumpers mounted at approximately 450mm above the ground can cause severe loading to the knee and lower leg of an adult and to the pelvis and upper leg of a child, with knee injury possibly the most likely to cause permanent disability. These injuries result from bending moments and shear forces required to accelerate the lower leg and also from crush forces at the point of impact.

Lowering the bumper gives an improvement for the adult, moving the impact away from the knee to the less vulnerable lower leg. For the child, the impact moves away from the pelvis and closer to the knee. Although serious knee injury to the child has not been a feature of accidents in the past, a change of this nature may put knees slightly more at risk for some age groups.

The introduction of a spoiler (air dam) mounted less than 50mm behind a 450mm bumper (in effect, a deep bumper) reduces knee bending moments and shear forces, and, if the upper part of the bumper is compliant, this then gives improvements similar to those obtained with a low bumper.

This suggests that the injury potential of a bumper or bumper/spoiler combination is influenced by its height above the ground and its effective vertical depth.

Typical simulation results are shown in Table 1.

The 40km/h simulations also show that the total energy absorbed by the bumper and spoiler is 1,000 to 1,200J (approximately 600J per leg) for all car shapes except those with zero bumper lead, and the effective mass of the adult leg striking the bumper ranges from 8 to 10kg.

If the onset of serious knee injury is set at 6° angular rotation of the knee joint(3), then serious injury from bumper contact would probably be avoided by bumpers meeting the following recommendations.

Bumper Recommendations

It is recommended that the appropriate impact force shown in Table 2 is not exceeded when a bumper is struck at any point at a velocity of 40km/h (11m/s) by a leg impactor of 10kg mass that spans the total effective depth of the bumper. In Table 2, the recommended force varies with respect to the height of the centre of the bumper above the ground and the effective vertical depth of the bumper.

A spoiler will only effectively help to reduce knee injury if it is mounted less than 50mm behind the bumper.

Typical safety bumpers (spoilers) absorb approximately 500 to 600J of energy from each adult leg in a 40km/h impact.

Leading Edge of Bonnet and Wing

The bonnet leading edge is the single most important area controlling the characteristics of an impact to a pedestrian.

Table 1. Results of child and adult leg impact simulations for different bumper arrangements

Bumper Plus Spoiler			Adult		Child	
Height of Centre Above Ground (mm)	Total Vertical Depth (mm)	Total Stiffness (kN)	Lateral Angular Rotation of Knee Joint (degrees)	Knee Shear Force (kN)	Knee Bending Moment (Nm)	Pelvic Acceleration (g)
350	100	4	0.3	1.4	239	65
450	100	4	6.1	3.4	189	98
450	30	4	11.7	3.0	—	—
350	280	6.5	3.7	2.2	250	75

Table 2. Recommended leg impactor to bumper loads for different bumper arrangements

Height of Centre of Bumper (and Spoiler) above ground (mm)	Recommended Safe Loads (kN) For Vertical Depths of Bumper (and Spoiler) of	
	100mm	300m
350	5	7
450	3	—

Increasing the bonnet height and reducing the bumper-to-bonnet-edge lead causes a progressive increase in the energy of the bonnet edge contact and a consequent reduction in head impact velocity.

In the simulations, the energy absorbed by the bonnet leading edge in a 40km/h impact with an adult ranges from 64 to 1,025J as shown in Table 3.

Table 3. Energy absorbed by the bonnet leading edge with respect to bonnet height and bumper lead in simulations of a 40km/h impact with an adult

Bumper to Bonnet Lead (mm)	Energy Absorbed by Bonnet Edge (J) for Bonnet Height of		
	600mm	720mm	850mm
0	312	700	1025
150	64	341	564
250	—	134	425
350	—	115	269

The effective mass striking the bonnet edge ranges from 5kg for a 600mm-high bonnet to 16kg for one 850mm high.

Adult and child tolerance levels are generally not exceeded if the leading edge stiffness does not exceed 5kN.

Serious injury from contact with the bonnet leading edge would probably be avoided if the following recommendations are satisfied.

Bonnet and Wing Leading Edge Recommendations

It is recommended that the impact force not exceed 5kN when a 16kg hip impactor strikes the leading edge of a bonnet, wing, or head lamp surround in a fore and aft direction at the velocities shown in Table 4. These velocities are appropriate for the bonnet edge arrangements shown with respect to a vehicle impact of 40km/h (11m/s).

Table 4. Hip impactor velocity m/s with respect to position of bonnet leading edge

Bumper to Bonnet Lead (mm)	Hip Impactor Velocity m/s for Bonnet Heights of		
	600mm	720mm	850mm
0	6	9	11
150	3	7	8
250	—	4	7
350	—	4	6

The effective vertical depth of the leading edge is important. Essentially the deeper it is, the safer it is.

Although it may be possible to design a nearly vertical high car front with an acceptable stiffness characteristic, this shape is inherently dangerous because it is likely to knock a small child forward to the ground. This increases the risk of being run over.

Bonnet Top

This section considers head impact with the top of the bonnet or wings, the scuttle, and windscreen lower edge.

In the simulations, child head impact is confined to the forward region of the bonnet up to 800mm behind the bumper. Impact velocities are about 10m/s for all but the 850mm-high bonnets, which are generally closer to 7m/s.

Adult head impact is, with one exception, more than 1,000mm behind the bumper with impact velocities, at right angles to the bonnet, ranging from 8 to 14m/s.

From the simulations, typical adult head impact velocities normal to the bonnet are shown in Table 5.

Table 5. Simulation results showing impact velocity of adult head normal to bonnet top, in relation to bonnet height and bumper lead

Bumper to Bonnet Lead (mm)	Head Impact Velocity (m/s) for Bonnet Heights of		
	600mm	720mm	850mm
0	12	9	8
150	13	11	8
250		13	8
350		14	9

On the basis of these simulation results, current head protection standards would be met if the structures under consideration satisfy headform impact at the velocities specified in the following section.

The simulation results are based on the performance of a dummy that, although improved at the knee and hip joint, still has a torso that is too stiff. The headform impact velocities would, therefore, be more representative if they were based on the results of a large number of cadaver tests.

Bonnet Top Recommendations

The top of the bonnet and wings, scuttle, and windscreen lower edge would meet current safety standards for the head if existing HIC or acceleration acceptance levels are not exceeded when struck by headform impactors at velocities in accordance with those recommended in Table 6. These impact velocities, at right angles to the

Table 6. Recommended headform impact velocity with respect to car shape and position of impact point

Distance of Test Point Behind Bumper (mm)	Bumper to Bonnet Lead (mm)	Recommended Head Impact Velocity (m/s) for Bonnet Heights of 600mm	720mm	850mm
Under 800	All	10	10	7
Over 800	0	12	9	8
	150	13	11	8
	250	—	13	8
	350	—	14	9

surface of the bonnet and wings, are appropriate for the bonnet edge arrangements shown with respect to a vehicle impact of 40km/h (11m/s).

Two sizes of impactor are proposed, one representing a child headform for tests on the forward section of bonnet within 800mm of the bumper and an adult headform for the rear section more than 800mm behind the bumper.

Conclusion

It has been shown in various simulations and tests that, for the areas of a car important for pedestrian safety (the bumper, bonnet leading edge, and bonnet top), the protection requirements may vary considerably according to the overall shape of the front of the car.

It can be shown the major safety characteristics of these areas may be isolated and examined (with due regard to the overall shape of the car) to assess their potential for causing injury. Methods of testing each of these areas are proposed, and performance criteria are suggested based on a maximum safe impact speed of 40km/h and an acceptable injury level of severity AIS 2.

These test criteria are—

- Bumper—Assessed by impact test using a 10kg legform. The maximum recommended impact force is adjusted with respect to the height aboveground and the vertical depth of the bumper.
- Bonnet Leading Edge—Assessed by an impact test using a 16kg hipform. The impact velocity is adjusted with respect to the height of the bonnet edge and the bumper-to-bonnet lead. The recommended maximum impact force is 5kN.
- Bonnet Top—Assessed by a conventional headform impact test using adult and child headforms. The impact velocity is adjusted with respect to the height of the bonnet edge, the bumper-to-bonnet lead, and also the location of the impact point.

It is suggested these performance criteria may be used as the basis of recommendations for the pedestrian safety performance of cars and used as preliminary guidelines before final recommendations are made for regulatory tests. These proposals formed the basis of the U.K. contribution to the EEVC ad hoc group on pedestrian protection.

Experimental Simulation of the Pedestrian Impact

G. Stürtz
Daimler-Benz AG, Sindelfingen, Federal Republic of Germany

Abstract

Higher complexity of accident events makes it more difficult to analyze the efficiency of protection measures for pedestrians than for vehicle occupants. Considering the quality of transformation of the results found (dummy quality) as well as their statistical reliability (reproducibility), it is necessary to find a methodically clear solution.

The special problem of pedestrian accident simulation will be explained by examples showing the complexity of accident events, by valuation of protection measures, and by the reproducibility and transmissibility of results.

Advantages and disadvantages of experimental methods (integrated or component tests) to valuate the vehicle exterior will be shown, using our own test results, as well as results taken from literature. Following this, a procedure is derived.

Finally, car design characteristics are described that improve the protection of exterior road users.

Introduction

In the Federal Republic of Germany in 1983, 70 percent of the pedestrians and two-wheel riders—exterior road users—were impacted by a passenger car. Exterior road users have a rate of 46 percent among fatally injured traffic participants(1).

Among exterior road users, the protection of pedestrians has priority since they show a higher rate and absolute term of fatalities. Contrary to passenger car occupants, the distance of deformation for impact pulses is considerably shortened and the ratio of mass differs extremely. Vehicle impact as the main cause of trauma is overlapped by an additional trauma caused by the road surface.

Mitigation of accident trauma can be achieved by measures concerning hardness and plasticity of the impact, as well as accident kinematics. These are in conflict with other design characteristics.

Valuation of protection measures is more difficult for vehicle exterior safety than for passenger occupant safety. This is caused by the higher complexity of accident events. Considering the quality of transformation of the results found, as well as their statistical reliability, it is necessary to find a solution to the problem, at least for qualitative statements.

Problem of Accident Simulation

The main problem of pedestrian accident simulation will be explained by statements regarding the complexity of accident events, the efficiency of protection measures, and the reproducibility and transmissibility of results.

Simulation of Accidents With Occupants and Pedestrians

Principal differences exist between the simulation of accidents with passenger car occupants and pedestrians with regard to accident and traffic participant parameters (Figure 1).

		Occupants	Pedestrians
Accident Frequency (p.c.)		60[1]	77[2,3]
Braking of Vehicle		Yes	Yes[4]
Velocity of Traffic Participant Perpendicular to Impact Direction		No	Yes
Impact Direction of the Traffic Participant		Frontal	Divers
Physiological Data			
• stature[3,5]	$\bar{x}$ (cm)	173	160
	R: 5 - 95% (cm)	157-179	101-176
• age[3,5]	$\bar{x}$ (years)	24	31
	R: 5 - 95% (years)	15-64	3-80
• male sex (p.c.)			

1 Daimler-Benz accident data
2 60 percent for the six most frequent types of collision
3 Diversion by literature (1,2,3)
4 Lowering of contact zones
5 Severe or lethal injured traffic participants(1)

Figure 1. Selected parameters of accidents with traffic participant in the case of passenger car frontal impacts

In accidents involving pedestrians, the individual types of collision represent smaller percentages of the accident events than in accidents involving passenger car occupants (a maximum of 20 percent).

In contrast to occupant accidents, the motion sequence in pedestrian accidents is mostly three-dimensional, and the head impact of adults occurs later.

The simulation of pedestrian speed at impact $v_{ç}$ = 9km/h(2) and the resulting favorable increase of the contact zone has to be omitted, otherwise reproducibility would be drastically reduced.

In case of pedestrians, a higher range of stature and age of traffic participants has to be considered. This means also a greater range of different biomechanical load capacities, and it requires a stronger differentiation in the

anthropometry and characteristics of the dummies. Sex-specific signs have to be considered more intensely.

The selected parameters show a higher complexity of the pedestrian accident and of its simulation.

Valuation of Protection Measures

The behavior of a dummy is different from that of a living human being. This results in different kinematics, position of contact zones, and accident loads. Protection measures, therefore, can only be valuated qualitatively (with reference to the type of dummy). Efficient points of application for protection measures can be found by correlation of trauma and cause of injury (accident research)(2,4).

Transmissibility of Results

Dummies are at present insufficient substitutes for living human beings. Only in individual cases(2) can results of simulation be transferred to real cases by derived correlation. The low simulation quality of dummies is contradictory to the required highly sophisticated accident simulation.

For analyses of exterior passive safety of passenger cars, dummies require an extensive revision. For instance, the adult pedestrian dummy (Hybrid II P ≙ 95 percent pedestrian) developed for occupant safety analyses in frontal impacts was only modified by replacing the pelvis/thigh region. At present, there exists no typical adult dummy. Regarding the different body regions, the situation is as follows(5,6):

neck-/lumbar vertebra	too stiff; differences between ante-, retro- and lateral flexion are not considered
thorax/shoulders	too stiff
pelvis	geometrically incomplete (child)
thighs/shanks	not fracturable
knees	no lateral flexion possible

Figure 2. Restrictions of the simulation quality of dummies in the case of pedestrian accident loads

It is especially unfavorable that for some significant traumatized body regions—spine and lower extremities—no relevant mechanical loads are measured. On the other hand, some mechanical loads—thorax acceleration—have no biomechanical correlation.

Injury criteria that are found by biomechanical research and transferred as protection criteria to dummies are mostly known for sagittal load directions. For lateral loads, which are typical for pedestrians, they cannot be transferred. The little knowledge in the field of the biomechanical load capacity of children involves basic problems for the main group of pedestrians.

Reproducibility of Results

Reproducibility of accident loads in the case of pedestrians colliding with passenger cars—especially with adults—is not insured. This applies to a lesser degree to vehicle contact zones and to a greater degree to contact regions on the body as well as to accident loads. The main reasons for this are that accident kinematics are mostly three-dimensional; there is a high lag in time between the first contact and head impact, and there is a scatter of measured dummy values within the limits specified for dummy element tests (Part 572, *Federal Register* NHTSA).

Integrated and Component Tests

To find a starting point for the determination of the traumatic effect of vehicle elements and also as a basis for accident simulation, data of "in depth, at scene" individual case analyses of traffic accidents should be used (Federal Highway Research Institute, BASt/Daimler-Benz AG).

The correlation of injuries and their causes, using specific accident data of vehicle manufacturers, results in efficient points of application(7).

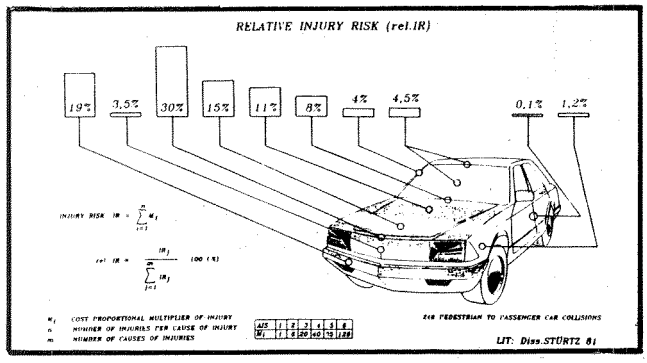

Figure 3. Points of application for pedestrian protection measures

In addition to the fundamental problems of accident simulation, the advantages and disadvantages of different present-day experimental methods are shown in detail. They are used to valuate the vehicle exterior. This aims at the definition of a procedure to reach maximim efficiency of protection measures.

Integrated Tests

An integrated test or full-scale test means a complete simulation of vehicle/pedestrian collisions, considering relevant accident parameters.

Analyzed in the following are the influence of the type of vehicle, the stature of the pedestrian, and the vehicle impact speed on the reproducibility of vehicle impact points, kinematic values, and accident loads. For this, the CCMC/AHP-type of collision is used.

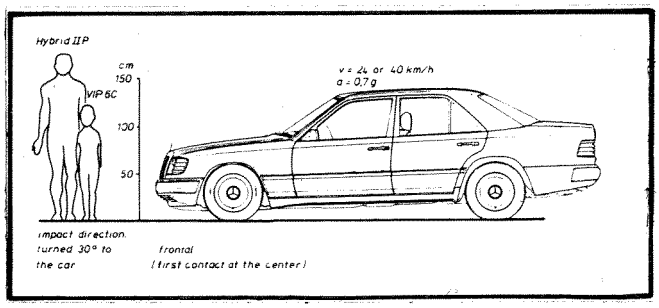

Figure 4. Full-scale simulation of vehicle/pedestrian collision

When using the coefficient of variation (V) as a measure of reproducibility, the following findings can be derived from Figures 5 and 6:

- In the case of accident load, V depends on the type of pedestrian, type of vehicle, and sometimes on the vehicle impact speed.
- For velocity and direction of head impact, as well as for the wrap around distance, V has low values.

The reproducibility of accident loads for collisions between passenger cars and pedestrians is not sufficient for kinematic values; on the other hand, it is.

Component Tests

A component test or subsystem test means an impactor/vehicle collision where the impactor with different quality simulates body regions. The test concerns kinematic accident parameters.

The following examples are shown for the three vehicle areas causing the highest trauma. The endangered body regions of adult pedestrians are simulated by the impactor.

Front Bumper

Tests with translatoric horizontally guided impactor: The latter is of wood and has a semicylindrical shape. Defined are impactor mass, impact and rebound speed, protection criteria, and test zone.

Unrealistic is the lack of simulated soft tissue and the high radius of curvature of the contact zone. The latter will reduce the normal depth of deformation. The adaption of the adult pedestrian is traumatically significant and, in principle, also possible for children. The advantage of a low, induced impact force and, therefore, also a low contact mass cannot be measured, but simulated by mass correction. The reproducibility is classified as good.

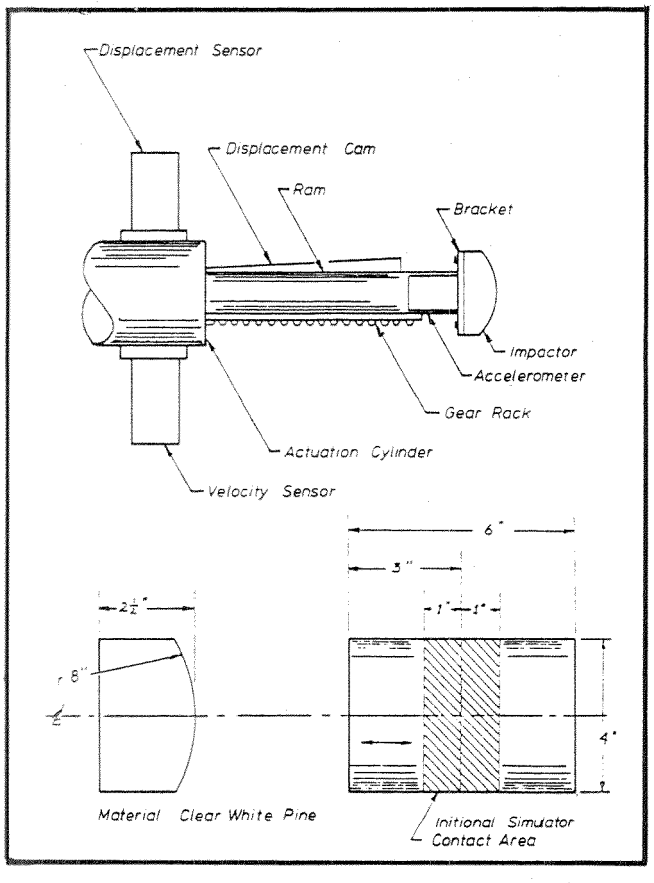

Figure 7. Simulator for shank impact(8)

Upper Front End

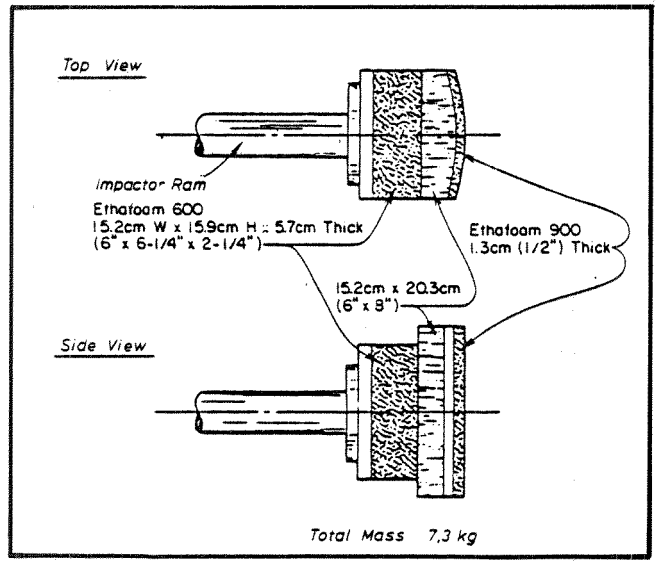

Figure 8. Simulator for hip/thigh impact(9)

Tests with translatoric horizontally guided impactor: The latter has a semicylindrical shape. The material is wood, in the contact zone, covered with foam. Defined is the impactor mass. The impact velocity has to be varied depending on the bumper position.

The adaption to the hip/thigh impact of adult pedestrians is traumatically significant but not described for the child's thorax and head impact. The reproducibility is declared as good.

Bonnet and Fenders

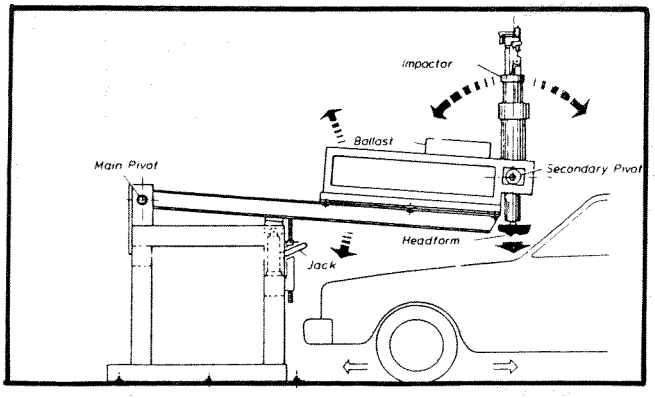

Figure 9. Simulator for head impact(10)

Tests with translatoric vertically guided impactor: The latter is a modified Part 572 dummy head with frontal orientation. Defined are impactor mass, impact speed, protection criteria, and test zone.

The adaption to the adult pedestrian is traumatically significant and, in principle, also possible for children. The reproducibility is declared for the HIC with a variation smaller than 25 percent and is very good in general.

In General

Component tests can basically be classified as simple and having a good reproducibility, also of accident loads. They allow large-area qualitative valuation of vehicle areas. To reach a higher level of simulation quality, the impactors have to be developed more realistically. The kinematic input values should be derived by mathematical or experimental simulations of the vehicle/pedestrian collision. Existing test devices—head impact pendulum-have to be considered.

Consequences

Integrated tests should be used only to find contact zones on the vehicle, as well as kinematic values of the loaded body region, because of the poor reproducibility of accident loads. They are also suitable to adjust mathematical models.

Contact zones are specific to each vehicle. Therefore, they can best be determined by the car manufacturer. Valuation of contact zones should be carried out at present and in the near future by component tests only. The latter, however, have to be better adjusted to the living human being.

Measures to protect pedestrians are in conflict with other design characteristics. Diversity and range of influencing factors cause various and partially contrasting requirements for the protection of pedestrians.

Evolutionary design characteristics to improve the protection of exterior road users are shown in the following, based on Mercedes-Benz Series 201 and 124.

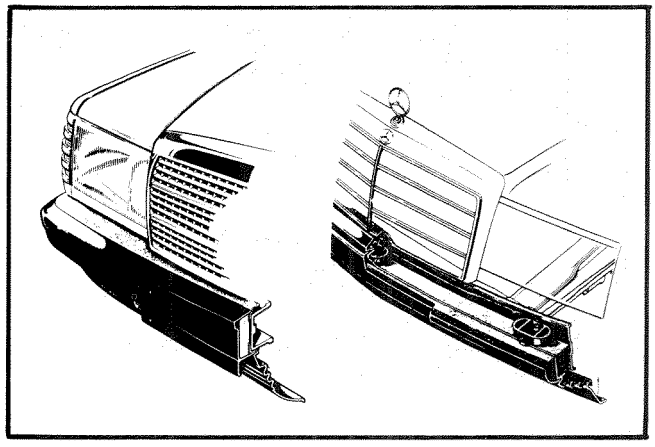

Figure 10. Front end

The front end has a smooth surface causing large-area initiation of the impact force (mitigating soft tissue injuries). The protective strip and the flashing of the bumper are made of visco-elastic material. In front of the bumper bending support there is an energy-absorbing foam, which is getting thicker to the vehicle sides. Taking the Mercedes-Benz Series 123 as a basis, the maximum force is reduced for the 201 and the 124. The point of first contact is lowered up to 50mm in the case of the 124, which reduces in addition the bending load in the lower extremities. The radiator grille is of thin sheet metal that has been reduced in thickness to 0.8mm. Thereby it has become a deformation zone.

The front end of the bonnet is rounded off, and its frame is deformable by using a Z-profile and punching. The headlamp units can, in the case of the 124, shift backward under load. Taking the 123 as a basis, the maximum force is reduced by 10 percent for the 124.

Vertical rigidity is reduced by using punched fenders and increasing the clearance between the wheel arch and the top of the fender. Taking the 123 as a basis, the maximum force is reduced by 30 percent for the 124.

The single axis of the wiper system and the cross member is covered. In contrast to the 123, the sheet metal of the 124 bonnet has a 10mm higher clearance to the bonnet cross member. Taking the 123 as a basis, the maximum force is reduced by 20 percent for the 124.

The external shell of the pillar is made of thin sheet metal. Taking the 123 as a basis, the maximum force is reduced at low impact speeds for the 124.

The large volume lateral roof frame has a smooth surface and can be well deformed under the impact of two-wheel riders. There is only one external shell, which

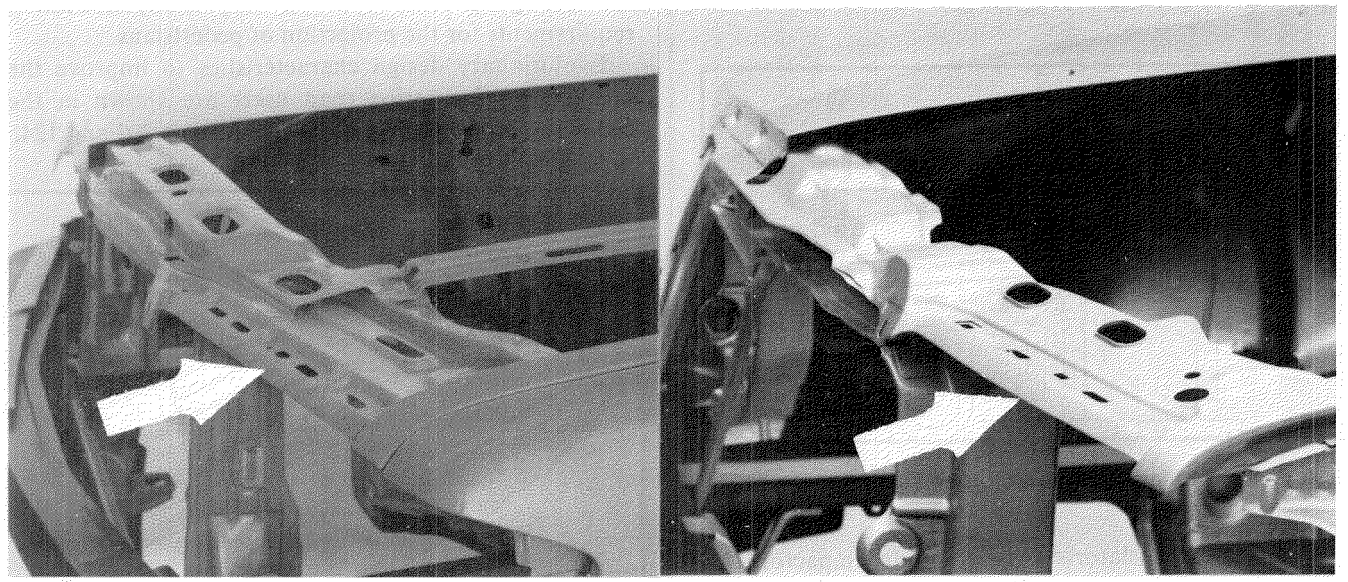

Figure 11. Substructure of upper front end

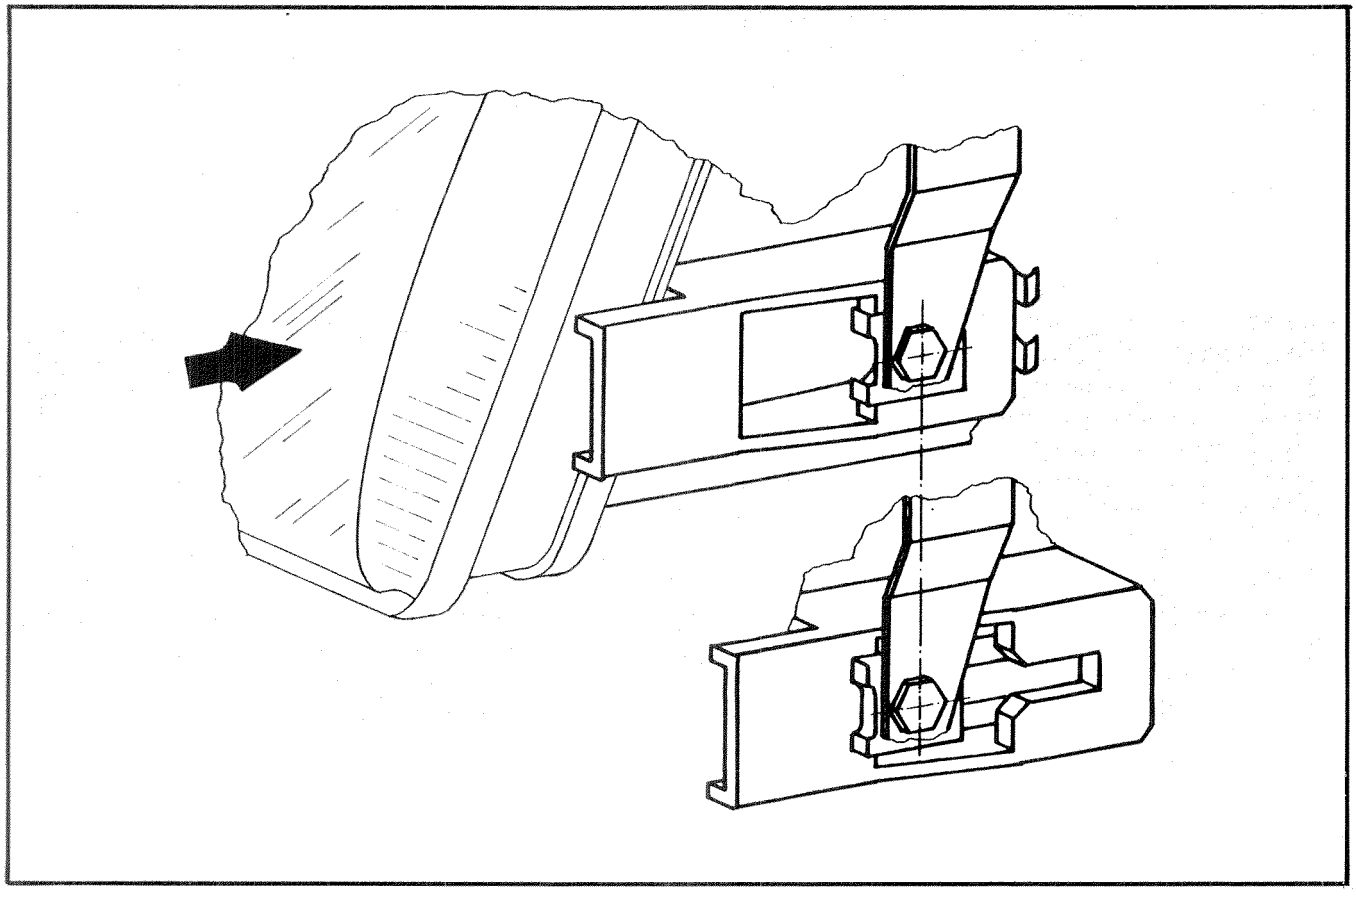

Figure 12. Kinematics of the headlamp under impact load

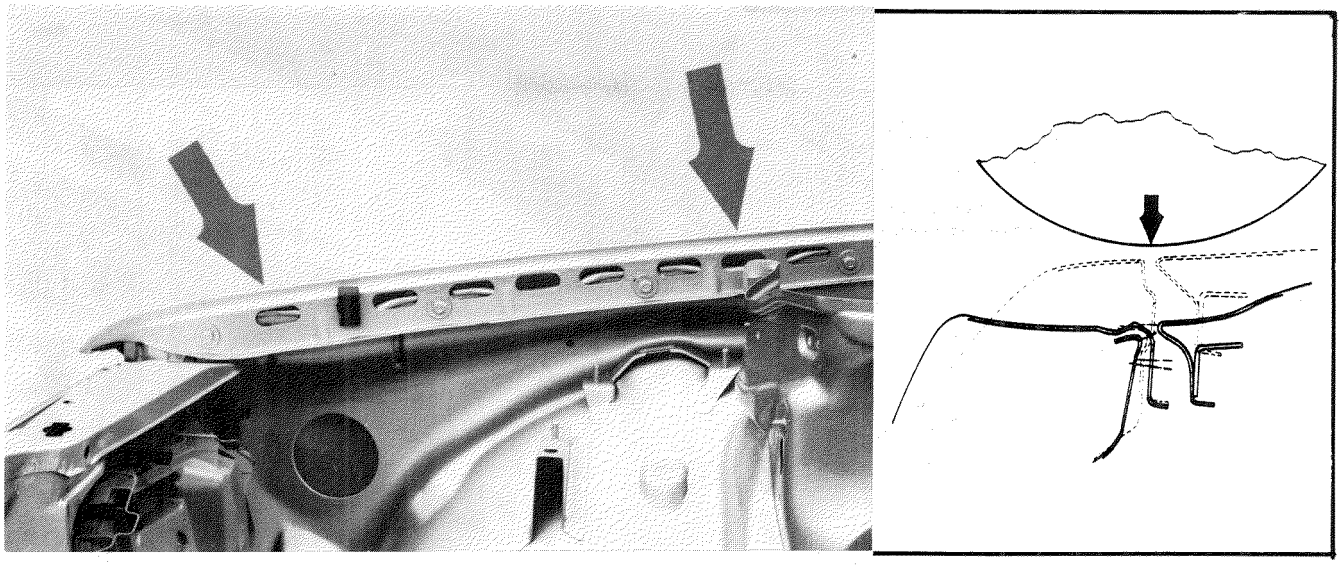

Figure 13. Transition from bonnet to fenders

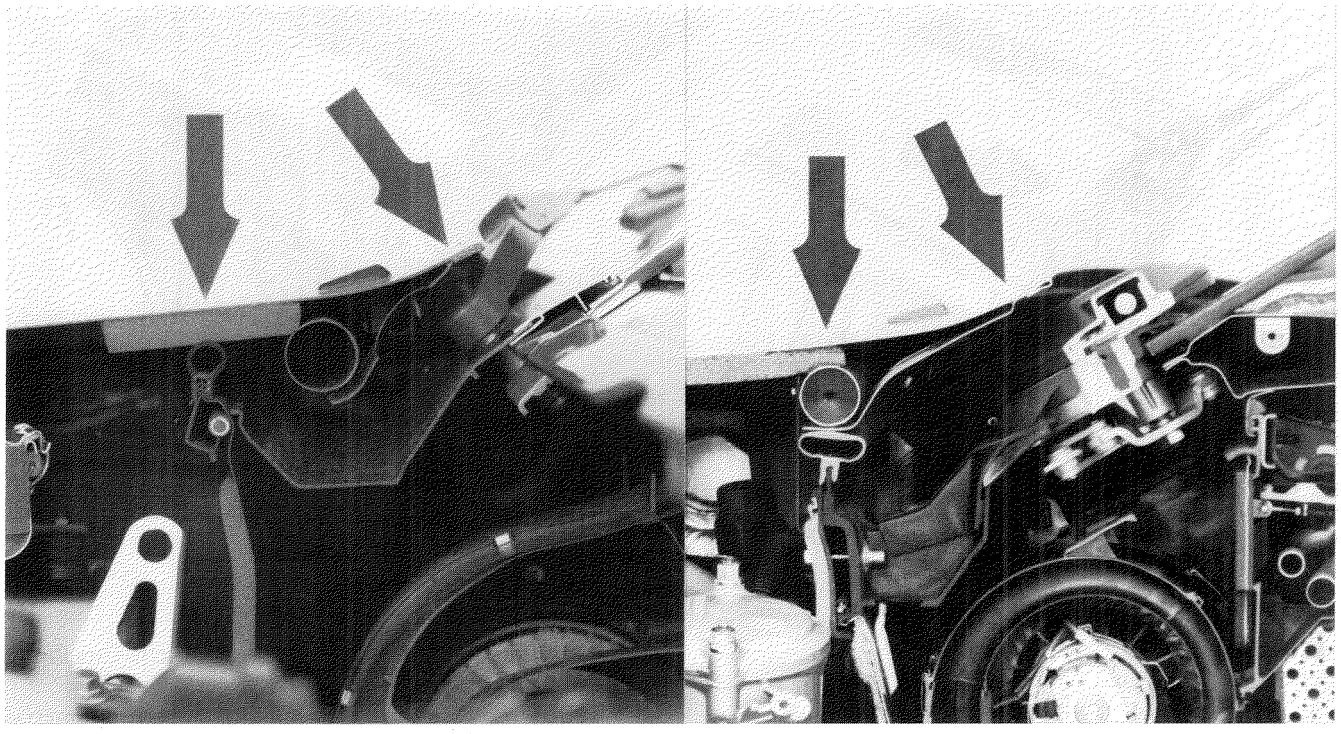

Figure 14. Upper end of bonnet

is made of thin sheet metal. Taking the 123 as a basis, the maximum force is reduced by 10 percent for the 124.

The high exposure of pedestrians to trauma, mostly a result of basically different impact partners, shows that vehicle-specific measures will have only limited efficiency in the future. A substantial reduction of the number of severely or fatally injured pedestrians will only be possible if, in addition, other measures are enforced. These are traffic education, separation of traffic areas, as well as improvement of visibility.

Leg Protection for Riders of Motorcycles

B.P. Chinn and
P. Hopes
Transport and Road Research Laboratory, Department of Transport, Crowthorne, United Kingdom

M.A. Macaulay
Brunel University, Uxbridge, United Kingdom

Abstract

A major cause of serious injury in motorcycle accidents is the rider's leg being trapped between the motorcycle and a car. This paper gives results from a number of full-scale impact tests of motorcycles with and without leg-protecting fairings. Motorcycles were crashed into a flat, rigid barrier inclined at 30° to their direction of travel. Three basic configurations were studied: motorcycles with no leg protection, with hard leg protection that absorbed negligible amounts of energy, and with soft leg protectors that absorbed 5 to 10 percent of the kinetic energy on impact. The use of a leg-protecting fairing substantially reduced damage to a dummy rider's legs in crash tests, and a protector that absorbs some energy seems preferable to one that does not. These results were achieved without increasing the risk of other types of injury.

Introduction

A major cause of serious injury in motorcycle accidents is trapping the leg of a rider between the motorcycle and a car(1). It has been suggested that a suitable fairing attached to the motorcycle could prevent this happening. Few tests of such fairings have been reported, but from these it appears a fairing could alter the dynamic behaviour of the rider during impact in such a way that he might be more likely to receive some other type of injury(2,3).

This paper gives results from a series of full-scale impact tests of motorcycles with and without leg-protecting fairings. As well as damage to the leg of the dummy rider, the dynamics of rider and motorcycle during impact were studied to check that the leg protectors used did not increase the risk of other types of injury.

Test Programme

The initial series of tests involved medium-sized motorcycles of 175cc engine size running into a flat, rigid barrier similar to those used in conventional motor car impact tests but only 1.23m high to simulate the height of a car roof. The barrier was inclined at 30° to the direction of travel of the motorcycle, as shown in Figure 1, and was faced with a sheet of 15mm plywood. The speed at impact was 48km/h. Subsequent tests were performed with light stepthrough motorcycles of less than 100cc engine size, heavy motorcycles of 800cc engine size running into the rigid barrier, and a heavy motorcycle running into the side of a stationary Morris Marina car at the same angle as the rigid barrier.

Three basic configurations were studied: a motorcycle with no leg protection, one with a hard leg protector that

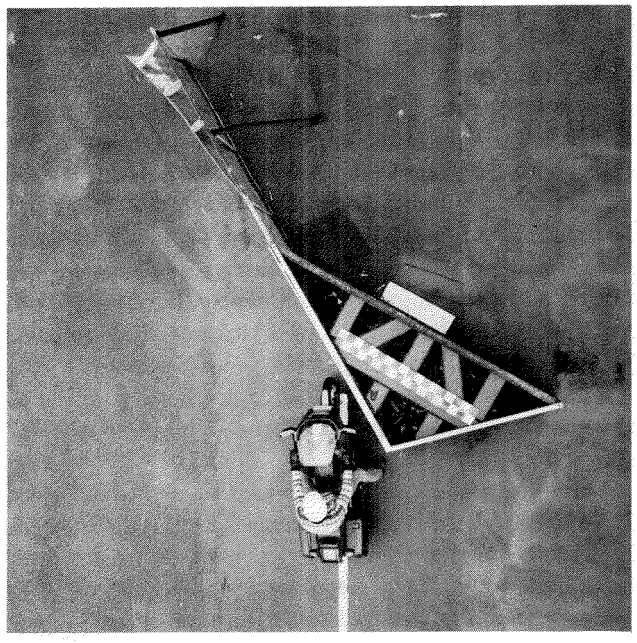

Figure 1. Overhead view of oblique barrier impact test of a motorcycle

absorbed a negligible amount of energy on impact, and one with a soft leg protector that absorbed about 5 to 10 percent of the total kinetic energy on impact. This energy absorption took place within the protector, and no energy-absorbing padding was used in front of the leg except with the heavy machines where padding had to be used because the protector was situated well forward of the rider's leg. This padding contributed very little to the total energy absorption and has been ignored.

Hard protectors were tested only on the medium-size machines. Some development tests of soft protectors were also made on these machines, but no attempt was made to optimise the energy absorption of the protectors.

The dummy rider was a 50th percentile male OPAT with the standard legs replaced by damage-indicating legs using aluminum honeycomb glued to thick flat plates. Two estimates of damage were used; the energy absorbed was related to the likelihood of bone fracture, and an estimate was made of the surface area of the leg that would have been lacerated. These legs are described more fully in (1).

Results

The energy absorbed by the leg of the dummy rider is shown in Figure 2. Also shown is a tentative limit of 20J suggested for the maximum energy that can be absorbed by the leg in (1). Mean values that break the upper and lower leg bones in bending are also given. A range of one standard deviation is shown about the mean of each set of measurements. This would include about 70 percent of the population, assuming a Gaussian distribution at breaking loads. These values are estimated from results given in (4) and (5).

Only the results for the final version of the soft protector are given. For the medium-size motorcycle, there is a consistent reduction from the damage with no protection for the leg, to some with a hard protector, and more with a softer one. The behaviour of the heavy motorcycles is anomalous. The machines used had horizontally opposed flat twin engines, and a cylinder head made contact with the barrier and altered the behaviour of the motorcycle completely. It did not rotate, and the impact was similar to a violent frontal impact. The leg damage was fairly low.

The addition of a soft protector produced rotation of the motorcycle and increased the damage to the leg slightly.

Estimates of lacerated surface area are shown in Figure 3. They follow the same pattern as the energy absorbed. Details of damage estimation are given in (6) for both bone breakage and lacerated surface area.

Leg protectors changed the dynamics of motorcycle and rider during the impact. Two simple parameters are used to summarise these changes: the forward velocity of

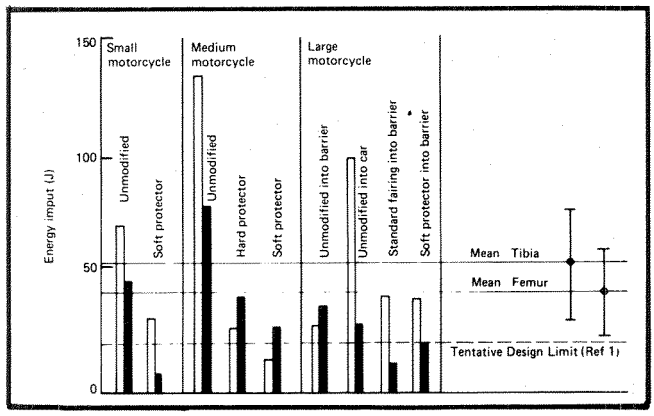

Figure 2. Energy absorbed by leg in tests of motorcycles into oblique barrier at 48km/h (one test into car)

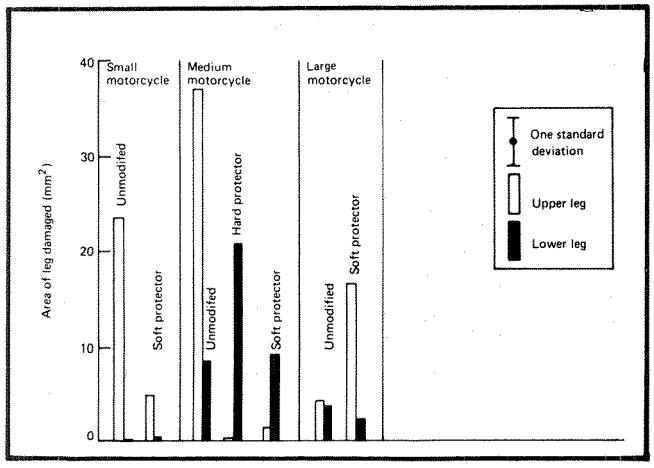

Figure 3. Areas of legs damaged in tests of motorcycles into oblique barriers at 48km/h

the dummy's head as it crosses the plane of the barrier, and the mean angular velocity of the motorcycle in the horizontal plane over the first 100ms of the impact. These are shown in Figures 4 and 5. Note that the forward velocity of the rider's head can be greater than the velocity of the motorcycle because he pivots about his hips and his torso can have rotational as well as translational velocity.

With the medium-size motorcycles, there is a consistent reduction in the forward velocity of the rider's head from that for no protector, for a hard protector, and for a soft protector. With the light motorcycles, there is no difference in forward head velocity, but, with the heavy motorcycles, the addition of a soft leg protector reduces the forward head velocity by about 35 percent.

The average angular velocity of the motorcycle during the first 100ms of the impact shows a reduction with the light and medium motorcycles and an increase with the heavy motorcycles when soft leg protectors are fitted.

When a heavy motorcycle with no leg protectors was run into a motor car, the protruding cylinder head deformed the car structure, which absorbed some of the kinetic energy. The behaviour of the motorcycle and rider

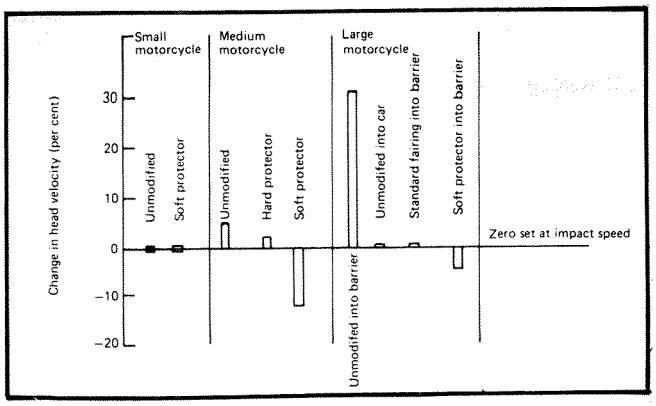

Figure 4. Change in forward velocity of head in tests of motorcycles

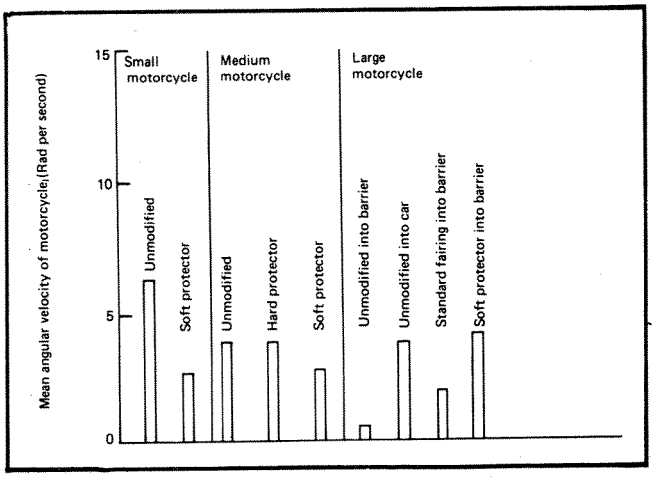

Figure 5. Mean angular velocity of motorcycle during first 100ms

was then similar to that of the unmodified medium-size machine and its rider.

Discussion

The main test programme used a flat, rigid barrier because it is generally found with motor cars that tests with a rigid barrier are easier to perform and the results are more consistent and easier to analyse than tests with a deformable barrier. In the rigid barrier test reported here, the use of a leg-protecting fairing on the motorcycle substantially reduced damage to the dummy rider's leg except for the heavy motorcycles. Leg damage was already fairly low on these machines, and it increased damage to the upper leg in these test circumstances. The cylinder head on the horizontally opposed engine of the heavy motorcycles prevented rotation of the motorcycle and stopped it violently, increasing the forward velocity of the rider's head. The addition of a soft fairing reduced this velocity appreciably. This indicates a greatly reduced chance of head injury, which more than compensates for slightly greater damage to the leg.

When a heavy motorcycle was run into a stationary car instead of a rigid barrier, it rotated and trapped the rider's leg causing severe damage.

A leg protector that absorbs some energy on impact appears to be preferable to a hard one that does not. The soft leg protectors used absorbed about 5 to 10 percent of the kinetic energy of the motorcycle plus rider, but no attempt was made to optimise the amount of energy absorption. Leg protectors reduced the forward velocity of the dummy rider's head. They also reduced the average angular velocity of the motorcycle in a horizontal plane except for the heavy motorcycle where a protector increased this velocity. They also effectively eliminated pitching of the motorcycle in a vertical plane.

In the initial tests using medium-size motorcycles of conventional design, the soft protectors absorbed about 10 percent of the kinetic energy of the motorcycle plus rider. The protectors used on the small and large motorcycles were modified so they should again have absorbed about 10 percent of the kinetic energy, but, in each case, they absorbed only about 5 percent. With the heavy machine, this is almost certainly because of the interaction of the engine cylinder head with the barrier; with the smaller machine, the reason is unclear. It may be because the rider sits in a different way with legs together instead of straddling the petrol tank. At present there is no theoretical basis for 10 percent energy absorption, which should be taken as a tentative empirical value.

When the heavy motorcycles were run into stationary motor cars, the effect of the protruding cylinder heads were less marked because the car deformed to absorb some of the motorcycle's energy. This machine can therefore be regarded as inherently aggressive, and it seems likely that the addition of suitably designed soft leg protectors would make it less aggressive.

Conclusion

The impacts of motorcycles into a rigid barrier inclined at 30° to their direction of travel reproduced the trapping of the rider's leg that has been reported from accident studies. This simulation was less successful for the heavy motorcycles tested, where protruding cylinder heads prevented rotation of the motorcycles. When a heavy motorcycle crashed into a stationary motor car, trapping of the leg occurred.

The leg protectors tested reduced the energy input into the leg of the dummy rider appreciably from a level at which severe damage is certain to one below the level needed to break the leg bones of 50 percent of the population. Leg protectors that absorb some energy on impact also reduce the forward velocity of the rider's head.

Application of Fluidics Technology to the Development of Antilock Brakes for Motorcycles

Robert R. Purves
Jet Propulsion Laboratory, California Institute of Technology

Abstract

This work was undertaken to develop antilock brakes for motorcycles utilizing the advantages of fluidics technology. Fluidic components are immune to electromagnetic interference, resistant to severe vibration, and potentially low in cost. The vehicle and brake control components were modeled. Using a system approach to the design, a nonlinear computer analysis was performed to determine acceptable delays and frequency functions for rapid and stable response. Emphasis was given to examining the transient characteristics of two functions of angular motion (acceleration and jerk) at the onset of wheel lock. Based on results of computer analyses and instrumented braking tests, angular acceleration was selected to initiate brake control. The control system components being developed are comprised of a unique pneumatic/fluidic velocimeter, a fluidic differentiation circuit, a fluidic amplifier, and a fluidic/electric threshold detector for toggle control of brake pressure. The development status of these components is discussed. The brake-pressure modulator is not being developed for this phase of the work. Results indicate a fluidic control system is feasible if the design focuses on minimizing the time response of the pneumatic/fluidic components.

Introduction

Safe braking of a two-wheeled vehicle depends on the existence of sufficient lateral force at the tire/road contact to maintain control and balance. If the wheels lock during braking, steerability of the front wheel and in-line travel of the rear wheel are lost. Capsizing of the vehicle following loss of control during braking accounts for a large number of motorcycle accidents. A solution to this problem is the use of an automatic antilock brake system.

A number of prototype antilock brakes are in existence, but to date none have appeared on production vehicles. These prototypes can be classified according to whether they are electronically or mechanically controlled. Although designs using electronic control are potentially more capable of adapting to road conditions than a simple all-mechanical type, they also tend to be more expensive to manufacture, subject to electromagnetic interference, and generally more sensitive to the harsh environment of the motorcycle. This work was undertaken to determine the feasibility of applying fluidics technology to a design that would be low-cost yet have most of the advantages of both the electronic and all-mechanical types.

Fluidic devices amplify pressure of a fluid such as air in much the same way that electronic devices amplify voltage. Fluid flow is analogous to current flow; there are components in fluidics equivalent to resistors, capacitors, and diodes. Amplifiers, filters, and logic circuits are feasible.

Although fluidic circuits do not have the frequency response and gain possible with their electronic counterparts, they do have characteristics advantageous for some applications. Fluidic circuits are not affected by nearby radio transmissions or by the electrical noise that exists near a motor's ignition system. Fluidic devices are not as sensitive to damage in a high vibration or extreme temperature environment as most electronic devices. In some applications, fluidic designs have proven to be less costly than their electronic equivalent.

Because of these advantages, fluidic technology has been used in a variety of applications. A computer using fluidic components has been designed for a Grumman fighter aircraft control. DC-10 and L-1011 aircraft depend on fluidic circuitry for operation of thrust-reverser and environmental-control systems. A military tank navigation system utilizes a fluidic motion sensor instead of a gyroscope. Fluidic components are also used for a variety of industrial controls where severe environments preclude the use of electric devices.

Fluidic antilock brakes have been designed by Boeing for commercial aircraft and by the Army's Harry Diamond Laboratories for military trucks. Efforts toward the design of fluidic antilock brakes for motorcycles were begun by Harry Diamond Laboratories in 1975. Two studies of control system concepts resulted(1,2). In 1978, Garrett Corporation continued the previous work and developed a fluidic/mechanical angular jerk (rate-of-change of acceleration) sensor for use in sensing the onset of wheel lock(3).

Scope

The work described here is a continuation of that started by Harry Diamond Laboratories and Garrett Corporation, with emphasis on system analysis and motorcycle braking tests to determine design requirements for control system components. The status of the component design effort is included. Design details and test results are given for development models of a fluidic angular velocimeter, fluidic amplifiers and differentiator, and fluidic control logic. These constitute the major components of the control system, except the brake-pressure modulator, which was not developed for this task. This latter component, therefore, was treated conceptually for system design purposes.

Approach

Past studies for applying fluidic technology to motorcycle antilock brake design focused primarily on sensors. Little consideration was given to the response requirements for other components that made up the control system. No analyses were made regarding the stability of the overall system, which includes control components and the nonlinear dynamics of the motorcycle with its tire/road interface.

The approach of this study was to analyze antilock brakes as a closed-loop, nonlinear control system with parameters chosen for stable operation and a reasonable stopping distance. The analysis objectives were to justify which variable of wheel motion (acceleration or jerk) to use for feedback and to identify the response requirements of the system components. These objectives were achieved by computer analyses and by motorcycle braking tests that provided data for determining computer model constants. These tests also supplied data for studying the wheel dynamics during braking as wheel lock occurs.

System Design

The system approach to antilock design and development is a departure from traditional approaches. Historically, antilock brakes have been developed by a combination of qualitative and trial-and-error methods. An alternate approach using classical control principles was used here in an attempt to characterize the components more accurately before fabricating them.

Basically, an antilock brake system is a device installed in the hydraulic brake line between the master cylinder and the wheel's brake assembly. It functions to prevent the braked wheel from locking up while the vehicle is in motion. The antilock system does this by automatically modulating the applied brake pressure so the braked wheel never has a tangential speed that is much less than the vehicle's forward speed. By doing this, the tires are able to retain most of their lateral force capability, allowing the vehicle to remain steerable and under the operator's control. In most cases, the stopping distance is shortened in comparison to a locked wheel stop.

As shown schematically in Figure 1, the antilock system consists of three key components:

- Modulator
- Controller
- Sensor

Together, these elements provide the antilock system function. Referring to Figure 1, the operator initiates the force command to the system. This action causes the vehicle and braked wheel to decelerate. A transducer senses the rotational action of the wheel and communicates this information to the controller. When a preset threshold of some function of wheel speed (usually deceleration) is exceeded, the controller unit, which is an on-off toggle, initiates a rapid command to the modulator, which

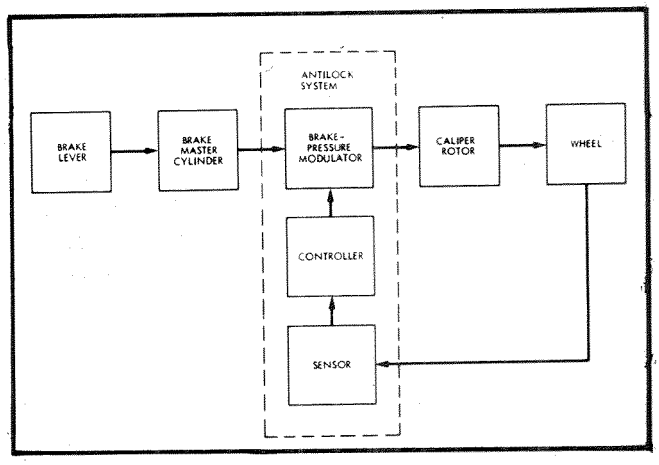

Figure 1. Basic antilock brake system

causes reduction of hydraulic pressure. As the wheel begins to recover speed, a second threshold is crossed, and the brake pressure is reapplied. The system continues cycling until the vehicle is near rest, or the brake command is reduced below the first threshold. This nonlinear cyclic action is called the limit cycle.

Antilock system requirements include such parameters as response, performance, operation, and reliability. These have been reviewed elsewhere in some detail(4). For this work, however, the main focus was on response-centered requirements.

Summary of Analysis Results

In the analysis,[1] the simplest feedback system that would result in a feasible, minimal-cost control system was sought. Results presented here pertain to the particular analysis model assumed, that is—

- Suzuki GS1000 SN (1979) with a rider weighing 165 lb
- Dry and wet asphalt road conditions
- Wheel angular-acceleration feedback
- Single-loop control, as illustrated in Figure 1
- Sudden and sustained application of front brakes by the rider

Under these conditions, several parameters were varied to achieve stable antilock brake action with reasonable stopping distances. These were—

- The magnitudes of wheel acceleration (toggle thresholds) at which brake pressure is released to prevent lockup and then reapplied to continue stopping (α_1,α_2)
- The rates at which brake pressure is dumped and reapplied by the modulator upon receiving commands by the controller (P_d,P_r)
- Total delay of control system components including brakes (τ_T)

An optimum design was computed as follows:

α_1 = -97rad/s^2
α_2 = 0rad/s^2
P_d = -3,600psi/s
P_r = 2,000psi/s
τ_T = 20-30ms

These values gave low-mu stops of -0.23g and high-mu stops of -0.54g at a limit cycle rate of 13Hz.

Perturbations of ±50 percent in each of these design parameters gave little change in performance and stability. This indicates a desirable level of insensitivity to controller variations. Perturbations somewhat beyond 50 percent gave sharp changes in stability and performance in most cases.

[1] Analysis work related to the system design was performed by Dynamics Research, Inc., of Torrance, California, under contract to JPL. Details of this work are given in (5), which is a companion paper to this paper.

Analysis of toggle width ($\alpha_2 - \alpha_1$) and bias ($\frac{\alpha_2 + \alpha_1}{2}$) values showed the effects of these parameters on limit-cycle stability. In particular, a wider toggle gives more lag and ultimately lockup, whereas a narrower toggle gives less lag and no reapply (no stopping). A more negative toggle bias lenghtens the dump well time, resulting in lockup. More positive biases reduce the dump dwell time, resulting in poor stopping performance.

For acceleration feedback and the type of controller and modulator assumed, stability of the control system operation was easily achieved. However, stopping performance was very sensitive to the net time delay in the system. A delay of 110ms was clearly unacceptable, while a 20 to 30ms delay gave reasonably good results.

Analysis of pressure dump and reapply rates showed that dump rates primarily affect the stability of the system, while reapply rates mainly affect stopping performance. In particular, higher dump rates give higher limit-cycle frequencies and higher stability, and higher reapply rates (within some limits) give shorter stops.

Sensing the Onset of Wheel Lock

Wheel lockup must be anticipated by sensing some function of wheel rotational motion such as angular velocity, acceleration, or the rate-of-change of acceleration (jerk). In a limit-cycle type of control, this function would be monitored for a predetermined threshold level, which, when reached, would start the release/apply cycle of brake pressure. Clearly, angular velocity is not an appropriate function for threshold detection. However, acceleration and jerk are feasible candidates for consideration since either changes rapidly as wheel lock occurs, regardless of vehicle speed.

The purpose of the following section is to compare acceleration and jerk as suitable feedback parameters for brake control.

Three methods of comparison have been used here:

1. Computer model analysis, where a model of a braking motorcycle has produced time domain plots of acceleration and jerk for several types of road surfaces
2. Braking tests, where wheel motion parameters at lockup were recorded during road testing of a motorcycle and the acceleration and jerk responses were compared
3. Control system analysis, where the stability of a closed-loop brake control system was compared for acceleration and jerk feedback

Computer Model Analysis

Analyses of the computer model indicate there are no apparent advantages to using jerk rather than acceleration for brake control. In fact, for some surfaces such as gravel

and glare ice where the maximum tire/road stopping force occurs with the wheel locked, jerk does not give a usable signal, while acceleration does.

Figures 2 through 5 illustrate the computer analysis. These plots show, as a function of time, torque on the wheel due to the brake (T_B), which represents the input function; torque on the wheel due to the tire/road interface (T_R), which is a function of the mu/slip curve; wheel angular acceleration, which is a function of the net torque on the wheel or $T_R - T_B$; wheel angular jerk, which is the first derivative of angular acceleration; and angular velocity. Each plot is for a particular road surface characterized by its mu/slip curve. Only that period of time prior to lockup is significant.

Accompanying each set of wheel transient curves is a mu-slip curve for the road surface considered. To make them more amenable for computer entry, these mu-slip curves are simplified versions of data in (6).

These plots show that jerk does not cross zero at maximum road torque, as concluded in a previous study. Figures 2 and 3, dry and slippery asphalt, show a sudden decrease in jerk and acceleration very near the maximum road torque. However, Figures 4 and 5, gravel and glare ice, show that acceleration produces a much stronger response. If system noise is taken into consideration, as discussed in the following section, it is unlikely the jerk signal would be strong enough to be useful.

Braking Tests

The real braking situation differs from computer simulation in significant ways. The computer simulation assumes a constant tire/road interface during braking, represented by a mu/slip curve. It does not take into account sudden variations in road surface, such as thin patches of dirt, bits of debris, painted lines, oil spots, etc. Such variations in the coefficient of friction can significantly affect the motion of the wheel when it is on the verge of locking. These perturbations in acceleration and jerk constitute a noise level that the control logic must contend with. It is clear that consideration of the signal-to-noise ratio is of primary importance in designing a threshold-sensing control system if false triggering of brake-pressure release or application is to be minimized.

A jerk sensor, since it differentiates angular acceleration, will amplify acceleration noise in direct proportion to its frequency. This means that noise levels, whether the result of road surface variations, brake, frame, or suspension vibrations, or background noise present in the sensor/controller system, can be many times greater if jerk rather than acceleration is sensed. Unfortunately, reduction of this noise by filtering is generally not an acceptable solution because filters introduce a delay in response that seriously degrades control system performance.

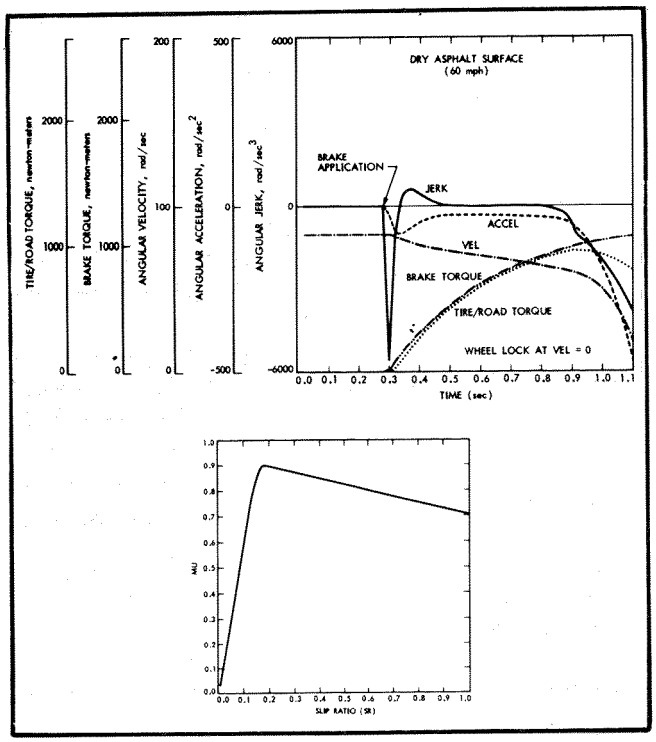

Figure 2. Braking wheel dynamics—dry surface

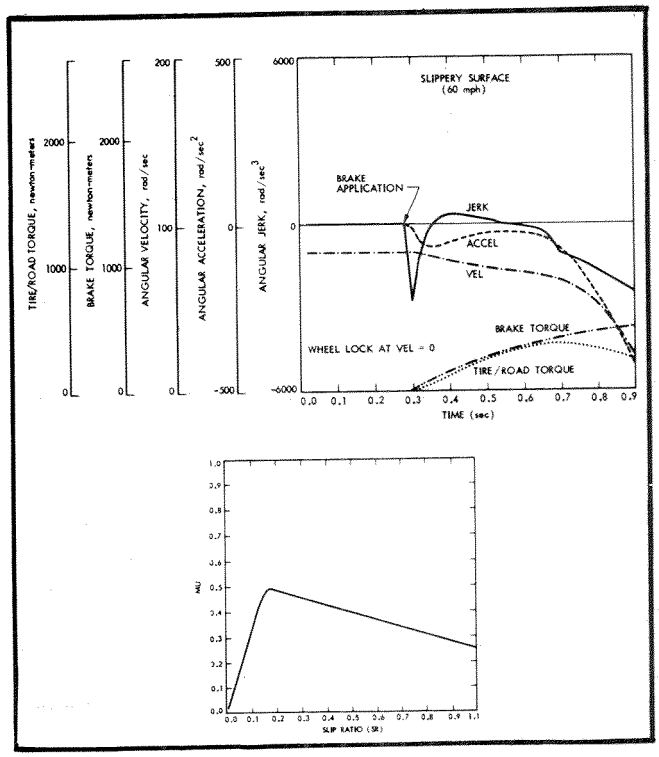

Figure 3. Braking wheel dynamics—slippery surface

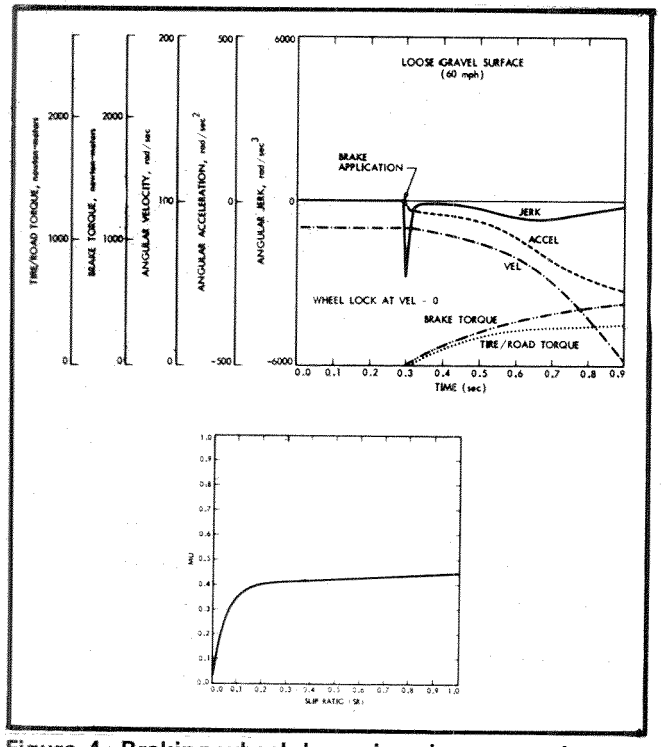

Figure 4. Braking wheel dynamics—loose gravel

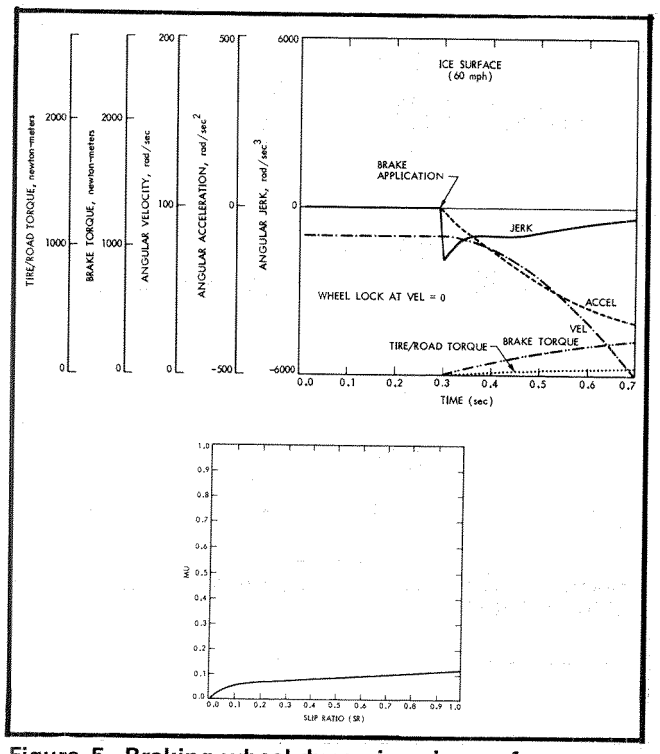

Figure 5. Braking wheel dynamics—ice surface

A series of braking tests were run using a motorcycle (Suzuki GS 1000) instrumented to record wheel dynamics. To simplify the analysis and instrumentation, braking was done on the front wheel only. The road surface was dry asphaltic concrete, a commonly used material. In each test, the front brakes were applied suddenly and hard enough to cause the wheel to lock and skid. Parameters recorded on a magnetic tape recorder included wheel angular velocity and angular acceleration. Upon playback of the tape, acceleration was electronically differentiated to produce jerk. For visual comparison, all signals were then recorded on an oscillograph, from which Figures 6 to 11 were produced. These figures illustrate what is happening to the wheel as it approaches and achieves a locked condition.

Brake pressure, which represents the input to the brake system, was not measured during these tests because of the tape recorder's limited channel capacity. The rider was instructed to apply the brakes suddenly and hard until lockup occurred and then release them for a normal stop. Although he may not have applied the brakes at the same rate each time, each test run does represent a braking situation that could occur in reality. To be usable, jerk and acceleration signals must show good characteristics regardless of how lockup is approached and how much noise is present.

In playing back the data, each channel was filtered to reduce noise. To identify the effect of filtering, four-pole low-pass filters with cutoff frequencies of 4, 8, 16, and 32Hz were compared. The effects on the same data for three cutoff frequencies are shown in Figures 6, 7, and 8.

The 8Hz filter was judged best, considering the compromise between low noise and rapid response. To show the delay effect of each filter on the acceleration and jerk, the filter for the velocity channel was fixed at 20Hz.

Referring to the figures, three traces that represent the motion of the braked wheel (angular acceleration, angular jerk, and angular velocity) are shown. The point at which the wheel velocity suddenly rises is when the motorcycle rider released the brakes enough to resume normal braking.

Starting with Figure 8, each figure is for a different stopping event (run). The velocity trace indicates where wheel lock and release occurred. It also shows several instances of impending lock before actual lockup occurred. In each case, acceleration and jerk traces show a response to these events as well as to the noise. These records are typical of all the runs (25) and show acceleration signal level at impending lock is greater, relative to the noise level, than the jerk signal level. In fact, in Figures 9 and 11, the jerk signal has no distinctive characteristics and would not be useful for initiating brake-pressure release.

Control System Analysis

The closed-loop analysis presented in (5) was made for each of the feedback parameters being considered. The results indicated that acceleration would give stable operation and jerk would not. Jerk feedback would be stable if the proper network were added, but this would be equivalent to making the jerk transducer an accelerometer.

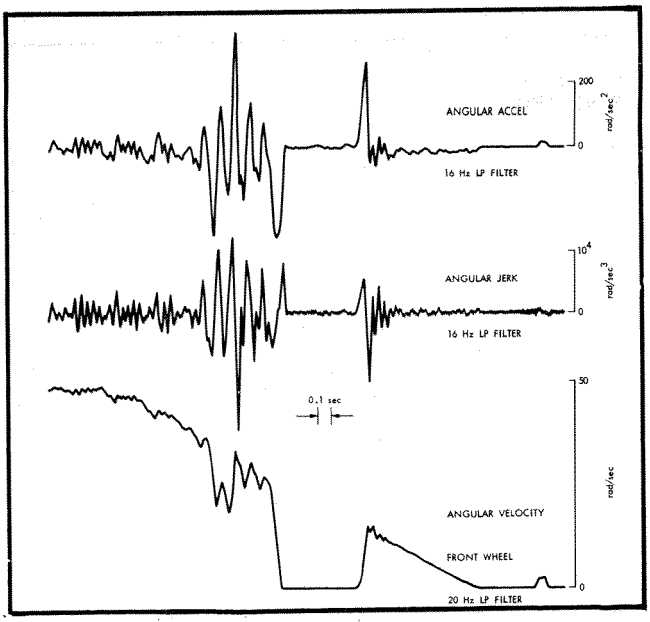

Figure 6. Run 6, 16Hz filter

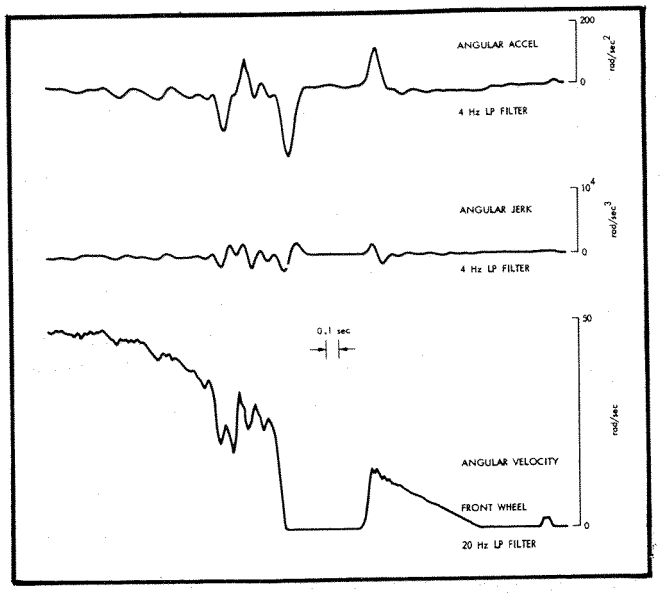

Figure 7. Run 6, 4Hz filter

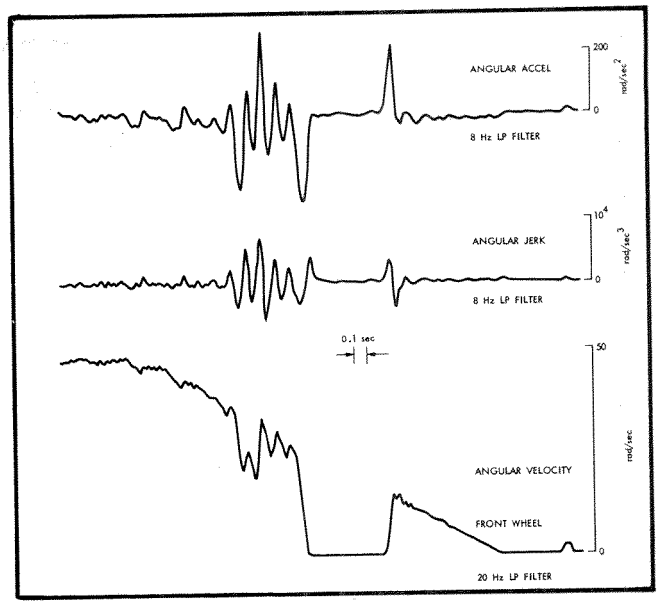

Figure 8. Run 6, 8Hz filter

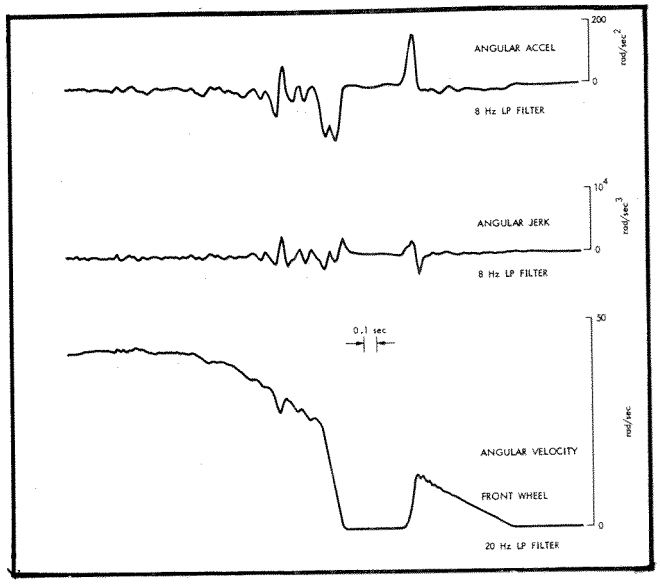

Figure 9. Run 7, 8Hz filter

Comparison Summary

When wheel lock begins, a pulse occurs in both the jerk and acceleration signals; however, if the pulse were used to initiate control action, the two signals compare as follows:

1. At impending lock, the acceleration signal is consistently greater in magnitude relative to the noise level.
2. For gravel or glare ice road surfaces (or other surfaces where the maximum stopping force occurs at lockup), the jerk signal has poor characteristics near lockup and is of such low magnitude that in the presence of noise it would be useless.
3. Closed-loop analysis shows that, for the control system concept proposed for this task, jerk feedback does not produce a stable control cycle, whereas acceleration does.

Component Design

The overriding physical requirements for a motorcycle antilock brake control are that it be small and resistant to the environment. It also must be inexpensive. Preferably it should be a single unit mounted near the wheel's brake caliper and coupled to the wheel to operate the sensor and the modulator. An example of how the unit could be mounted on the front fork is shown in Figure 12.

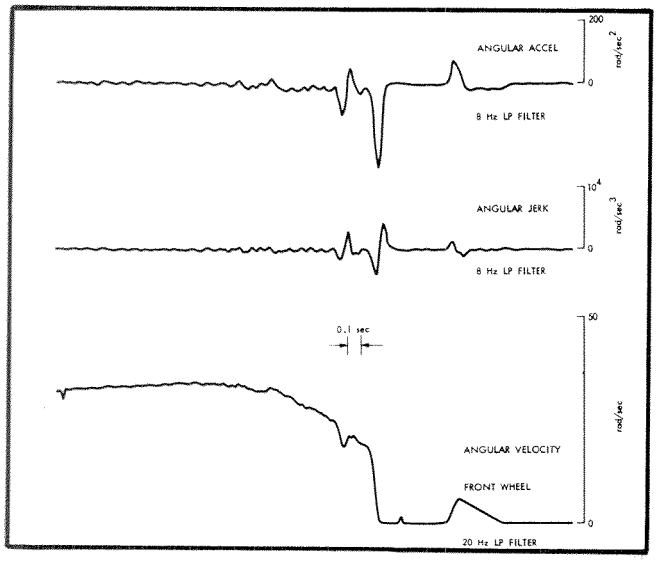

Figure 10. Run 8, 8Hz filter

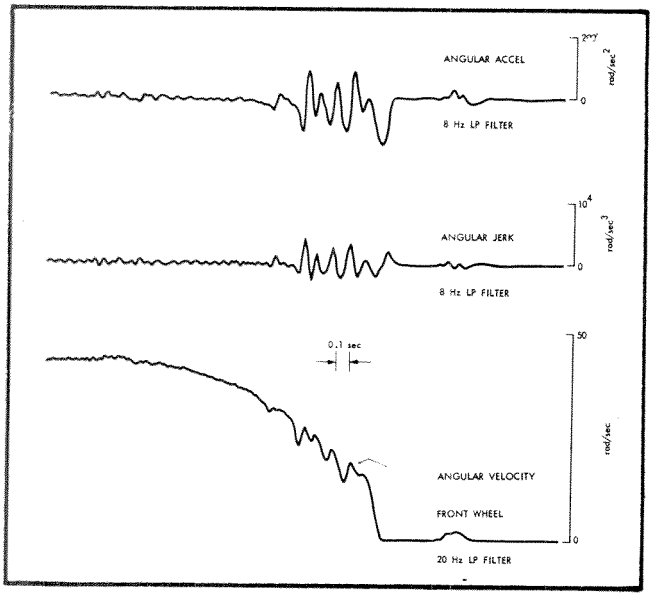

Figure 11. Run 10, 8Hz filter

For an experimental model, coupling to the wheel would be by belt and pulleys. The hydraulic line from the brake master cylinder would terminate at the modulator, with a short line connecting the modulator to the wheel cylinder. Also connected to the unit would be two hoses, one to the intake manifold vacuum and one to the carburetor air-filter housing (for clean air). One wire to the vehicle's battery would be required to operate the modulator's control solenoid.

The complete brake-control unit would be configured as shown in Figure 13, with the components combined in a cylindrical shape about 100mm in diameter and 90mm long. The final dimensions would depend on the size of the modulator. As presently conceived, the modulator would be close to the size shown.

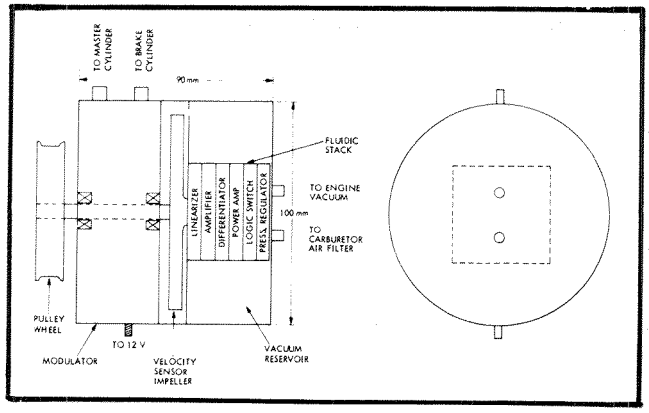

Figure 13. Control system packaging concept

Sensor

It was concluded by analyses and tests that wheel angular acceleration best indicates impending lockup. This variable can be sensed directly with an accelerometer or indirectly with a velocity sensor and a differentiating circuit. The latter approach was taken here because of the simplicity of the velocity sensor as compared with accelerometers. Past fluidic/pneumatic sensor designs, based on principles of inertia or centrifugal force(7), have involved moving weights and other moving parts with points of friction. Reducing friction to acceptable levels is a major design problem. Also the rotating, fluid-filled toroidal-type sensor(1) requires a rotating pneumatic coupling to transmit pressure changes to fluidic amplifiers. This rotating coupling presents a significant design problem to minimize leakage and noise on the pressure signal.

The sensor developed here has several advantages over past fluidic concepts and designs:

- One rotating part
- No rotating pneumatic coupler
- No friction problem
- Less expensive to fabricate
- More compact

This sensor, as shown in Figure 14, is basically a centrifugal pump with pressure sensed at the input rather than the output. Sensing the pressure at the input eliminates the problem of pressure pulses, or noise, that appear on the pump output. In addition, a fluidic circuit applied in a unique way is used to linearize the pressure signal.[2] Linearization is necessary to make the acceleration signal amplitude independent of velocity when the velocity signal is differentiated.

Referring to Figure 14, the impeller is a disk with six air ducts connected to a common opening in the center. Rotation of the disc causes air to flow from the center to the perimeter, in the manner of a centrifugal pump. The case is fixed. The air inlet is through a fluidic resistor and two orifices that function to linearize the relationship between the pressure across the resistor, or output, and the impeller angular velocity. Two small capacitances are formed by the volumes following the orifices.

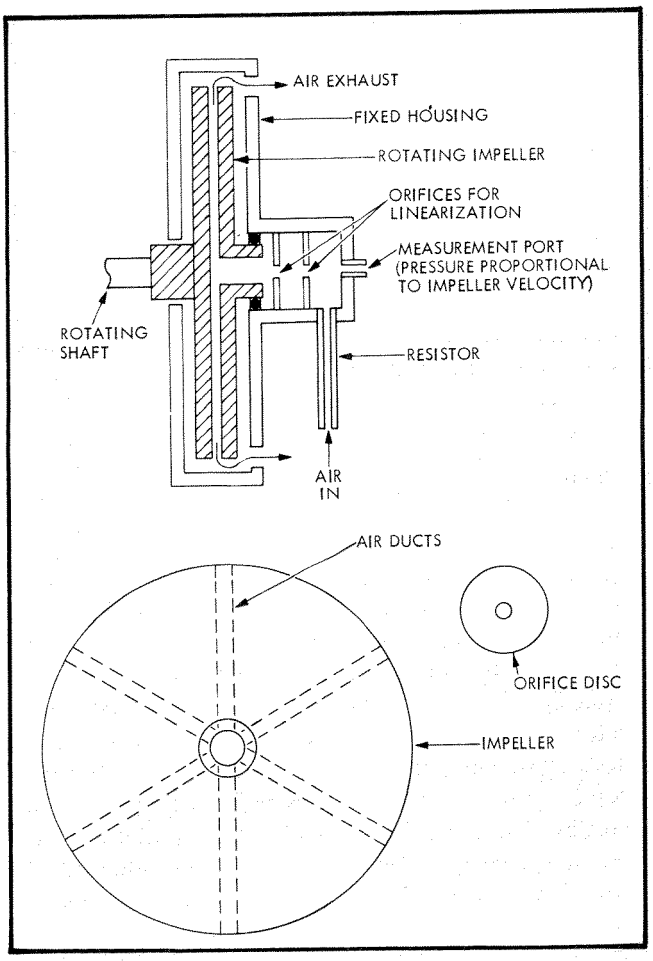

Figure 14. Angular velocity sensor—functional representation

The output pressure developed by a centrifugal-type pump, pumping fluid through a resistance load, varies as the square of the angular velocity or shaft speed. Thus,

$P_1 = K_1\omega^2$

where

P_1 = Pressure drop across the pump
K_1 = Constant of proportionality
ω = Pump speed in radians per second

Assuming the load resistance to be a linear element such as a tube or a pipe whose length-to-diameter ratio is sufficient to establish laminar flow (flow in which laminar shear forces reach from the pipe inside walls to the centerline), the flow through the device would be directly proportional to the pressure drop across it. In the case of the nonlinear pump applied to the linear (capillary) load resistance, a flow rate, Q, that is proportional to the pump pressure, or proportional to ω^2, would result. However, if a nonlinear resistance, such as an orifice, were substituted for the linear load resistance, a flow that is influenced by the nonlinear characteristics of the new load resistance would be established.

Referring to Figures 15 and 16, an orifice, Ro, which allows a fluid (in this case, air) to flow through it to a lower pressure region on the output side establishes a flow rate, Q, that is proportional to the square root of the pressure drop across it, P_2. This is true regardless of the ratio of orifice to pipe diameter in which the orifice plate is inserted. Since $P_1 = P_2$:

$$K_1\omega^2 = K_2q^2, \text{ so } Q = \sqrt{\frac{K_1}{K_2}}\,\omega,$$

which states that the circuit flow rate is proportional to speed.

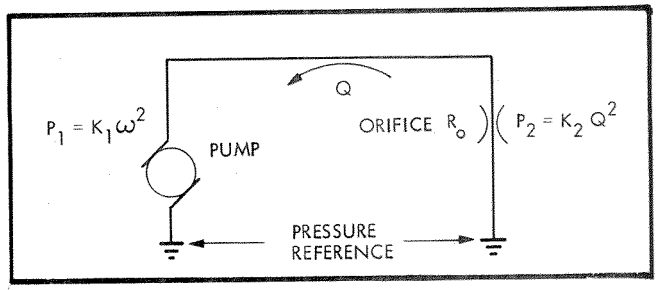

Figure 15. Pump and orifice circuit

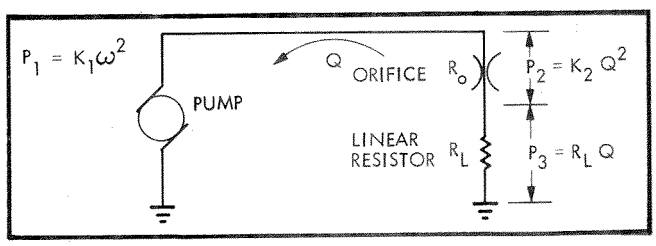

Figure 16. Circuit with linear resistor added to measure flow rate

[2] Patent applied for

The addition of R_L, however, introduces a nonlinearity as follows:

Now $$P_1 = P_2 + P_3$$

or $$K_1\omega^2 = K_2Q^2 + R_LQ$$

or $$Q^2 + \frac{R_{LQ}}{K_2} - \frac{K_1}{K_2}\omega^2 = 0$$

Solving for Q, $$Q = \frac{-R_L}{2K_2} \pm \sqrt{\frac{R_L^2}{4K_2}^2 + \frac{K_1\omega^2}{K_2}}$$

Q is no longer a linear function of ω. However, if, by design, R_L is an insignificant part of the total load, or $R_L << K_2$, Q will be proportional to speed, or, as before:

$$Q = \sqrt{\frac{K_1}{K_2}}\,\omega$$

However, when R_L is small, the pressure P_3 is small; therefore, a tradeoff of linearity for signal sensitivity must be made.

It can be shown that the addition of orifices may be used to linearize flow (see Figure 17). An analysis similar to that above shows that adding orifices diminishes the nonlinear effect of R_L by making R_L a smaller part of the total load.

For the experimental model of the sensor, two orifices, of a size determined by test, gave the desired degree of linearity. The linearization effect is shown in Figure 18. Without linearization, the pressure output versus velocity closely follows a square-law curve, as expected. With the linearizer, the curve is linear to within ±1.5 percent, if the portion below 1,000rpm is not used. One-thousand rpm is equivalent to 16km/h, which is below the required operating range of the antilock control.

Since the velocity output must be differentiated to get acceleration, the slope of the velocity curve is the significant characteristic. Over the range of interest, the slope variation of the nonlinearized curve is ±300 percent, while that of the linearized curve is ±15 percent, a twentyfold improvement.

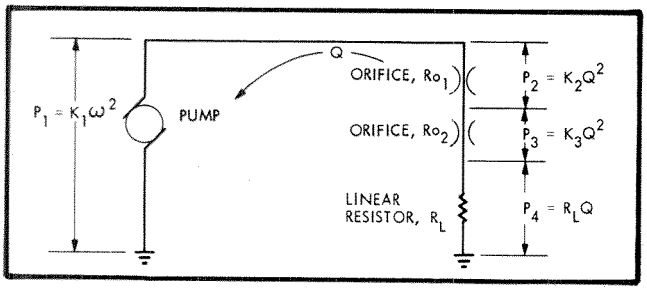

Figure 17. Multiorifice linearizer

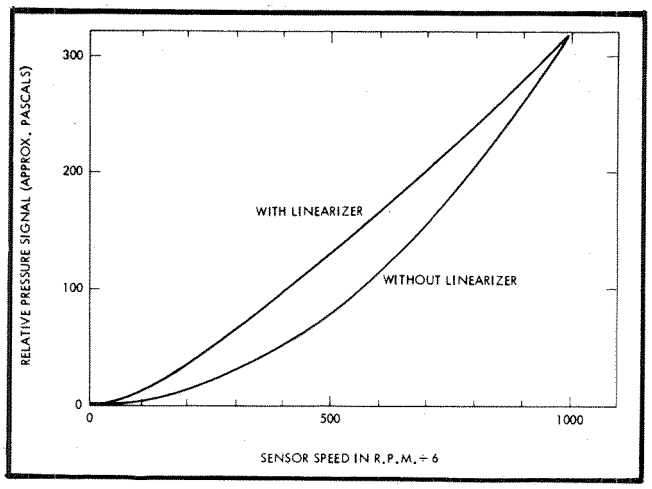

Figure 18. Effect of linearizer

Testing the sensor was done by using an electric motor with closed-loop speed control (Figure 19). The speed was varied with a DC voltage input. By using a linear-ramp voltage generator, the motor speed was accurately programmed to produce a known acceleration. Also, a sine-wave voltage generator was used to produce the frequency and phase response curves shown in Figure 20. For this test, the motor ran at 3,000rpm, and its speed modulated with a sine-wave. The results show the transducer has a flat attenuation response to 12Hz, the frequency limit of the test apparatus. Phase shift is about 9° at 12Hz. Assuming the sensor has a transfer function similar to a single-pole low-pass filter, the measured phase response is that of a filter with a cutoff frequency of 76Hz and a time delay of 2ms. This delay is well within our requirements for a total system delay of 20 to 30ms.

The experimental model of the transducer with the fluidic stack is shown in Figure 21. The case and impeller are made of acrylic resin. Details of the impeller and orifice disks are shown in Figure 22. The two disks, which are metal with 0.6mm orifices, are shown with two spacer-cavities.

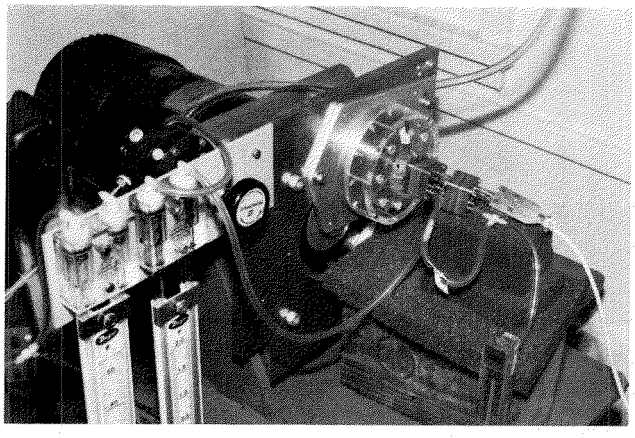

Figure 19. Sensor test apparatus

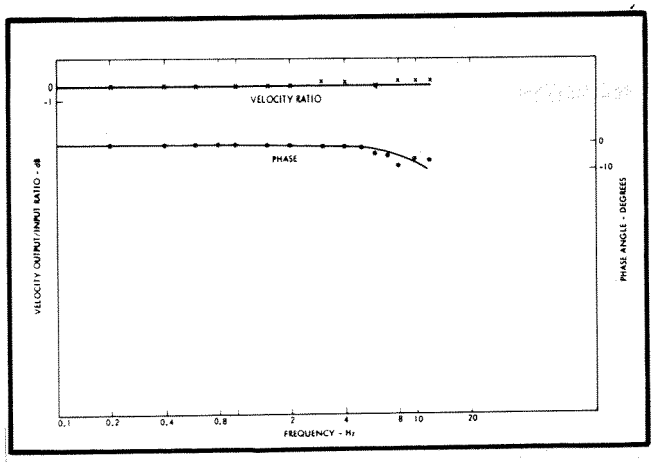

Figure 20. Sensor frequency response

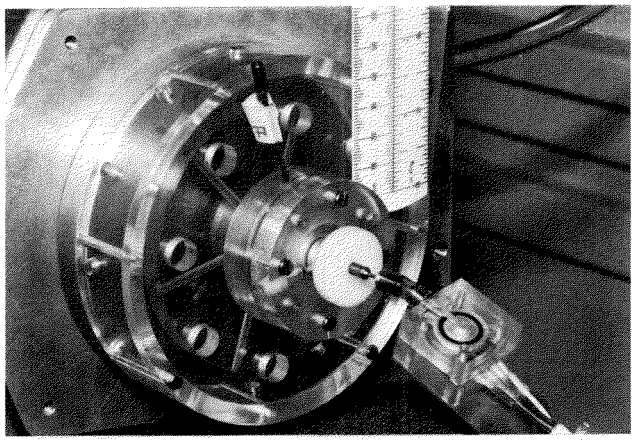

Figure 21. Velocity sensor

Fluidic Circuits

Referring to Figure 23, the fluidic circuitry following the velocity transducer is comprised of a preamplifier, a differentiator, a driver amplifier, and a power amplifier

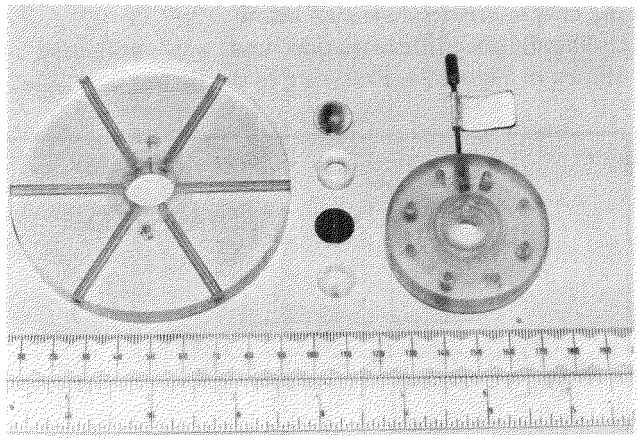

Figure 22. Sensor impeller and orifice disks

to operate the logic switch. This diagram represents the experimental setup, which operated from a positive pressure source. The final version would operate from engine vacuum and would include a vacuum reservoir and a pressure regulator to control the operating pressure to about 11kPa. The fluidic elements would be stacked and attached to the sensor, as shown in Figure 13.

Differentiator

In order to have a simple, low-cost sensor, a velocity type was designed. Since an acceleration signal is required, the velocity signal must be differentiated. While several approaches may be taken, the circuit shown in Figure 23 was fabricated and evaluated first because of its simplicity. It consists of diaphragm capacitors and resistors, equivalent to a single-pole RC high-pass electrical network. This approach to differentiation is valid over a limited range of frequency, being most effective at low frequencies. The design goal was to select component values that

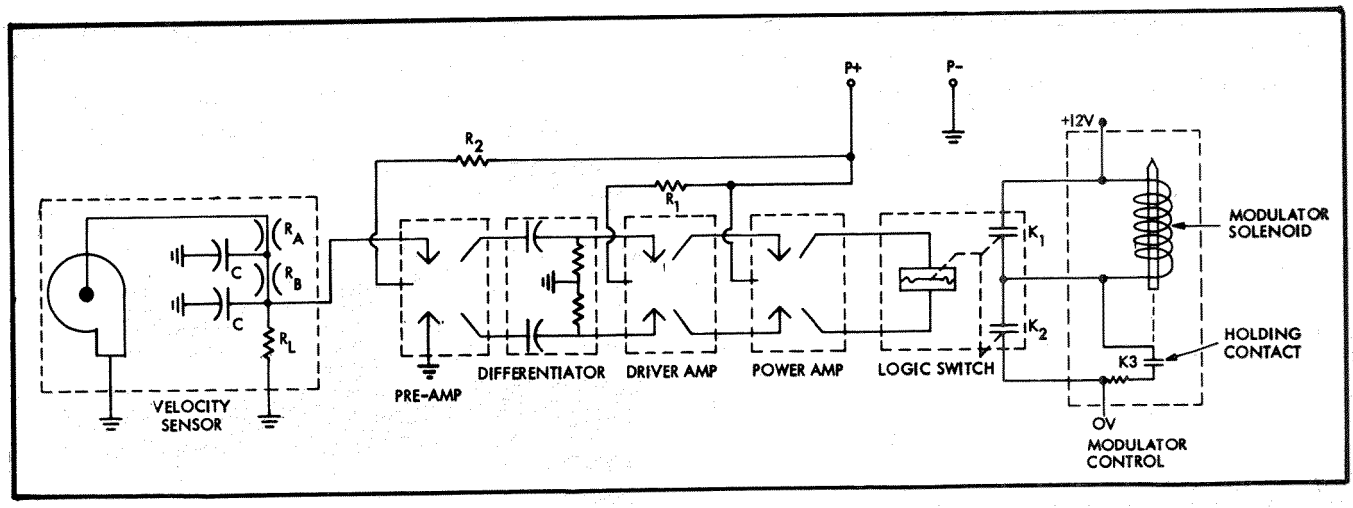

Figure 23. Schematic diagram of control system

would result in an acceptable compromise of the competing characteristics discussed below.

The fluidic differentiation unit was configured as shown in Figure 24. Referring to the figure:

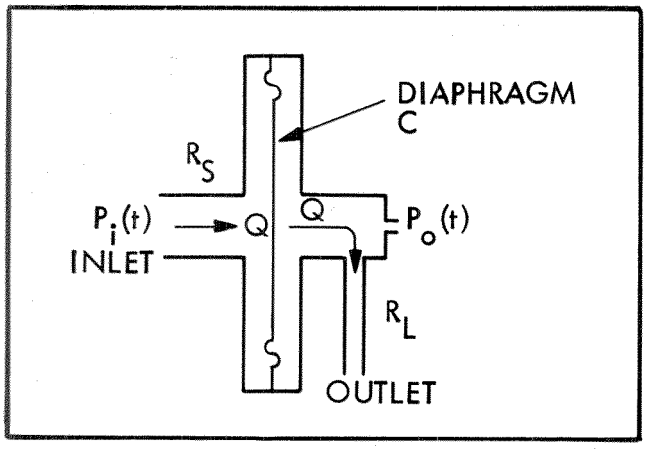

Figure 24. Fluidic differentiator

R_L = load resistance

R_S = input source resistance

$Q(t)$ = volume flow rate

$P_i(t)$ = input pressure

$P_o(t) = Q(t)R_L$ = output pressure

where P_i, P_o, and Q are a function of time, t.

C = diaphragm capacitance

$$= \frac{A^2}{K_D}$$

A = diaphragm area

K_D = diaphragm spring constant

Summing the pressure drops across each element,

$$Pi(t) = R_s\, Q(t) + \frac{1}{C}\int Q(t)\,dt + R_2\, Q(t)$$

$$Pi(s) = Q(S)\left[(R_L + R_s) + \frac{1}{SC}\right]$$

where S = Laplace variable

$$\frac{P_o(s)}{P_i(s)} = \frac{Q(S)R_L}{Q(S)\left[R_L + R_S + \frac{1}{SC}\right]} =$$

$$\left(\frac{R_L}{R_L + R_S}\right)\left(\frac{ST}{ST + 1}\right)$$

where $T = (R_L + R_S)C$

Since R_L is significantly larger than R_S, by design,

$$\frac{P_o(S)}{P_i(S)} = \frac{ST}{ST + 1}$$

This equation is the transfer function of a true differentiator, S, with a gain of T, combined with a simple one-pole low-pass filter, $\frac{1}{ST + 1}$, having a time-constant T, and a cutoff frequency $F = \frac{1}{2\pi T}$ Hz.

For this device to be an acceptable differentiator, the low-pass filter must have a small T to reduce the effects of phase shift and attenuation on the control loop, and reduce the lag in response. However, as shown by the transfer function, reducing T also reduces the differentiator's sensitivity, producing an undesirable effect on the signal-to-noise ratio. Since excessive noise on the acceleration signal will cause erratic operation of the control logic, careful attention must be given to minimize noise generated before the differentiator.

Results of evaluation tests are shown in Figures 25 and 26. Figure 25 is the frequency response in terms of attenuation and phase shift of the sensor/differentiator combination (hereafter referred to as accelerometer). These curves represent the relationship between input angular acceleration of the sensor and the pressure output of the fluidic driver amplifier (see Figure 23). The following conclusions may be drawn from these results:

- The cutoff frequency (-3db) of about 1.5Hz is much too low for use in the control loop. It should be about 10 times higher to reduce the effect of phase lag on the closed-loop limit-cycle frequency. As the limit-cycle frequency becomes lower, the stopping time increases to an unacceptable duration.
- The time-constant equivalent of a 1.5Hz cutoff frequency is about 100ms. This delay, added to other delays in the system, is too long to prevent wheel lockup in a panic stop.

Figure 26 shows the results of a transient test where a sudden acceleration (velocity ramp) was applied to the accelerometer. Preliminary analysis (see System Design) concluded that the threshold of wheel acceleration for triggering the reduction of brake pressure should be -97rad/s^2. Accordingly, for test purposes, the acceleration input was adjusted to a somewhat higher level of about ±130rad/s^2. The transient response of the accelerometer shows an unacceptable time constant of about 100ms (time to reach 63 percent of final value), which was predictable from the frequency response results.

To get satisfactory performance from the differentiator, the RC time-constant must be decreased by about a factor of 10, and the gain must be increased by adding another stage of fluidic amplification.

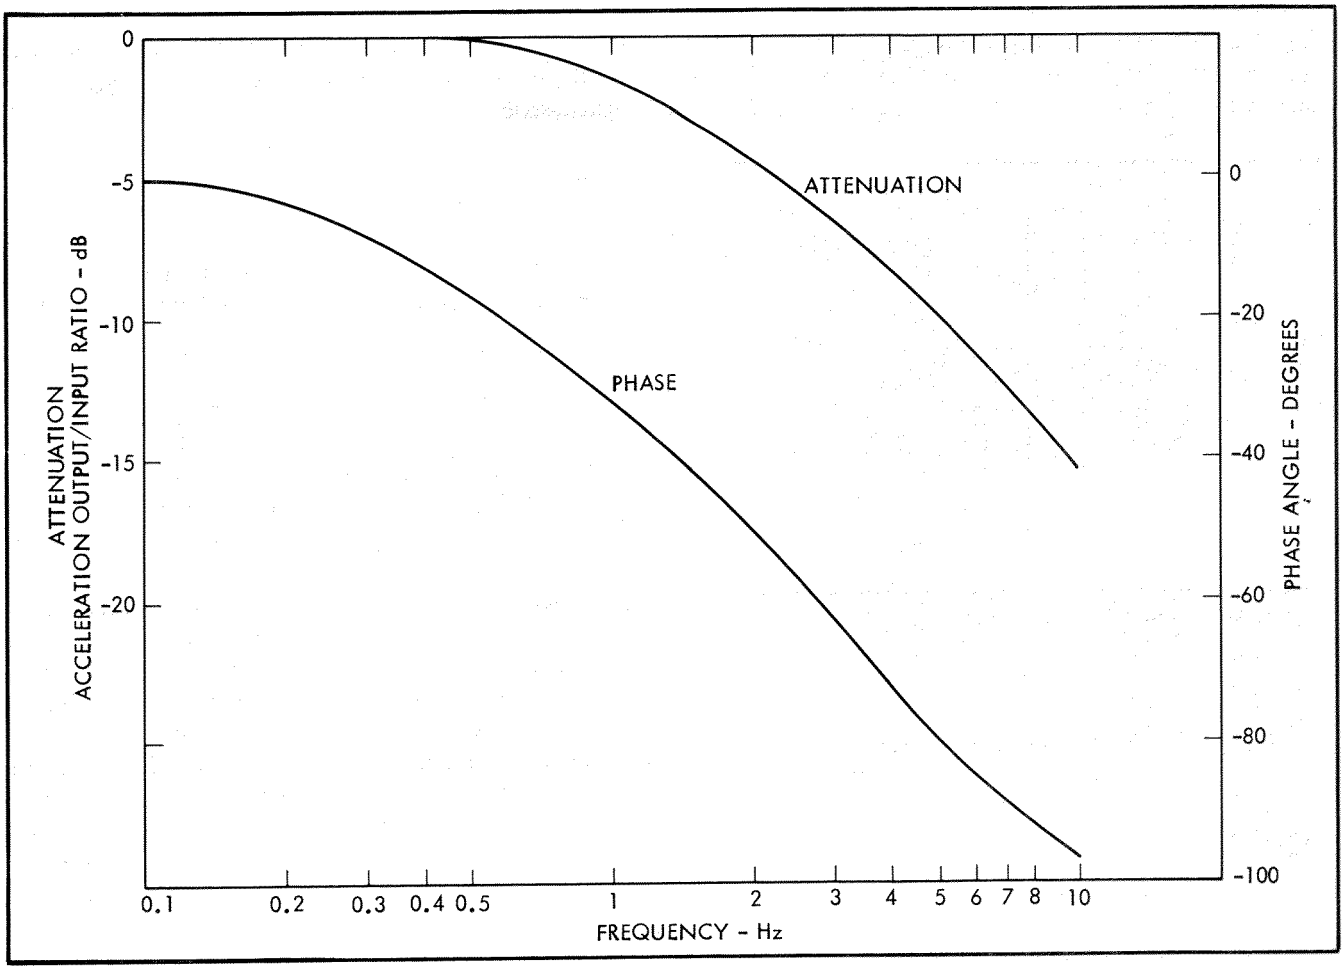

Figure 25. Combined sensor/differentiator frequency response

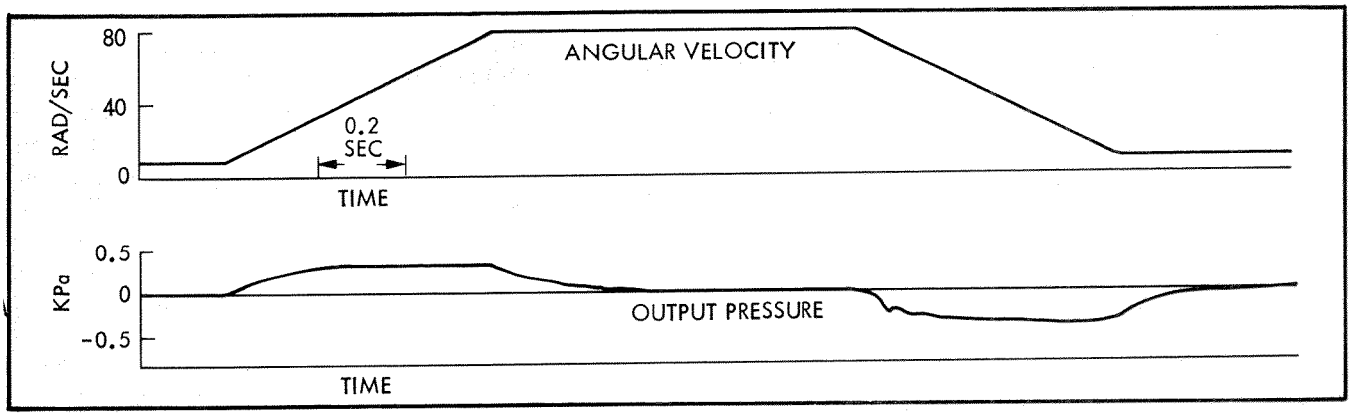

Figure 26. Sensor/differentiator response to acceleration step

Figure 27 shows the fluidic stack attached to the sensor. For convenience, the stacks were divided into two parts, one for the preamp and differentiator and another for the succeeding amplifier stages. The first stack is made up of the laminates shown in Figure 28. Most are standard C-format laminates from Harry Diamond Laboratories. The exceptions are those in the second row with large round holes. These are the differentiator capacitors, which, for the experimented model, have latex diaphragms of 0.15mm thickness, rather than metal diaphragms.

Control Logic

The function of the control logic is to initiate reduction of brake pressure at the correct level of wheel deceleration, and then to initiate increased pressure at the correct level of wheel acceleration. It does this by switching the modulator solenoid on or off in response to the acceleration pressure signal from the fluidic power amplifier (Figure 23).

An adjustable differential-pressure switch and a solenoid-controlled switch comprise the control logic.

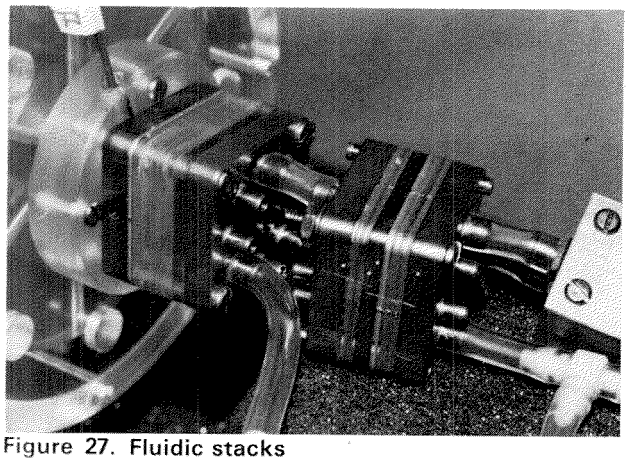

Figure 27. Fluidic stacks

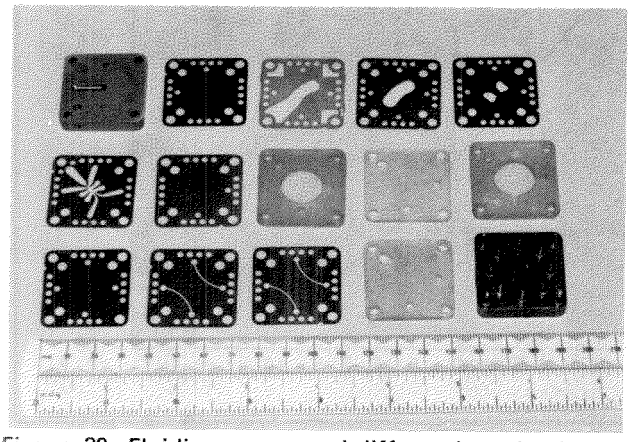

Figure 28. Fluidic preamp and differentiator laminates

The logic switch shown in Figure 29 has adjustable contact spacing, which permits an independent adjustment for deceleration and acceleration logic levels. The solenoid switch, which is closed when the solenoid is energized, is needed to hold the solenoid energized while the logic switch is changing direction between contacting positions.

The relationship between the switch action (control command) and the resulting braking dynamics is shown by the computed data in Figure 30. The cyclic action shown is the intentional result of the nonlinear form of control. The smoothly changing frequency of the limit-cycle rate indicates a stable control system.

Because the sensitivity of the logic switch developed was not compatible with the pressure levels produced by the fluidic circuits, an overall test that included the logic switch could not be run. To do so will require more fluidic amplification ahead of the switch. This modification is in progress.

Modulator

The function of the modulator is to reduce hydraulic pressure rapidly on command from the logic switch and then rapidly apply pressure on another command. The result should be a quick stop without wheel lockup. It is also necessary that the modulator not interfere with normal braking and the antilock action stops when the vehicle operator releases the brake lever.

Since the modulator was not developed as part of this work, the analysis model of the control system assumed a hydraulic type rather than the slower acting pneumatic type, which is probably not capable of operating with delays less than 20ms.

To explain the modulator's operation, the configuration shown in Figure 31 was chosen. It is simple and similar in concept to one developed by Mullard Research and TRRL in England(8).

Referring to Figure 31, normal braking occurs when the solenoid valve is closed. If the wheel is about to lock

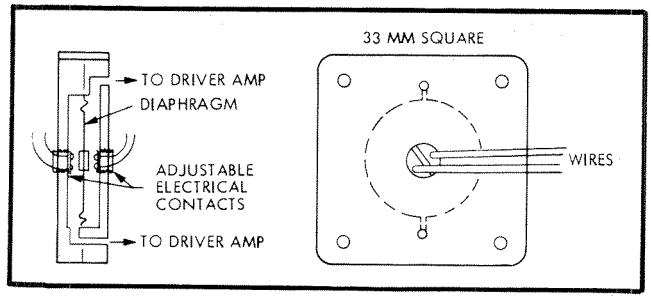

Figure 29. Pressure-operated logic switch

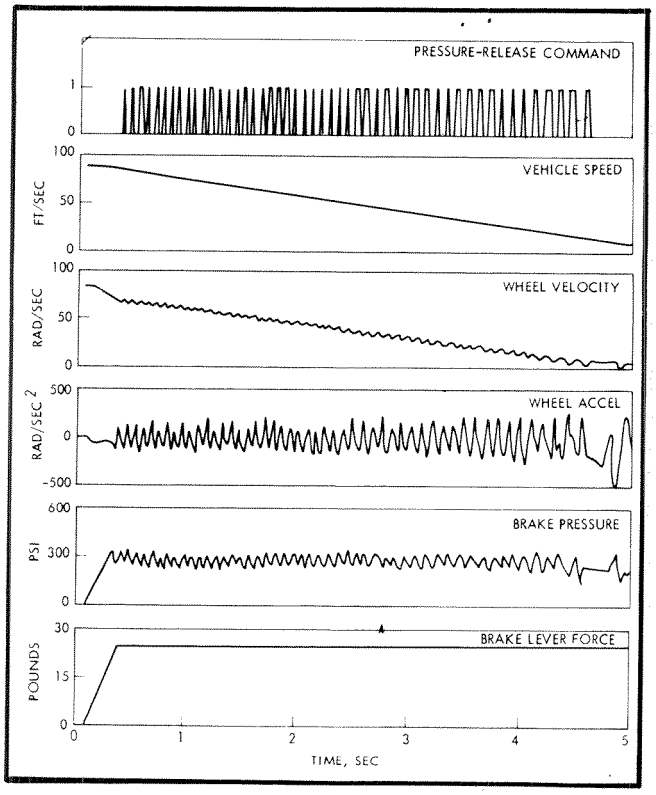

Figure 30. Brake control action

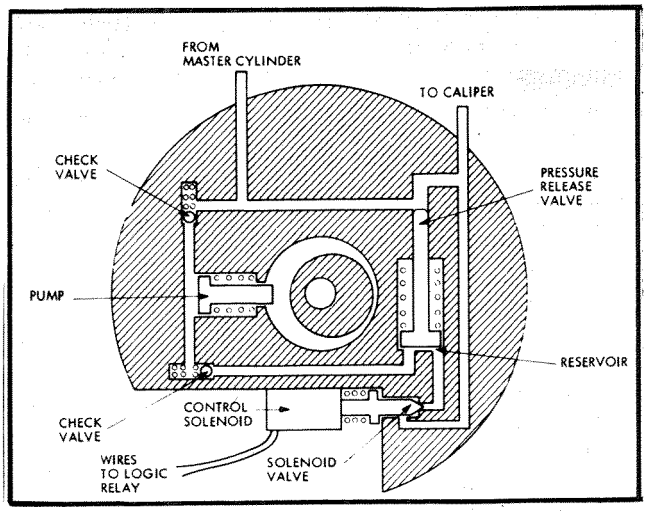

Figure 31. Modulator concept

because of high brake pressure, the solenoid will open the valve, allowing pressure to move the reservoir piston to block the connection between the master cylinder and the caliper and to provide a volume for pressure reduction in the caliper line. The pressure in the caliper line also forces the pump piston against the cam, and some fluid is forced back into the line. When the solenoid is deenergized, the valve closes, causing the reservoir piston to move back, opening the line to the caliper, and causing the pump to force excess fluid back into the line.

Design requirements dictate a fast-acting solenoid and rates of pressure change to match those specified in the System Design section.

Conclusion

The fluidic velocity sensor developed for this application met requirements for simplicity, compactness, and functional capabilities. It adapts well to the fluidic stack concept of fluidic circuitry, and its response time is negligible.

The differentiator must be modified to reduce its time-constant. This should present no particular problem if attention is paid to low-noise component design. Other types of differentiators that would not require moving parts, such as diaphragm capacitors, should be investigated. Also, more signal amplification must be included in the design modifications to operate the logic switch.

Analysis concludes that an acceleration feedback loop will give reasonable stopping distances for the road surfaces considered. Optimization of performance for a greater variety of surfaces would require adaptive techniques using more sophisticated logic involving other parameters, such as wheel slip. Such techniques are within the capabilities of fluidic technology but may be too complex for an inexpensive and compact brake-control system.

Although more work is needed for verification, it appears that a fluidic control system is feasible. The design challenge is to achieve fast response in the fluidic components.

Acknowledgments

This research was carried out by the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, for the National Highway Traffic Safety Administration, Department of Transportation, under contract with Harry Diamond Laboratories.

Accidents of Motorcyclists — Increase of Safety by Technical Measures on the Basis of Knowledge Derived From Real-Life Accidents

M. Danner,
K. Langwieder, and
A. Sporner
HUK-Verband, Automobile Engineering Department

Abstract

Technical safety measures call for detailed knowledge of how accidents occur. Accidents involving two-wheel vehicles pose particular problems in describing the course of the accident and injury severity as well as ascertaining the causes.

Using material covering approximately 3,500 accidents with motorized two-wheelers, a realistic classification system is explained and problems of the different two-wheel categories are shown in this paper.

Experimental and mathematical simulations of the main accident type lead to some suggestions on how to change the motorcycle by adding some safety elements to reduce the injury risk of the driver.

A safety motorcycle is introduced that can improve, in a positive way, the flight path of the driver after an impact without being unrealistic.

Introduction

Safety research for motorcycles, compared with motorcar research, has only begun. Therefore, it is important not to aim at general solutions but to find the main causes of accidents after analyzing the characteristic features of accidents. Only then will it be possible to search for improvements, i.e., new safety elements to reduce the motorcyclists' risk of being injured and to make motorcycling safer in the future.

In the early 1970's, one of the first institutions to record and evaluate motorcycle accidents systematically was the HUK association. This started when the number of motorcycles was lower than ever; for example, in 1972 there were 198,221 motorcycles and, in 1984, 946,572. This early research made it possible to utilize a fundamental basis of accident analysis and experimental simulation that put us in a position to introduce sensible technological measures concerning the decrease of injuries.

To date, more than 3,500 motorcycle accidents have been evaluated and recorded in EDP data files by HUK engineers. These accidents mark the starting position for further experimentation and mathematical models. The study of accidents in which motorcycles were involved shows a continuous downward trend after 1982 (Figure 1). The number of accidents with motor-assisted bicycles and motor-assisted bikes with kick-starters has been decreasing also. Only the accidents with light motorcycles have increased in the past few years. This is due mainly to the conduct of beginner adolescent cyclists.

Nevertheless, there were still 1,548 fatally and 30,544 seriously injured cyclists in 1984, so we need to keep trying to achieve more safety.

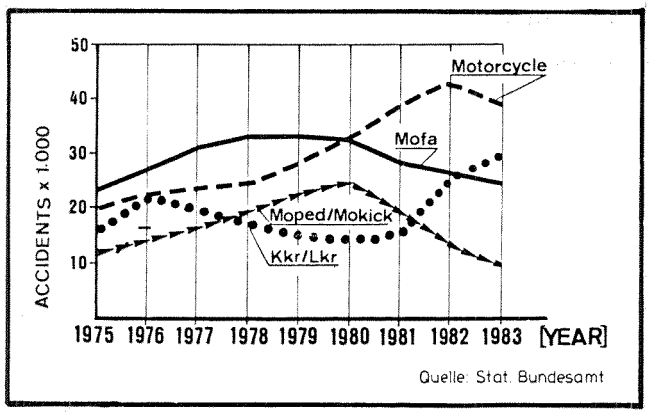

Figure 1. Accident with motorized two-wheelers

Technological Status Quo

Demonstration of accident numbers clearly shows it is not very sensible to evaluate motorcycle accidents invariably and generally. The main distinguishing features are summarized in Figure 2.

At present, there are four different types of motorcycles in the Federal Republic of Germany:

- 15-year-olds can drive a motor-assisted bicycle no faster than 25km/h.
- 16-year-olds can choose between the motor-assisted bicycle with kick-starter (no faster than 40km/h) or the Leichtkraftrad (80km/h).
- From 18 on, one can drive any motorcycle without any limits to the power, apart from the producer's voluntary limitation to 100hp.

The planned introduction of a graded driving license will place motorcycles in the following categories:

- Beginners' motorcycles up to 20kW power
- Motorcycles with unlimited power

There are characteristic accidents in each group of cycles. One has to make differences, especially between the light-powered motorcycles and the heavy ones. It is the exact knowledge of these sequences of motion that is the requirement for acquisition of realistic safety conceptions.

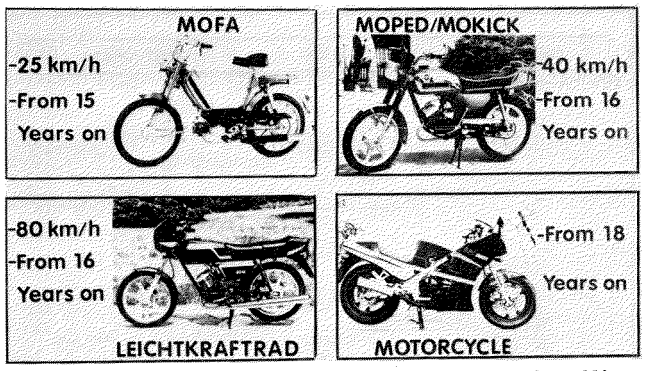

Figure 2. Motorized two-wheel vehicles in West Germany

Problems With Light-powered Motorcycles

From an extensive study of 1,700 accidents with motor-assisted bicycles(1) and from a special analysis of 1,000 accidents with Leichtkrafträdern(2), it can be seen that a main factor is found in the adolescent driver and his conduct. Lack of experience and a high readiness to take risks lead to driving maneuvers often resulting in an accident. Adolescent beginner drivers often recognize critical situations too late.

A further aspect limits the possible technological improvements. The design of motor-assisted bicycles and motor-assisted bikes with kick-starters (Mofa, Moped, Mokicks) hardly permits additional parts on the cycle because they are constructed with the lowest possible weight to achieve competitive power. Furthermore, if safety devices are to fulfill their function, they must have a certain solidity that is difficult to obtain on a light frame.

As we will show, this is especially true for side collisions, which are predominant with smaller motorcycles. This result leads to the conclusion there will be only limited success in technological safety measures for light motorcycles.

On the other hand, not all safety reserves known have been realized so far. Improvements can be found concerning the pedals of the motor-assisted bicycle, which have proved to lead to a higher risk of falling than footrests. Further improvements might be made in the lighting equipment and frame stability of cycles. Also, antimanipulation measures, which make it impossible to increase the power and speed, are among the desirable technological measures known but not yet fulfilled.

Accident Characteristics of Motorcycles

The analysis of all motorcycle accidents reveals sensible starting points, especially for heavy motorcycles, to influence the risk of injuries by technological measures. But first, the main characteristics have to be described that are typical of the motorcycle accident. Generally one can distinguish between single-vehicle accidents and collisions. The single-vehicle accident is being examined presently in research, and some possibilities can be seen already how to technologically influence the single-vehicle accident and the mechanism of injuries during the fall.

As far as collisions are concerned, there are, apart from the rare glance-off collisions, two completely different accident sequences (Figure 3):

- Collision of the vehicle involved against the motorcycle
- Collision of the motorcycle against the other vehicle

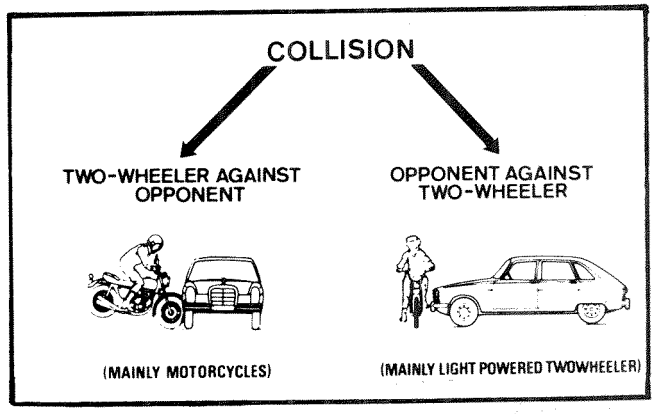

Figure 3. Collisions with two-wheelers

In the first case, the motorcyclist is impacted and run over by the other vehicle. The cyclist's kinetic energy is of less importance, and the sequence of motion is, in some respects, similar to that of an accident with pedestrians. In most cases, the casualty is caught by the other vehicle, hurled onto the bonnet, and eventually dropped. The injuries result mainly from contact with the other vehicle and are in first approximation proportional to its kinetic energy and shape aggressiveness. In other words, the faster and more edged the other vehicle, the more serious the cyclist's injuries. This type of collision happens most often with lighter motorcycles, such as the motor-assisted bicycle and the Moped/Mokick. As already mentioned, effective protective devices are difficult to realize, particularly as the light construction of these cycles does not permit a heavy protective bar in the area of the lower extremities.

In the second case of a collision of the cyclist with another vehicle, the accident sequence is completely different. Here the cyclist's speed and thus his kinetic energy is the central parameter for the motion path and the severity and kind of injuries. In addition, motorcycles and light motorcycles can be found in this group, and thus the requirements for the realization of technological measures are fulfilled.

The expensive and heavy touring motorcycles are ideally suitable for safety elements without giving up the characteristics of a motorcycle. Besides the promising prospects concerning technology, the relative frequency of this accident type—motorcycle against other vehicle—was a reason to deal more thoroughly with these problems. Figure 4, from another research project of the HUK association(3), shows it clearly.

About 60 percent of all accidents with motorcycles and Leichtkrafträdern belong to the category of motorcycle bumps against other vehicles. As for motor-assisted bicycles and Mokicks, this accident type is only 33 percent.

There are two reasons for a closer examination of this accident sequence: the frequency and the promising prospects for technological measures.

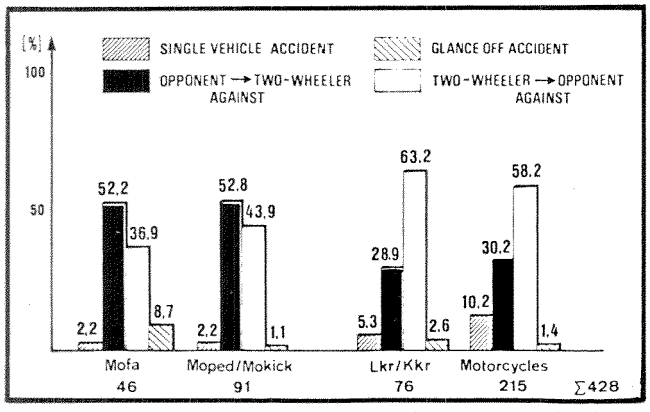

Figure 4. Distribution of motorcycles by main accident types

Accident Sequence

To find starting points for future safety elements, this collision sequence—the bump of a motorcycle against another vehicle—has to be divided into its single phases (Figure 5).

In the first phase—the precollision phase—the preconditions are determined for the kinds of motion in the second phase. The cycle, for reasons of its single-track construction, drive into the collision phase already in a falling way, and thus produce completely different motion sequences that do not occur with motorcar accidents(4).

During the collision phase, main differences can be seen in the direct bump of the cyclist against the other vehicle and in the overflight. This phase is decisive for the seriousness of injuries to the cyclist since the energy is reduced either by the cyclist's hard bump against the other vehicle or by the overflight.

The post-collision phase then shows the results, that is, whether the cyclist has suffered a bump or if he was able to destroy his energy by rolling onto the street.

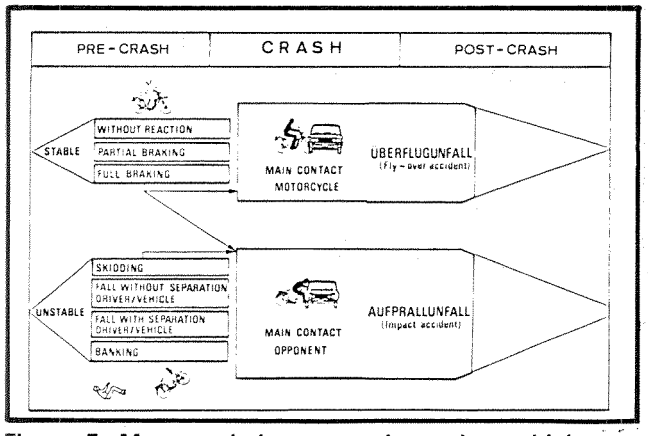

Figure 5. Motorcycle bumps against other vehicles

Motion Sequences and Injury Patterns

Starting points for developing protective measures are of greatest use during the precollision and the collision phase since the course is set here for the decision: bump or overflight.

How decisive this difference is shows the severity of injuries suffered by cyclists, divided into bump and overflight. The real accident sequence shows clearly that safety measures are possible only if they influence the cyclist concerning an overflight with its reduced strain (Figure 6). The seriousness of injuries increases according to an increase in speed, but the rate of seriousness after a bump in any speed range exceeds the rate resulting from overflight.

Which causes can be found for these different motion sequences?

The analysis of the real accident sequence(5) shows that cyclists on special types of motorcycles were more often able to start an overflight. These types were mainly enduros and cross-country motorcycles (Figure 7).

With similar collision speeds and similar vehicles, the cyclists were much more often able to overfly the other vehicle than the cyclists of normal motorcycles and light motorcycles. This result shows there are technological parameters that influence the path of motion. The knowledge of this then led to experimental and mathematical simulations of the possible influencing parameters. Possible parameters might be points that result on the one hand from the geometrical measurements of the motorcycle and on the other hand from defense reactions of the motorcyclist himself. If we first ignore the second point, then there is a variation of the parameters that determine the essential measurements and characteristic features of a motorcycle:

- Height of seat
- Seating position, influenced by the position and form of bench-seat, handlebar, and footrest
- Shape of contact surfaces: tank, handlebar, baffle-pad

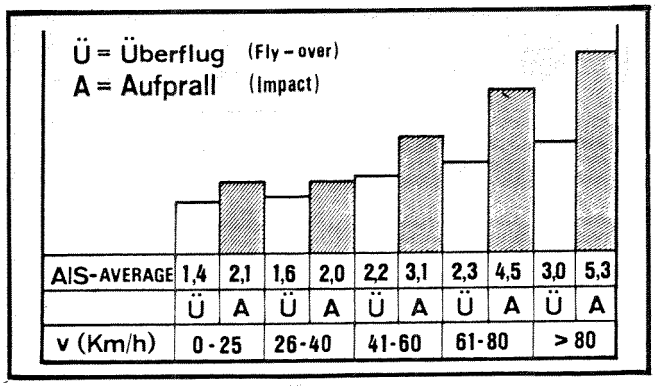

Figure 6. Injury severity with reference to collision speed

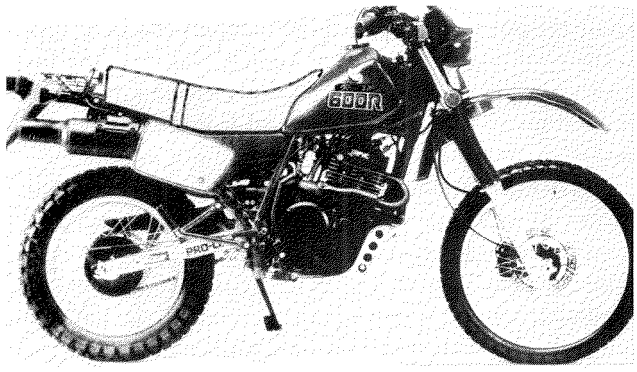

Figure 7. Cross-country motorcycle

Experimental Results

In the experimental part of the research, two series of crash experiments were carried out, which on the one hand very well complemented one another, and, on the other hand, led to important individual results—the real crash and the sledge-test.

In the real test, motorcycles of the same type were driven against different surfaces of a stationary vehicle (Figure 8).

Besides the decelerations of the motorcycle, the decelerations of the head and the chest of a 50th percentile Sierra dummy were measured; by means of high-speed film, a chronological description of all incidents in the first 200ms was made. The measured decelerations of the motorcycle permit the following conclusions (Figure 9):

- The form of deceleration sequence of the motorcycle can be varied theoretically by technological measures because it is determined essentially by the parts—tire, fork, and rim.
- Such a measure would not be successful with regard to the cyclist, since—
  - The cyclist is connected with the motorcycle only by sitting friction; therefore, a soft deceleration cannot be passed on to this body.

The deceleration of the motorcycle is strongly dependent on the geometry and rigidity of the impact point as the deceleration sequence with the rear crash shows.

Here, tire, fork, and rim could not deform themselves in the desired way because the motorcycle has driven under the rear of the car with its front wheel and has been decelerated only by the very hard contact between steering head and bumper. But there was no reaction to this different deceleration to be seen in the dummy's motion sequence.

The deceleration has a neglectable influence on the cyclist's motion path. Yet the chronological description of the single phases provides important hints (Figure 10). In the upper part of the figure, the dummy's activities are noted; in the lower part, the deformations and motions of the motorcycle. Both systems can be related to each other. If you take the case of a collision against the passenger compartment of a motorcar with a collision speed of 50km/h, the most important incidents happen during the first 100ms after t_0. This is a very short time for measures to have an effect, but there is a possibility to influence the cyclist's motion path in this time by varying some of the construction elements. The aim of a safety

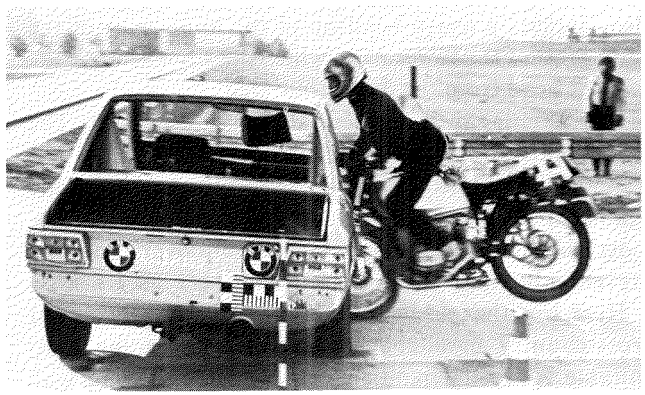

Figure 8. Motorcycle driven against stationary vehicle

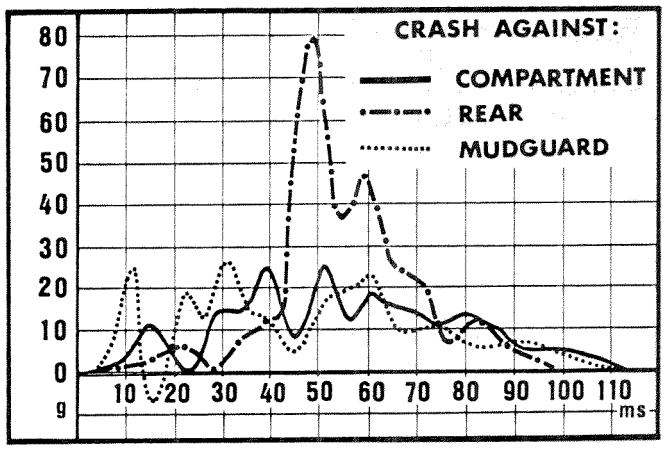

Figure 9. Measured decelerations of motorcycle

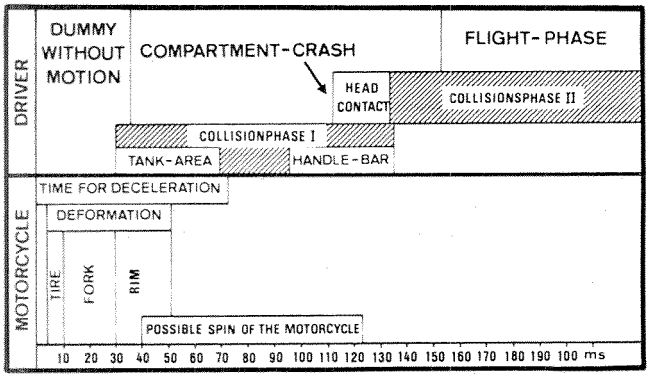

Figure 10. Chronological description of a 50km/h test

conception was to start an overflight and avoid the dangerous area roof edge for the cyclist's head(4).

The first contact after t_0 between dummy and motorcycle takes place after about 30ms. The lower part of the body bumps against the tank. On varying the shape of the tank, it has been shown that a tank-rising angle of about 40° to 45° is the best compromise (Figure 11).

First, a too-flat tank does not exercise any reactive power on the cyclist to raise the center of gravity; second, with a too-flat tank, the impact of the thighs against the handlebar is very hard because there is no speed reduction. A steep tank does raise the cyclist's center of gravity but also involves a heavy rotation of the upper part of the body around the lower part, which does not remove the cyclist's head from the dangerous area.

The handlebar is influential in two respects. The seating position is determined by its shape, and it is responsible for serious thigh injuries if there is an impact against it. The improvement must, therefore, find the most suitable seating position for an overflight and prevent a bump of the lower extremities (Figure 12).

Here, too, the middle course in the form of a touring or cross-country handlebar has proven to be the most suitable. A too-flat handlebar, as can often be found with sporting cycles, makes the cyclist sit in a very low position

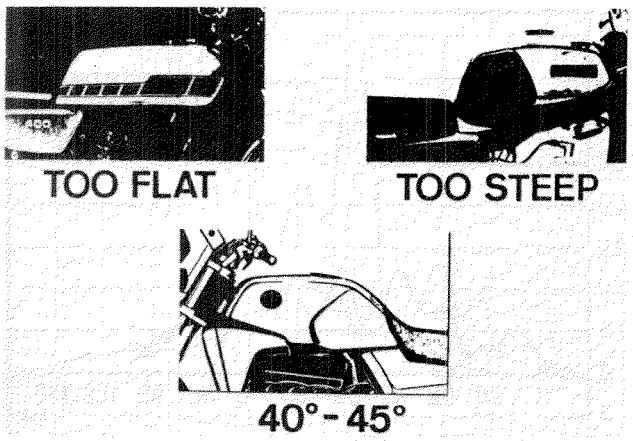

Figure 11. Shapes of fuel tanks

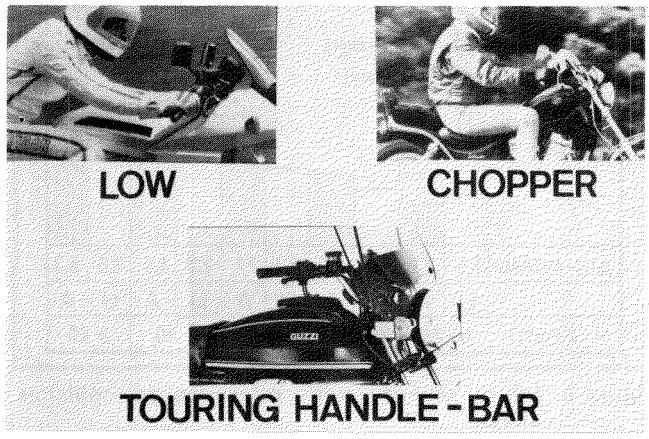

Figure 12. Handlebars

where the position of the head is relatively low in relation to the roof edge of the other vehicle. To raise the low position of the head by technological measures during the first 100ms so the head is removed from the dangerous roof edge area is extremely difficult, if not impossible.

A very high handlebar, also called a chopper handlebar, creates an optimal seating position but unfortunately develops characteristic features during the collision sequence that lead to the body getting caught on the handlebar, thus preventing the desired flight path. In addition, the seating height on chopper motorcycles is very low.

Mathematical Description of the Motion Sequence

All variations described so far have been carried out on a sledge installation with which it was possible to control the effects of the single parameters easily. At the same time, the motion sequence was calculated in a mathematical simulation program to obtain the rising powers and decelerations(5). By means of a converted passenger model with 10 degrees of freedom, it was possible to simulate the powers and motions of a cyclist who bumps against a stationary obstacle—a motorcar (Figure 13).

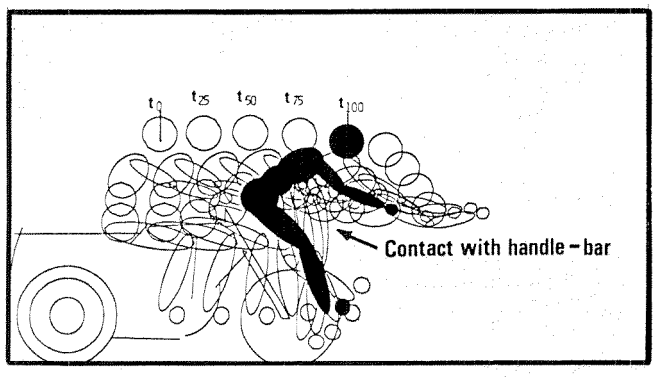

Figure 13. Simulation without leg-pad

Results

The first positive influence on the cyclist's path turned out arithmetically and experimentally after the introduction of baffle-pads in front of the cyclist's legs. Because of these, the bad impact of the legs against the handlebar could be prevented. Not only is the danger of thigh injuries averted, but also the danger of the body being caught on the handlebar—the so-called "flick-knife-effect",—can be eliminated in this way. An optimal function of this pad also includes absolutely necessary support of the entire lower leg. The full effect of the leg-pad could be observed afterward with the combination of a touring handlebar, as in this case the flight path was also influenced (Figures 14 and 15).

The dummy's body stretched and the bumping point of the head was some centimeters higher than it had been in the experiments without pad and with a sporting handlebar.

The possibility of influencing the flight path through the search for safety elements will continue within the HUK accident research.

In the past few years, there was no lack of suggestions on how to fix the cyclist by hold-back devices to the vehicle to minimize the risk of being caught on the bar. Looking at the patent applications, one can find constructions that try, some in a futuristic and others in an amateurish way, to force safety on the motorcycle. The probability of realizing these inventions is very low, as the effect of the new safety element is uncertain or the

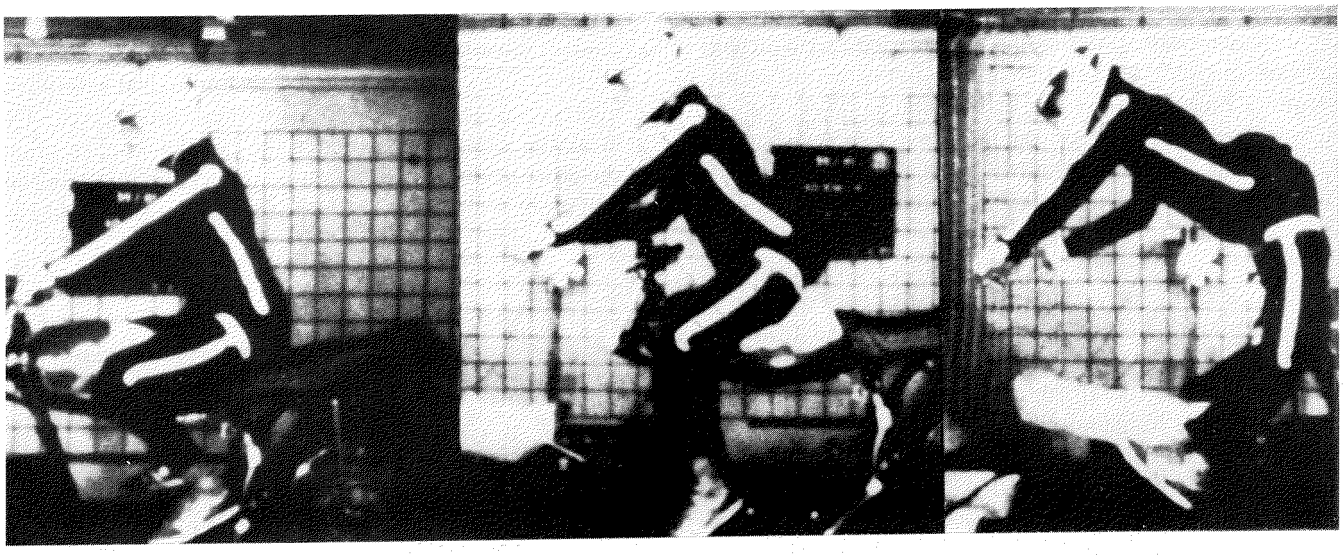

Figure 14. Test without baffle-pad

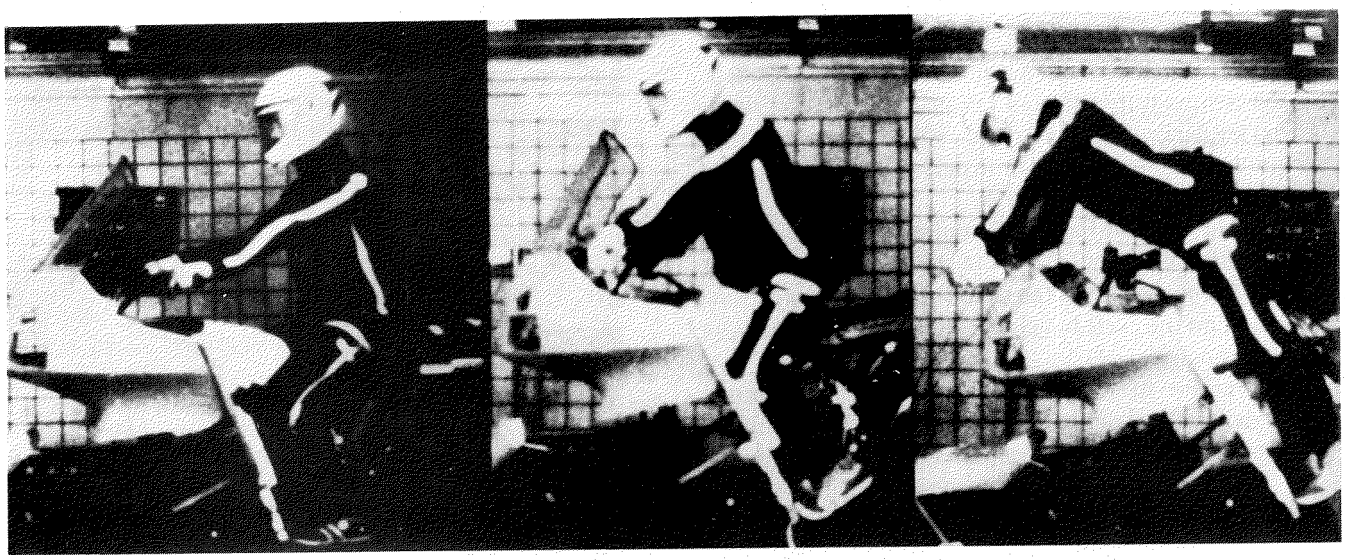

Figure 15. Test with baffle-pad (leg-pad)

conception of the entire motorcycle would have to be changed. The situation might be different with an additional safety element that has actually been applied for the car, namely, the airbag. At present, the airbag is one of the few car-safety elements that could also have an effect on motorcycles, but only if it is used additionally on the basis of the measures discussed and if it does not alter the characteristic features of the motorcycle. To fulfill these requirements, the effect of the airbag has to be extended. Concerning the motorcycle, apart from cushioning the impact, an influence on the flight path might be possible by means of the airbag. Compared to the car airbag, there are other priorities for the motorcycle airbag:

- Influence on the flight path and the driver movement
- Cushioning the impact between driver and other vehicle

Ten years ago, experiments were made(6) with airbags on motorcycles, at that time mainly to protect the cyclist from a bump against the other vehicle. They did not consider an influence on the flight path, so the shape of the airbag at that time had to be oriented to a support. Furthermore, this airbag had a volume of 200:1 and was very difficult to fill.

A further development of those ideas has not become known, except for an inflatable protective suit for the cyclist himself. This has never been able to fulfill its function entirely, since the filling was done with compressed air and therefore took longer than 150ms. This time period is long enough to protect the cyclist in a fall but not in a collision during which the decisive incidents take place during the first 100ms.

Fortunately, airbag technology has developed further because of activities in the motorcar sector and the basic knowledge can be taken over. Today filling the airbag (in its third generation) is done by burning solid fuel and no longer by compressed air (first generation) or by hybrid liquid gas (second generation). This defined burn-up with controlled expansion enables inflating times, dependent on the temperature, of about 30ms(7). As the chronological sequence of a motorcycle collision is known from previous experiments, this time period is long enough to realize a protective effect.

The volume of the bag, in the motorcar about 60:1, will not be sufficient for the motorcycle. Further points of improvement are also in the shape of the airbag and how to pack it on the cycle to achieve the two priority aims as much as possible.

The release of the fuel and the electronic control equipment have deliberately not been mentioned in this list. These partial system components are not yet important. First, it must be shown how the best influence on the cyclist can be achieved by coordinating all measures, and only then can the solution of these partial problems be tackled, which do not seem to cause substantial problems.

On the basis of these theoretical considerations and preparatory work already done, a first series of experiments has been started to observe the effect of the airbag experimentally. Figures 16 and 17 show the simulation of a collision with the sledge facility mentioned previously. The dummy is raised slightly by the airbag and thus is also removed from the dangerous area of the roof edge. In the further course, the airbag can soften the impact as it moves together with the body toward the vehicle.

Further research must show which of the designs mentioned above is most effective for the motorcycle and if there is a realistic chance to influence the flight path. Other problems, such as economical aspects or questions concerning bag activation safety, will have to be examined in following phases. Another future prerequisite would be that airbag system costs are reduced, since prices of about DM2,000 charged for a motorcar airbag are, of course, illusory for motorcycles.

Nevertheless, the search for technological safety elements must not fail because of these hindrances. The more the airbag is accepted in the car, the more certainly the costs of the system might be reduced in the long run, and it is not unrealistic to hope the motorcycle could also gain from this.

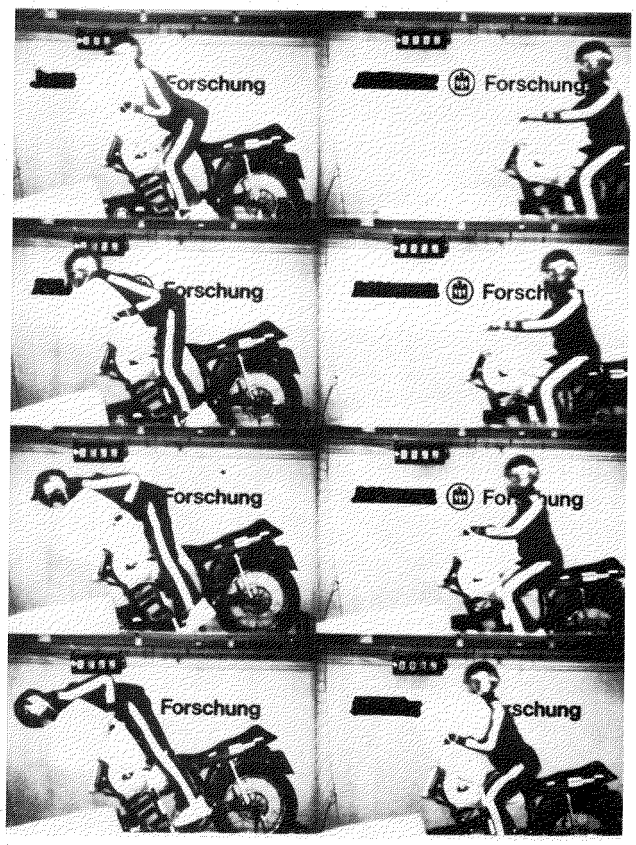

Figure 16. Simulation of collision with sledge facility

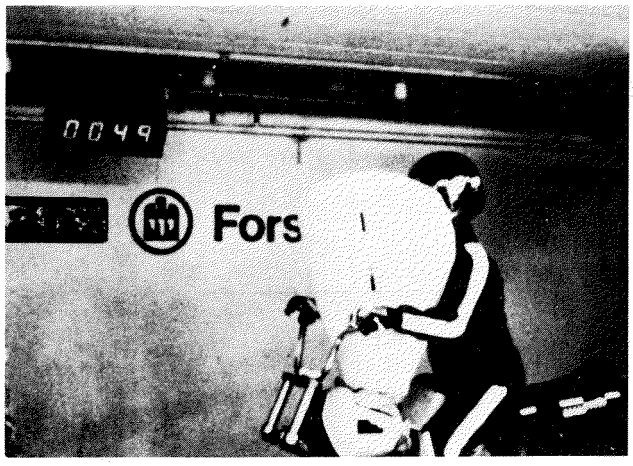

Figure 17. Simulation of collision with sledge facility

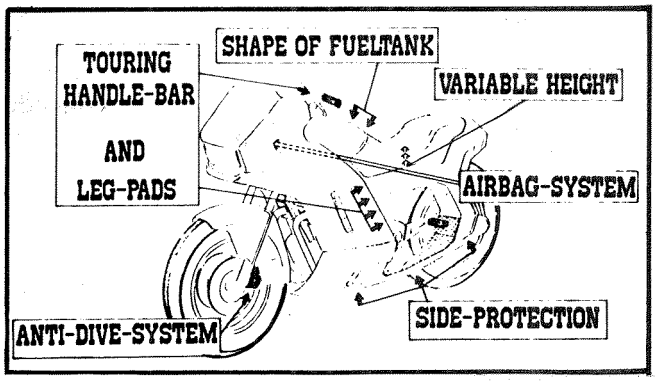

Figure 18. Summary of safety measures

Summary

The complex nature of motorcycle accidents requires an exact knowledge of motion sequences and accident characteristics in the search for technological measures aiming at increased safety. With some types of motorcycles, such as the light-powered motorcycles (Mofa, Moped, and Mokick), there seem to be only limited possibilities to influence safety by technological measures. This depends on their design and frame stability and on the collision mechanism since these motorcycles are impacted mostly by another vehicle.

Concerning heavy motorcycles, the prospects seem more positive, even if there cannot be total protection. Here, the collision of the motorcycle against the other vehicle is dominant and the design of the motorcycle permits additional technological measures that can increase safety.

On the basis of the analysis of real accidents and experimental and mathematical simulations, the following requirements have been worked out.

An effective safety element for the cyclist has to influence his motion path. The risk of being injured can only be reduced if the direct impact against the other vehicle is avoided. The sum of all possible measures is summarized once again in Figure 18. When bumping against a motorcar, the risk of suffering serious or fatal injuries can be reduced essentially by—

- A seating position as high as possible
- A touring handlebar combined with a baffle-pad in front of the legs
- An optimized tank
- An antidive system that does not make the cyclist's body dive during an emergency braking
- Perhaps an additional airbag system

Furthermore, the cyclist's legs can be protected additionally by integrated protective bars in side collisions and falls.

How realistic and easily carried out the discussed technological measures are can be seen in the latest models of some motorcycle producers who have already realized some safety elements. But since an improved protective effect is guaranteed only by the combination of all elements suggested, more developmental work remains to be done. It is to be hoped it won't be long before all technological safety measures already known will be realized.

Conclusion

The authors are indebted to all the member insurance companies of the HUK-Verband, in particular, for making their claims records readily available for this study; to the staff of the AZT for their help with the tests; and to the HUK staff who carried out accident analysis and evaluation work. The authors also owe a debt of gratitude to all the companies whose support made it possible to execute the various tests.

Analysis of Straight Running Stability of Motorcycles

Tomoo Nishimi,
Akira Aoki, and
Tsuyoshi Katayama
Japan Automobile Research Institute, Inc.

Abstract

In this paper, straight running stability without controlling behavior of the rider is analyzed with regard to a mathematical model of 12 degrees of freedom. This model has 2 degrees of freedom concerning leaning movement of upper body and lateral movement of lower body of the rider as well as 4 degrees of freedom of sideslip, yawing, rolling of motorcycle, and rotation of steering handlebar, and 6 degrees of freedom of frame rigidities.

Vibration characteristics of the rider's body influence both weave and wobble modes. Theoretical calculation results by using a mathematical model of 12 degrees of freedom are relatively and qualitatively similar to the results obtained by full-scale running experiments. The extent of quantitative coincidence between theory and experiment, however, varies with types of motorcycles. Parameters concerning vibration characteristics of rider's upper body influence weave mode, and those of rider's lower body influence mainly wobble mode.

Introduction

The studies on handling and stability of rider-motorcycle combinations have recently made remarkable progress. Particularly since the publication of Sharp's study report(1) on the straight-running stability of the rider-motorcycle combination, researchers in several countries have energetically participated in the analysis of the theme by adopting mathematical models(2,3,4,5). It is, however, still not experimentally ascertained fully that the theoretical calculation results using mathematical models can, or to what extent, represent the actual behaviors of the rider-motorcycle combination qualitatively and quantitatively. Furthermore, in addition to the dynamic characteristics of motorcycles, the vibration characteristics of the rider's body influence the straight-running stability of the rider-motorcycle combination, but the work to establish a rider model is still being gathered.

In this paper, a mathematical model of 12 degrees of freedom is introduced in consideration of the degrees of freedom concerning the frame rigidities and the rider's vibration characteristics, and the straight-running stability is studied without considering the controlling behavior of the rider. Six kinds of frame rigidities are adopted for this study as follows: torsional and lateral bending rigidities of the front fork, the main frame, and the rear swing arm. As to the vibration characteristics of the rider's body, leaning movement of the rider's upper body and the lateral movement of the rider's lower body are adopted. These characteristics are measured by means of an excitation bench experiment. Furthermore, a comparison is also made between the results of the theoretical calculation employing a 12 degrees of freedom model and those of the full-scale running experiments.

Vibration Characteristics of Rider's Body

Rider Model

Prior to the measurement of the rider's vibration characteristics, it is necessary to determine the degree of freedom of rider model. Observation of rider's movement on the running motorcycle indicates that leaning movement, lateral movement, yawing movement, and pitching movement are among the degrees of freedom. It is considered that, among them, the former two movements have primary influence on the straight-running stability, while the latter two have only secondary influence.

For the establishment of rider model, a 2 degrees of freedom model is adopted as the first step as shown in Figure 1. In this rider model, the rider's body is divided into two portions—upper and lower bodies. Then, it is assumed the upper body has a degree of freedom to lean with reference to the center of gravity of the lower body, and the lower body has a degree of freedom to make lateral movement only. Both upper and lower bodies are assumed to have concentrated mass, linear spring, and linear damper, respectively, and the moment of inertia of the upper body having the degree of freedom of rotation

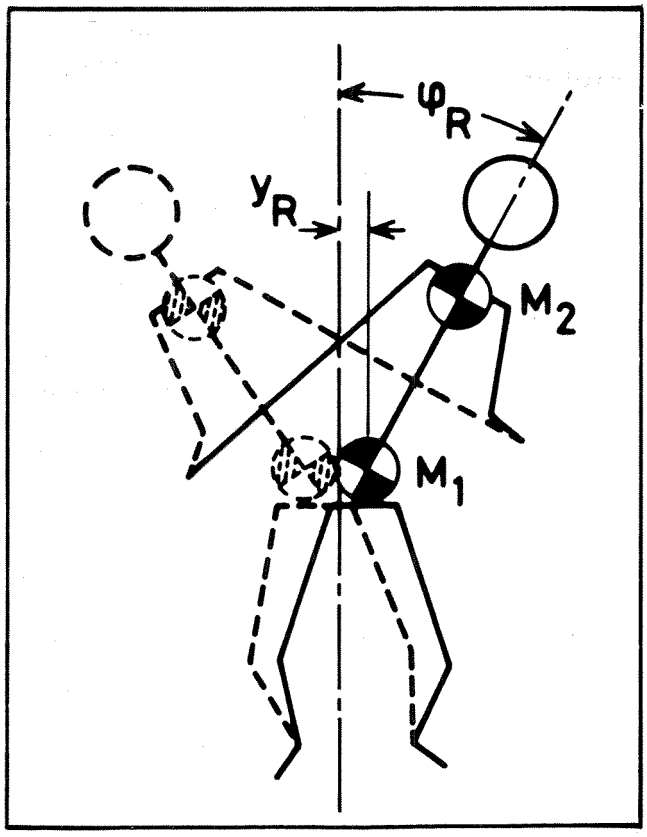

Figure 1. Rider model of vibration characteristics

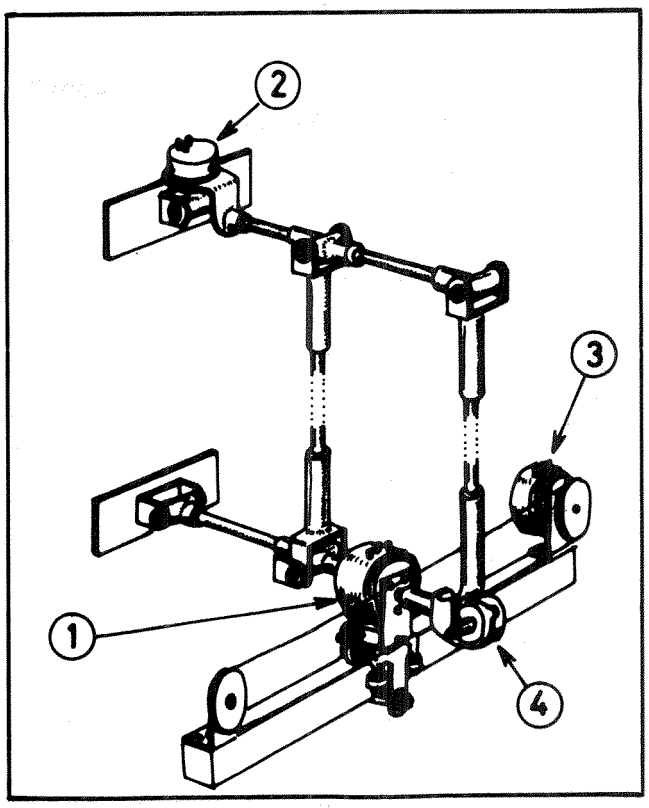

Figure 2. Rider's behavior measurement device

movement shall be represented as the product of squared radius of gyration and mass.

Experimental Method

As mentioned before, a rider on a motorcycle behaves with 4 degrees of freedom. Accordingly, a rider on a motorcycle placed on an excitation bench is also assumed to behave similarly, having these degrees of freedom. Hence, a rider's behavior measurement device as shown in Figure 2 was prepared, and the excitation experiment was performed with it. 1 , 2 , 3 , and 4 in Figure 2 are sensors (potentiometer) for the measurement of leaning angle, yawing angle, lateral movement, and pitching angle. Figure 3 shows a scene of excitation experiment with the device shown in Figure 2 being installed on a motorcycle and a rider.

The experimental method is that, as shown in Figure 4, a motorcycle is excited in rolling movement in reference to the axis through the centers of tire contact of front and rear wheels. The handlebar of the motorcycle was fixed in a straight-running position to restrict the movement of the motorcycle to rolling movement only. The Japan Automobile Research Institute (JARI) hydraulic excitation device(6) is used as an excitation source. The rider subjected to the excitation experiment was not given any special instructions and was allowed to behave freely.

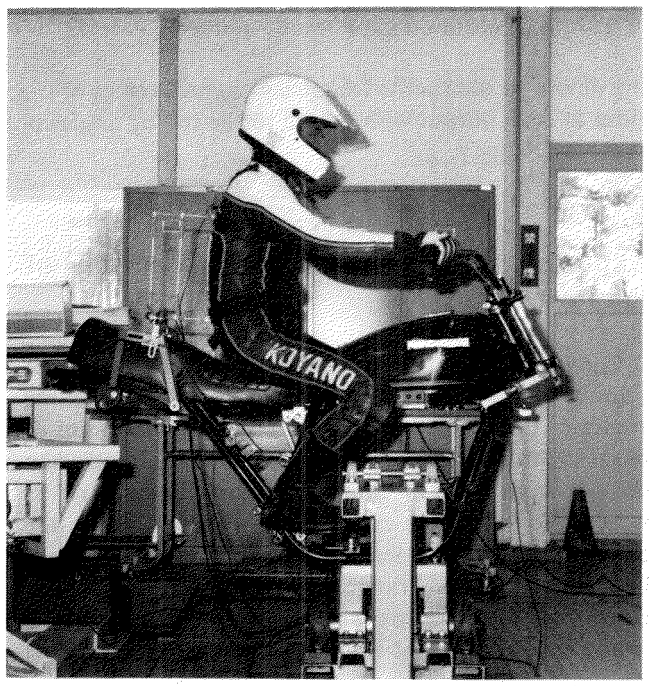

Figure 3. Scene of excitation experiment

Excitation method was a frequency sweep. The range of excitation frequencies was from 0.1 to 10Hz, and the amplitude of excitation was about 0.5°. The data collected from this experiment were processed by the data process-

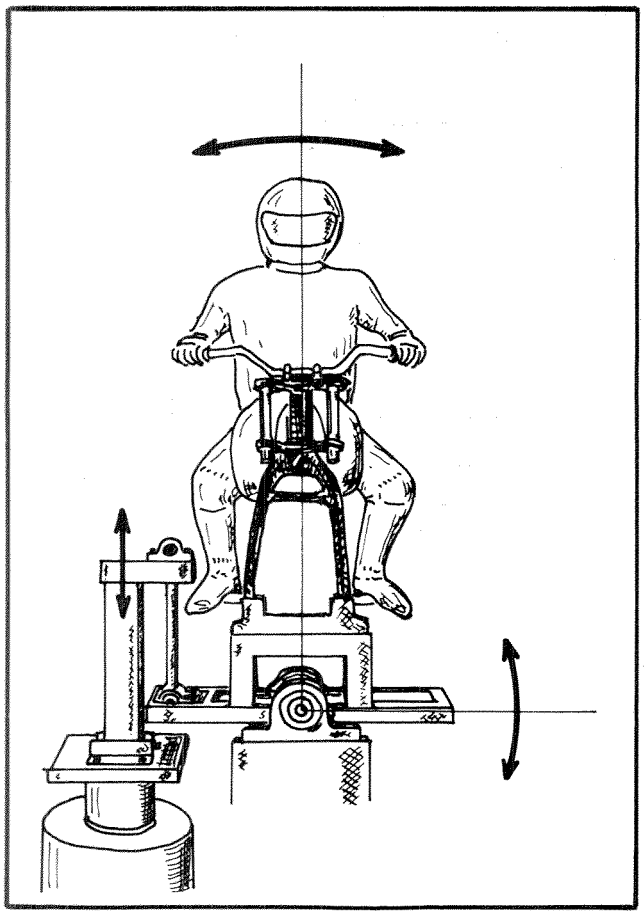

Figure 4. Excitation experiment method

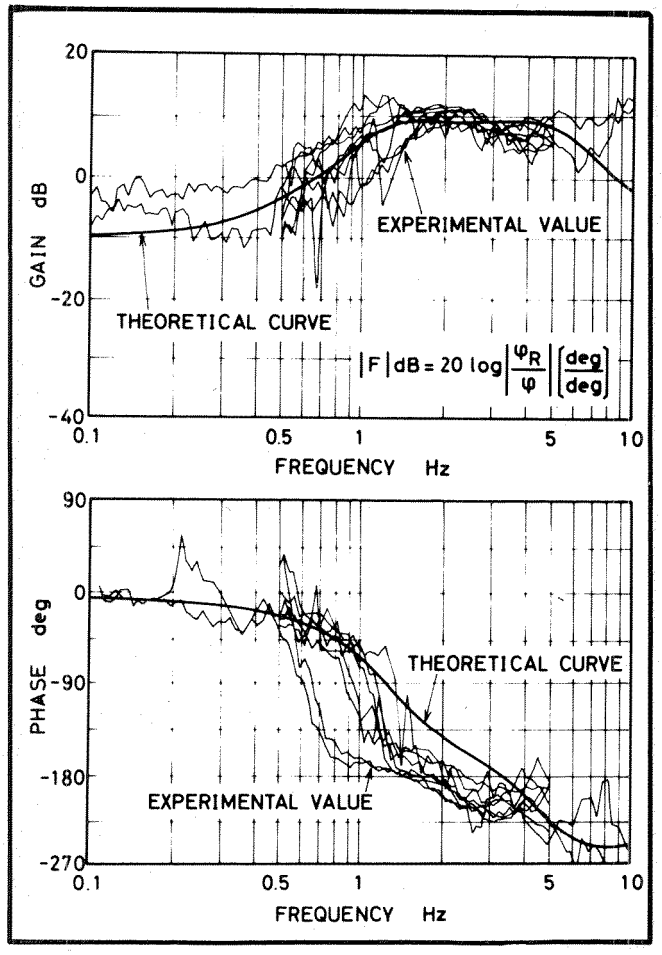

Figure 5. Measurement results of rider's vibration characteristics (without control of lean angle by rider)

ing device to obtain the frequency characteristics of the rider at each output with regard to the rolling angles of motorcycle body.

Experimental Results and Estimation of Parameters

Figures 5 and 6 show the measurement results of leaning angles of the rider with regard to the rolling angles of the motorcycle frame. From the viewpoint of phase characteristics, Figure 5 shows the condition when the rider conducted no controlling behavior (eight riders were subjected to the experiment). Figure 6 shows the condition that the rider behaved to control his upper body in a frequency range between 0.1 and 1.5Hz (six riders were subjected to the experiment). For this study, it is decided that straight-running stability is to be studied without considering the controlling behavior of the rider, and, therefore, values of parameters concerning the vibration characteristics of the rider's body were estimated, based on the measurement results indicated in Figure 5 and those of corresponding lateral movements (see Figure 7).

The estimation of values of these parameters are explained in the following. In the rider model (Figure 1), it is assumed that mass, position of center of gravity and moment of inertia of upper body, and mass and position of center of gravity of lower body are known, and that rigidities and damping of upper and lower bodies are unknown. Values of mass, position of center of gravity, and moment of inertia of upper and lower bodies are obtained by calculation using the data collected by JARI from living bodies and the data concerning individual portions of bodies collected by Chandler(7) from cadavers.

Figure 8 shows mass distribution in human bodies. Percentage value of each portion indicated in Figure 8 is a mean value of the data collected from six human bodies. Using this figure, the upper body comprises four portions, namely, head, chest, upper arms, and lower arms. Total mass of these portions amounts to 32.7 percent of total mass of human body. The lower body comprises three portions, namely, hips, upper limbs, and lower limbs. Their total mass amounts to 63.5 percent of total mass of human body. Here, it is considered that as hands or feet are rested on the handlebar or the footrest, respectively, these are not included in upper or lower bodies.

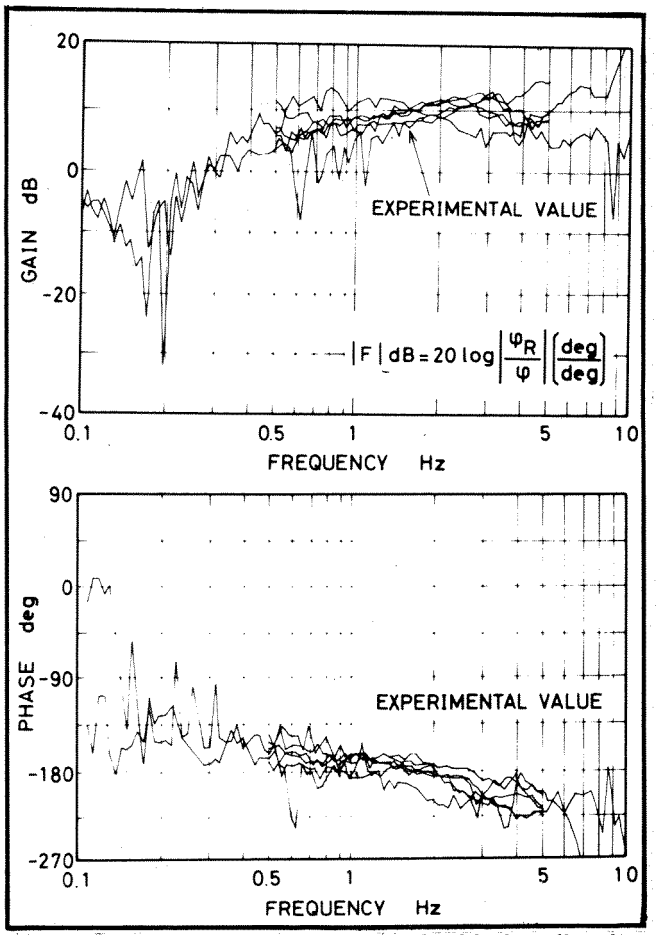

Figure 6. Measurement results of rider's vibration characteristics (with control of lean angle by rider)

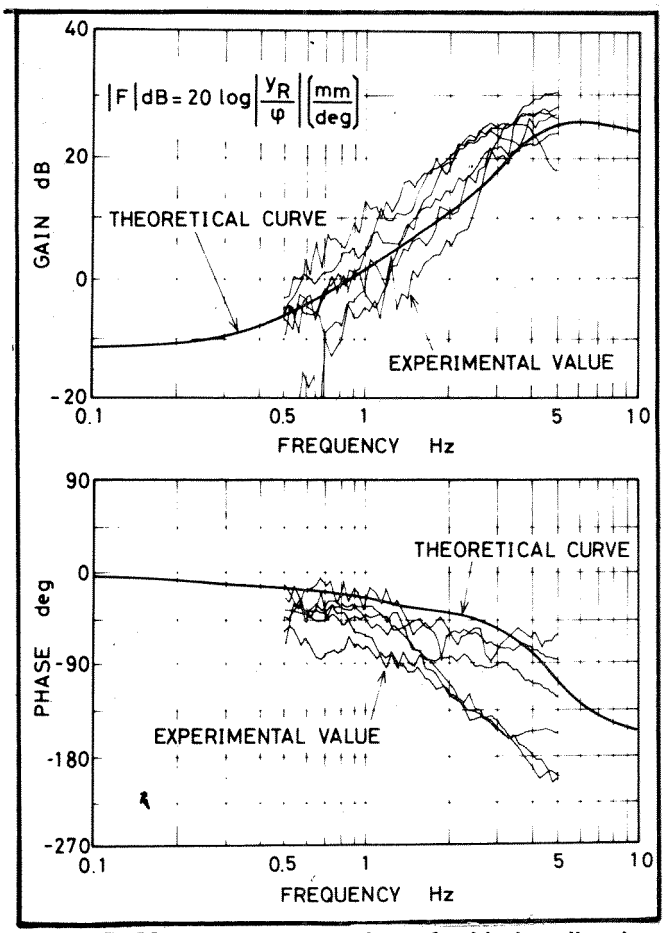

Figure 7. Measurement results of rider's vibration characteristics (without control of lateral movement by rider)

Centers of gravity of upper and lower bodies and moment of inertia of upper body are obtained through the process shown in Figure 9 from the rider's riding position determined by means of photographic measurement; centers of gravity are located at the one-third point from the top end regarding head and at the middle points regarding chest, upper arm, lower arm, hips, upper limb, and lower limb. From these values, centers of gravity of upper and lower bodies and moment of inertia of upper body can be calculated.

By using the above-mentioned data and applying transfer function of Equations (1) and (2), fixed curves in Figures 5 and 7 were obtained. In this case, each parameter value is indicated in Table 1. Parameter values of rigidities and damping of upper and lower bodies were selected from among those obtained by calculation by changing parameters step by step to make theoretical curves coincide with experimental results.

$$F_{y_R}(s) = \frac{y_R(s)}{\Phi(s)} =$$

$$K_R \frac{1 + A_{R1}s + A_{R2}s^2 + A_{R3}s^3 + A_{R4}s^4}{1 + B_1 s + B_2 s^2 + B_3 s^3 + B_4 s^4}$$

$$F_{\Phi_R}(s) = \frac{\Phi_R(s)}{\Phi(s)} =$$

$B_2 = M_2(h_2^2+e_2^2)/(K_2-M_2h_2g) + (M_1+M_2)/K_1 + C_1C_2/\{(K_2-M_2h_2g)\}$

$B_3 = C_2(M_1+M_2)/\{K_1(K_2-M_2h_2g)\}+ M_2(h_2^2+e_2^2)C_1/\{K_1(K_2-M_2h_2g)\}$

$B_4 = M_2\{(M_1+M_2)e_2^2+M_1h_2^2\}/\{K_1(K_2-M_2h_2g)\}$

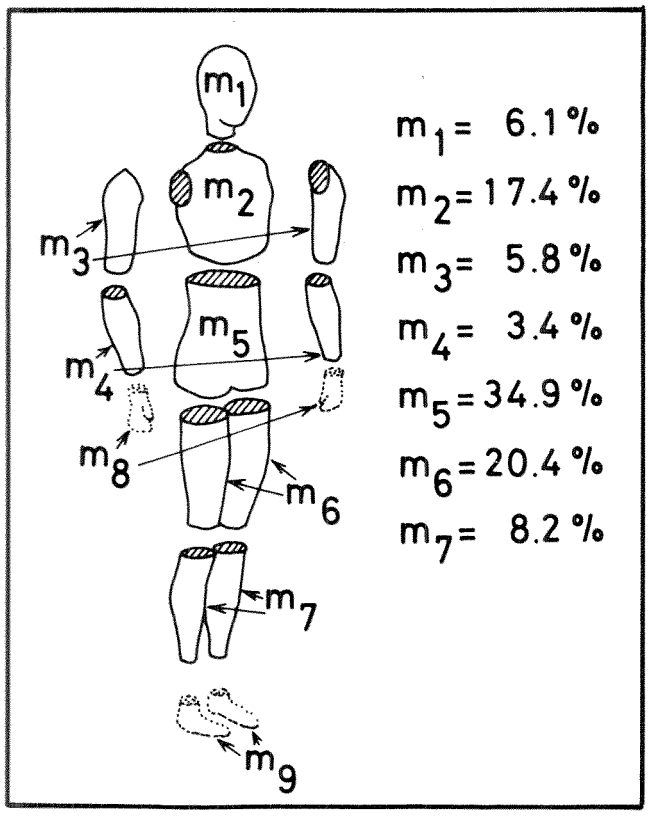

Figure 8. Rider's mass distribution(7)

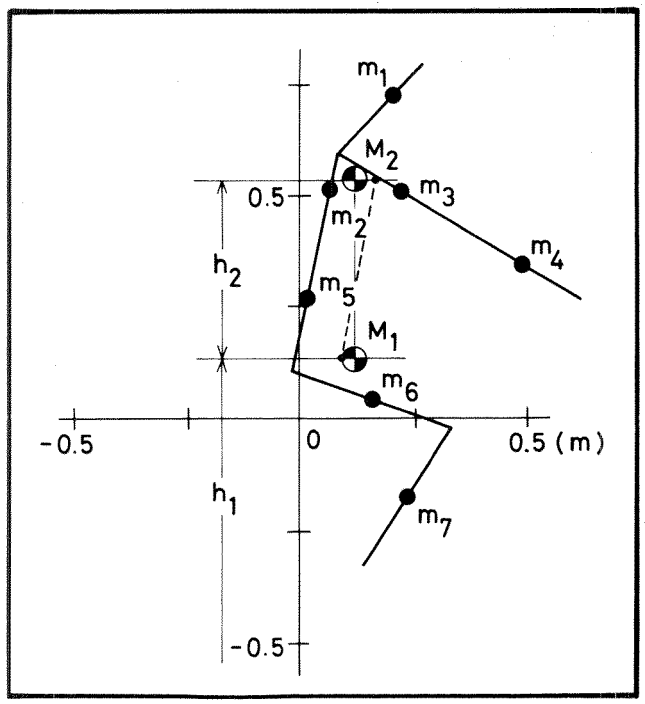

Figure 9. Mass centers (centers of gravity) of rider's upper body, lower body, and other portions

Table 1. Data of rider's vibration characteristics

M_1	4.2	kgs^2m^{-1}
M_2	2.0	kgs^2m^{-1}
e_2^2	0.041	m^2
h_1	0.87	m
h_2	0.39	m
K_1	3916.	kgm^{-1}
C_1	100.	$kgsm^{-1}$
K_2	32.0	$kgmrad^{-1}$
C_2	3.0	$kgmsrad^{-1}$

Then, natural frequencies and damping ratios in the directions of leaning and lateral movements are obtained by using these parameter values as follows:

- Natural frequency (leaning movement)—1.27Hz
- Natural frequency (lateral movement)—4.0Hz
- Damping ratio (leaning movement)—0.489
- Damping ratio (lateral movement)—0.321

For the analysis of straight-running stability, parameter values concerning rider's vibration characteristics obtained by calculation in accordance with these data are to be used hereafter.

Analysis of Straight-Running Stability

Mathematical Model

The mathematical models treated in this paper are based on some assumptions and simplifications as explained below.

The rider-motorcycle combination shall be composed of six masses as follows: (i) front wheel, (ii) front frame (excluding front wheel), (iii) rear wheel, (iv) main frame (motorcycle complete excluding (i), (ii), and (iii)), (v) upper body of the rider, and (vi) lower body of the rider.

The mathematical models shall be of 12 degrees of freedom that comprises: 4 degrees of freedom of sideslip, yawing, and rolling of motorcycle, and rotation of steering handlebar; 6 degrees of freedom of frame rigidities, i.e., torsional and lateral bending rigidities of front fork, main frame, and rear swing arm; and 2 degrees of freedom of leaning movement of upper body and lateral movement of lower body of the rider as mentioned before.

The controlling force inputted by the rider to the motorcycle shall be steer torque only. The controlling behavior of the rider shall not exist. Therefore, the rider-motorcycle combination, during running, is treated as one-input open-loop system.

The range of movement treated in this paper is limited within linear domain, and, therefore, each displacement is very small. The sine of angular displacement equals angular displacement itself, and the cosine of angular displacement equals 1. The product of each displacement and its differential shall be so small as to be negligible.

The motorcycle shall run on a flat and level road surface at a steady speed. The influence of pitching and vertical movement of motorcycle shall be negligible.

The front and rear wheels are represented as circular discs contacting the ground at a point, and no longitudinal slip shall exist. Forces and moments applied to the tires shall be lateral forces due to sideslip angle and camber angle, aligning moment, and overturning moment only. The transient characteristics of the tires shall be represented in the relaxation length (first-order lag element).

When steer angle is zero and motorcycle is in the upright position, all centers of gravity of six masses in the rider-motorcycle combination shall be located within plane XZ, a longitudinal plane of symmetry.

The rotating shaft of the flywheel of the engine shall be mounted on the motorcycle transversely to the longitudinal plane.

The rider-motorcycle combination shall run through stationary air. The change in load distributions on front and rear wheels during running shall be influenced by aerodynamic drag, lift, and pitching moment only. The change in tire characteristics due to change of loads on front and rear wheels shall be taken into consideration.

Aerodynamic force and moment that influence lateral movement of the rider-motorcycle combination shall be only the lateral force and the yawing moment due to air sideslip angle (sign is in reverse to frame sideslip angle) corresponding to frame sideslip angle.

Disturbance forces due to crosswind, uneven road surface, and driving and braking forces shall not be considered.

Torsional axis of the front fork, as shown in Figure 10, shall be in parallel with the steering axis and through the center of the front wheel axle. The front frame is composed of handlebar, steering head, steering stem, and front fork, which are considered to be connected with the front wheel through torsional springs.

The lateral bending of the front fork is in such a way as shown in Figure 10. The relation between bending deflection and deflection angle is assumed as follows:

$$\phi'_f = -C_{\phi f} s_f$$

Torsional axis of the main frame, as shown in Figure 10, shall be through the pivot of the rear swing arm, and torsion shall take place in reference to an axis perpen-

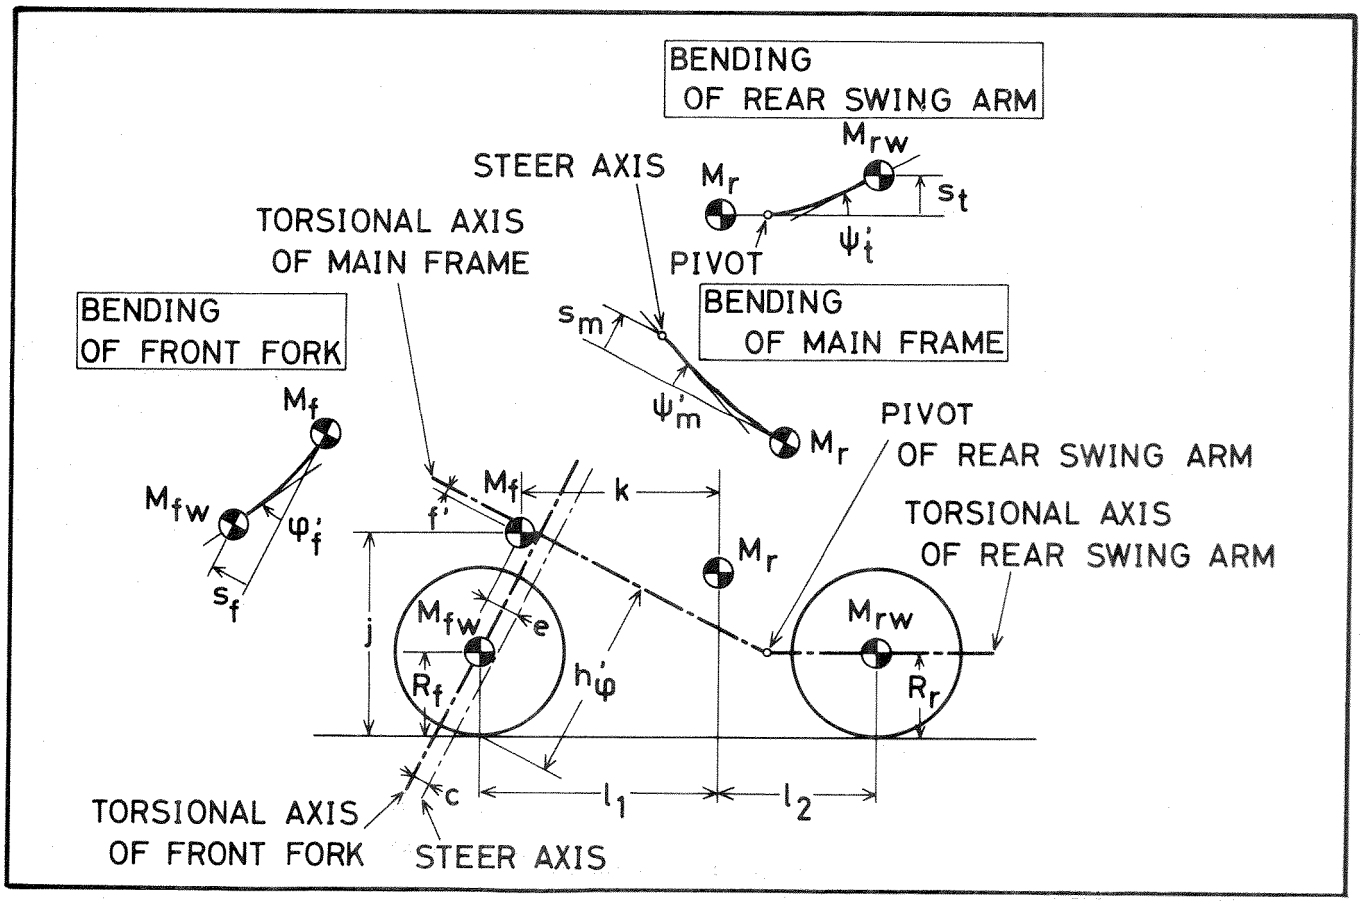

Figure 10. Motorcycle model in consideration of frame rigidities

dicular to the steering axis. The actual torsional axis, however, is slightly deviated upward from the said axis, but the said axis is adopted in this paper as an assumption for convenience.

The lateral bending of the main frame shall occur within a plane perpendicular to the steering axis as shown in Figure 10. The deflection angle, as in the front fork, shall be proportional to the deflection.

$(\psi'_m C_{\psi'_m} s_m)$

Torsional axis of the rear swing arm, as shown in Figure 10, shall be through the center of gravity of the rear wheel and in parallel with the road surface.

Bending of the rear swing arm shall take place within a plane perpendicular to the rear wheel including the torsional axis of the rear swing arm. As in the front fork and the main frame, the deflection angle shall be proportional to the displacement.

$(\psi'_t = -C_{\psi'_t} s_t)$

Rider model shall be as mentioned before.

The right-hand orthogonal axis system is adopted. Origin of the coordinate system can be represented as the projection point A of the center of gravity of the main frame on the road surface when the motorcycle is in an upright position as shown in Figure 11. The movement of the rider-motorcycle combination shall be represented in relation to the coordinate system mentioned below with point A as origin.

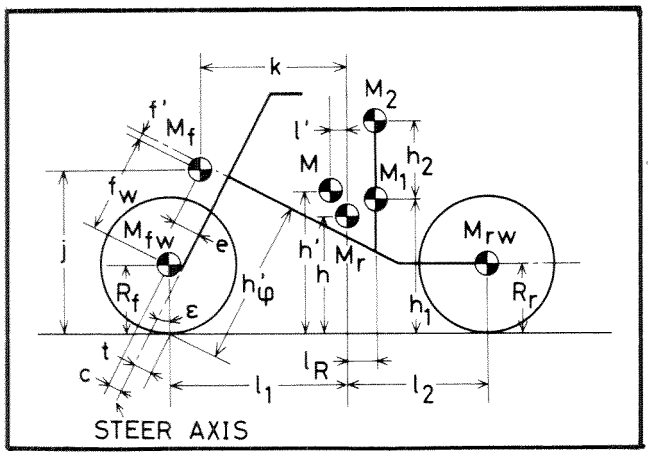

Figure 11. Motorcycle model in consideration of frame rigidities and rider's vibration characteristics

First, a coordinate system of $OX_0Y_0Z_0$, which is fixed to the road surface, shall be adopted. Here, X_0 means forward direction coordinate, Y_0 sideward direction coordinate, and Z_0 downward direction coordinate. Next, a coordinate system of $OX_1Y_1Z_1$ shall be obtained by rotating the frame by yaw angle ψ in reference to OZ_0 axis. Subsequently, a coordinate system of $OX_2Y_2Z_2$ shall be obtained by rotating the above coordinate system by roll angle ϕ in reference to OX_1 axis. Thus obtained coordinate system is fixed to the main frame. Further, rotation by caster angle ε in reference to OY_2 axis obtains a coordinate system of $OX_3Y_3Z_3$, rotation by angle ϕ'_m in reference to the torsional axis of the main frame obtains a coordinate system of $OX_4Y_4Z_4$, deflection by s_m perpendicular to the torsional axis of the main frame (i.e., rotation by the deflection angle ψ'_m) obtains a coordinate system of $OX_5Y_5Z_5$, and rotation by steer angle δ obtains a coordinate system of $OX_6Y_6Z_6$. This coordinate system is fixed to the front frame (excluding front wheel). When this coordinate system is rotated by ψ'_f in reference to the torsional axis of the front fork, which is in parallel with the steering axis and through the center of the front wheel axle, a coordinate system of $OX_7Y_7Z_7$ is obtained. In addition to the above, deflection by s_f perpendicular to the torsional axis (i.e., rotation by deflection angle ϕ'_f) obtains a coordinate system of $OX_8Y_8Z_8$. This coordinate system is fixed to the front wheel axle.

Meanwhile, rotation of coordinate system of $OX_2Y_2Z_2$ by ϕ'_t in reference to the assumed torsional axis of the rear swing arm to be in parallel with the road surface and through the rear wheel axle obtains a coordinate system of $OX_9Y_9Z_9$, and, in addition to this, deflection by s_t perpendicular to the said torsional axis (i.e., rotation by deflection angle ψ'_t) obtains a coordinate system of $OX_{10}Y_{10}Z_{10}$. This coordinate system is fixed to the rear wheel axle.

When the coordinate system of $OX_2Y_2Z_2$ is moved in the direction of Y_2-axis by lateral displacement y_R of rider's lower body, a coordinate system of $OX_{11}Y_{11}Z_{11}$ is obtained. In addition to the above, rotation by lean angle ϕ_R of rider's upper body in reference to X_{11} axis obtains a coordinate system of $OX_{12}Y_{12}Z_{12}$.

Equations of motion have been introduced by using Lagrange's equation as shown in Appendix I.

Measurement of Parameters

All the values of parameters used in the equations of motion, except for polar moment of inertia of engine flywheel, are based on the actually measured values. (Polar moment of inertia of the flywheel was calculated by assuming it to be 150 percent of the moment of inertia of the rear wheel in reference to its axle.) Individual values of parameters used for calculations in this paper are shown in Appendix II (see (8) through (12) for the measurement methods and results.).

Results and Discussion

It has been known that the vibration modes that govern the straight-running stability of the rider-motorcycle combination are three modes, namely, capsize, weave, and wobble modes. Capsize mode is an aperiodical rolling motion of the frame construction that occurs at a speed of about 50km/h or more causing slight instability. Weave mode is a coupled motion between yawing and

rolling motions of the frame construction. This is a vibration mode (1-4Hz) whose natural frequency increases in accordance with the increase of vehicle speed. Wobble mode is a high frequency vibration mode (6-10Hz) of the steering system, and its natural frequency does not vary with vehicle speed. In this paper, weave and wobble modes are studied as important modes that have influence on straight-running stability, and the influence of rider's vibration characteristics on straight-running stability is explained and compared with experimental results.

Figures 12 through 15 are comparisons between theoretical calculation results of 10 degrees of freedom and 12 degrees of freedom models and running experiment results with regard to four motorcycles. 10 degrees of freedom model means addition of 6 degrees of freedom concerning the frame rigidities to 4 degrees of freedom model, and 12 degrees of freedom model means addition of 2 degrees of freedom concerning rider's vibration characteristics to 10 degrees of freedom model. The running experiment results show damped natural frequencies and damping ratios of weave and wobble modes obtained from the frequency response characteristics of yaw angular velocity in accordance with the steer torque input measured by the pulse response method(13) (see Appendix III). The piston displacement

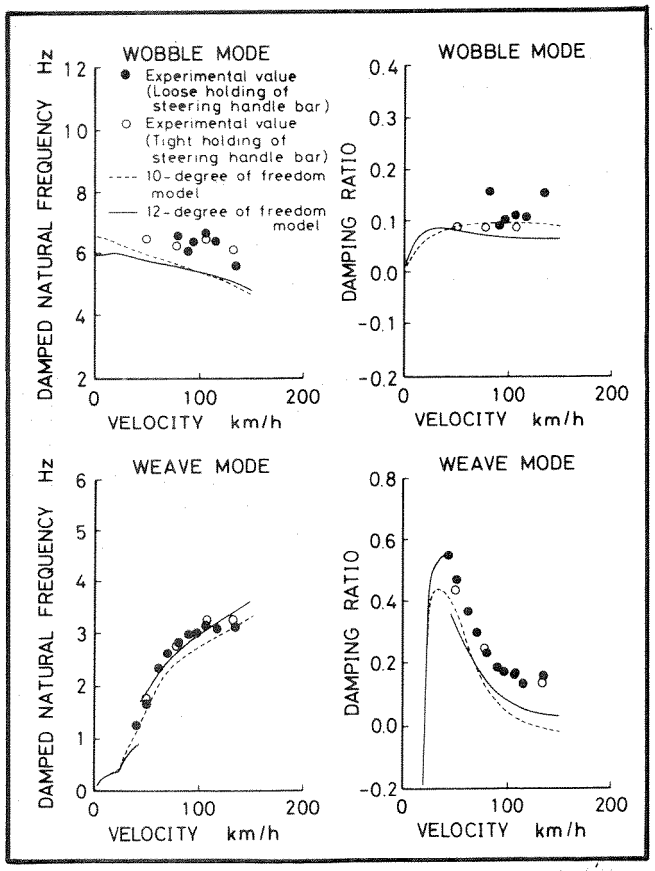

Figure 12. Comparison between theoretical calculation results and experimental results (experiment motorcycle A)

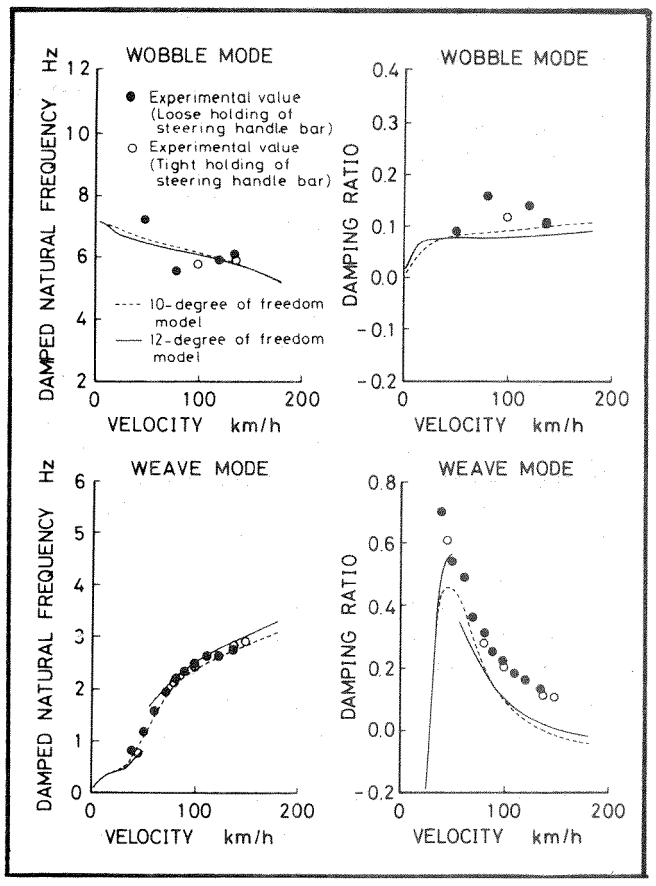

Figure 13. Comparison between theoretical calculation results and experimental results (experiment motorcycle B)

of four motorcycles A, B, C, and D are 400cc, 750cc, 250cc, and 1,100cc, respectively.

First of all, influence of rider's vibration characteristics is studied. Among the theoretical calculation results concerning 12 degrees of freedom model where rider's vibration characteristics are considered, the particularly notable matter is that weave mode shows discontinuity in a vehicle speed range between 40 and 60km/h. This is supposedly because, in this vehicle speed range, damped natural frequencies and damping ratios of weave mode are close to those of rider's lean mode causing interference between them. Weave mode and lean mode shall be determined by eigenvectors in the said range of vehicle speed.

Upon comparison between 10 degrees of freedom model and 12 degrees of freedom model with regard to the theoretical calculation results, it is recognized that rider's vibration characteristics have influence on weave and wobble modes; in weave mode, damped natural frequencies are increased in upper medium vehicle speed range, and damping ratios are decreased in medium vehicle speed range and increased in upper vehicle speed range. As to the damping ratios of the weave mode, the influence of rider's vibration characteristics given to medium- or small-size motorcycles such as A or C is

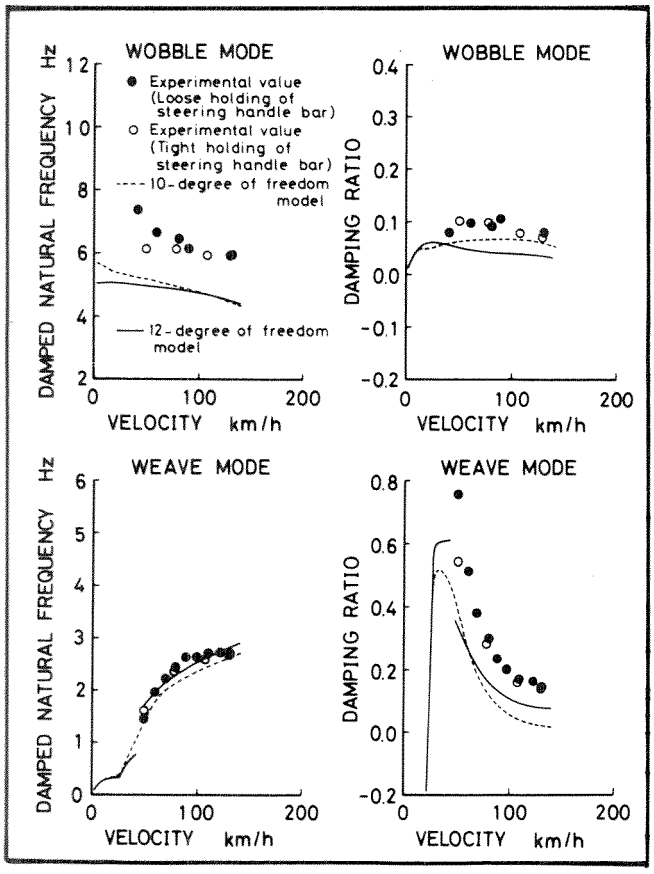

Figure 14. Comparison between theoretical calculation results and experimental results (experiment motorcycle C)

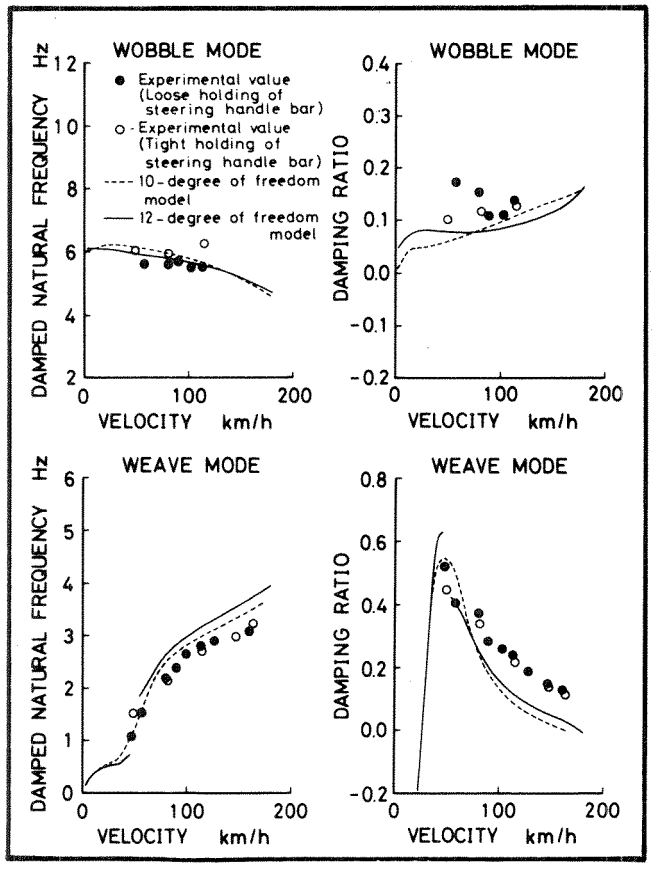

Figure 15. Comparison between theoretical calculation results and experimental results (experiment motorcycle D)

larger than that given to big motorcycles such as B or D. However, in the wobble mode, damped natural frequencies are decreased in lower medium vehicle speed range and damping ratios are increased in lower vehicle speed range and decreased in upper medium vehicle speed range.

When theoretical calculation results are composed with experimental results, the theoretical calculation results of the damped natural frequencies of weave mode in 12 degrees of freedom model coincide with the experimental results in medium- or small-size motorcycle A or C or in big-size motorcycle B, while the theoretical calculation results in motorcycle D, which is bigger than B in dimensions, show larger values than the experimental results in both 10 degrees of freedom and 12 degrees of freedom models. As to the damping ratio of weave mode, the theoretical calculation results of 12 degrees of freedom model show better coincidence with the experimental results of each motorcycle in the upper medium vehicle speed range than those of 10 degrees of freedom model. The discontinuity of weave mode in the lower medium vehicle speed range that was found in the theoretical calculation results has not been proved by the experimental results yet. As to the damped natural frequency of wobble mode, the experimental results show some scattering in their values, but the theoretical calculation results in big-size motorcycles B and D coincide with the experimental results very well, while the theoretical calculation results are somewhat smaller than the experimental results in medium- or small-size motorcycles A and C. As to the damping ratio of wobble mode, like in the damped natural frequency, the experimental results show some scattering in their values, but the theoretical calculation results in each motorcycle are regarded to coincide with many of the experimental results. As mentioned above, in each motorcycle, the theoretical calculation results of 12 degrees of freedom model coincide comparatively and qualitatively with the experimental results.

Finally, the influences of individual parameters on the rider's vibration characteristics are stated below. Table 2 shows the extent of influences of individual parameters concerning the rider's vibration characteristics in 12 degrees of freedom model on weave and wobble modes.

In this table, circle-marked items mean "large influence," triangle-marked items mean "noticeable influence," and hyphen-marked items mean "negligible influence." Table 2 is made with the theoretical calculation results obtained from four experiment motorcycles by changing parameters used for the calculations by ±10 percent, ±20 percent, and ±50 percent from their standard

Table 2. Influences of individual parameters on rider's vibration characteristics

	Weave Mode	Wobble Mode
Mass and moment of inertia	○	○
Rigidity of upper body	○	—
Damping ratio of upper body	○	—
Rigidity of lower body	△	△
Damping ratio of lower body	—	△
Height of center of gravity of upper body	○	—
Longitudinal location of rider's center of gravity	○	○

values within a vehicle speed range from 40 to 160km/h. From this table, it is understandable that the parameters concerning rider's upper body influence weave mode, and those concerning rider's lower body influence mainly wobble mode.

Conclusion

Straight-running stability of the rider-motorcycle combination with 12 degrees of freedom mathematical model was analyzed in consideration of rider's vibration characteristics and rigidities of frame. Before the analysis, rider's vibration characteristics were measured first by the excitation experiment, and the parameter values of 2 degrees of freedom concerning the leaning of rider's upper body and lateral movement of rider's lower body were obtained. Then, the theoretical calculation results of the said 12 degrees of freedom model were compared with the running experiment results. Next, the influences of individual parameters concerning the rider's vibration characteristics on the straight-running stability were studied.

Main conclusions reached in this research are as follows:

- Rider's vibration characteristics influence weave and wobble modes.
- Theoretical calculation results of 12 degrees of freedom model coincide comparatively and qualitatively with running experiment results, but the extents of quantitative coincidence vary with the types of motorcycle.
- Parameters concerning vibration characteristics of rider's upper body influence weave mode, and those of rider's lower body mainly influence wobble mode.

Acknowledgments

This paper is a part of the results of the research conducted by JARI for a long period of time under commission and financed by the Japan Automobile Manufacturers Association Inc. (JAMA). We would like to express our appreciation to the Motorcycle Handling and Stability Working Group of JAMA, which supplied experiment motorcycles and test riders for the running experiments of this research. We, also, are deeply thankful to the staff of JARI, Messrs. Motomiya, Sato, Okayama, Mogi, and Kobayashi, for the great cooperation extended to us for this research in the measurements of frame characteristics, tire characteristics, aerodynamic characteristics, etc.

This research was conducted independently by JARI, which is responsible for all results, knowledge, and other contents of this paper.

Folksam Traffic Safety Group, Karolinska Hospital, Stockholm, Sweden

Abstract

Injuries to motorcyclists lead to permanent disability more often than injuries to car occupants (10 percent versus 6 percent). The use of helmets has decreased the risk of head injuries. Other injuries leading to permanent disability are currently concentrated on the extremities (about 70 percent). Almost all are due to fractures located in joints where knees, elbows, shoulders, and ankles are the most common spots.

In a study based on 200 motorcycle accidents, it was shown the existing protective clothing had no effect on the incidence of fractures to knees, elbows, and shoulders. Based on that knowledge, a new motorcycle suit was constructed. The main goal was to find a shock-absorbing material to protect knees, elbows, and shoulders in an accident. Confor Foam, a medium-density urethane foam, was tested and found to possess relevant characteristics. The material was tested under experimental conditions and found to be sensitive to dampness and temperature with an optimal shock-absorbing effect of +10° to +30°C. Experimental studies on the protective effect of different kinds of leather indicated the importance of continuous tests of leather when manufacturing motorcycle suits. The protective effects of the safety suit have been studied in real-life accidents during a 2-year period. A preliminary study showed the number of fractures decreased significantly.

Background

Driving a motorcycle is one of the most dangerous modes of travel. Efforts to reduce the injury risk must concern both active and passive safety. Until recently, passive safety development was concentrated on head protection and motorcycle design. It has, however, been shown that leather clothing has some effect on the incidence and severity of soft tissue injuries among motorcyclists. Feldkamp and Junghans(1) showed severe injuries were reduced by protective clothing. The reduction of soft tissue injuries was also shown by Aldman(2) and Engström(3).

A motorcycle helmet consists of a shell and an inner shock-absorbing layer to prevent injurious forces from reaching the head(1). A motorcycle suit is to some extent constructed in the same way. It consists of a covering layer of leather and a shock-absorbing material on vulnerable spots of the body, knees, elbows, and shoulders(2). To be comfortable, the suit must have special properties to allow necessary movements. This concerns especially the shock-absorbing material covering the joints. The leather must be supple and also strong.

The insurance company Folksam, together with the Department of Traffic Safety at Chalmers University of Technology, has constructed a suit based on the knowledge from real accidents. This suit will be presented in this study, which consists of the following:

- Evaluation of the properties of the leather and shock-absorbing material
- Evaluation of the effect of the constructed suit on bodily injuries

Evaluation of the Properties of the Leather and Shock-absorbing Material

Objectives

The objectives of this study were to evaluate the following:

- Movements of the body in case of an accident
- Essential differences between different types of leather and between samples of the same type of leather
- Influence of temperature on the shock-absorbing material
- Influence of dampness on the shock-absorbing material
- Shock-absorbing ability in different suits with and without shock-absorbing material

Material and Method

The movements of the motorcyclist when meeting with an accident were studied by viewing films of real accidents in motorcycle races.

Goatskin and bovine leather were studied in laboratory conditions regarding wear and tear, strength, and firmness.

The shock-absorbing material Confor Foam, which is a polyurethane foam, was tested in real traffic at different

temperatures and under laboratory conditions. The temperature was measured inside the material and on the inner and outer surfaces.

The shock-absorbing ability was tested under laboratory conditions at different temperatures and with varying degrees of dampness.

Result

In single motorcycle accidents, the motorcyclist normally skids on the road. During that time, the motorcyclist will normally be in the same position. The moment the motorcyclist reaches the verge of the road, he/she will start to roll over or roll around. The vertical fall is normally low, but the horizontal speed can be very fast. This type of accident causes no dangerous injuries unless the victim hits something or the protective clothes are torn into pieces, which may result in contaminated wounds.

In a collision, the impact on the body can be hard and produce fractures to unprotected limbs. To protect the body from injuries, leather and Confor Foam should be used.

Test of Leather

Leather from goats and oxen was tested as to wear and tear. Pieces of leather were mounted on dummies that simulated an elbow or shoulder, e.g., a sharp and a round part of the body. The leather was subjected to a rotating road surface. The thickness of the different test pieces was measured (see Table 1). On an average, bovine leather was thinner than goatskin.

Table 1. Thickness of different test pieces of leather

Type of Leather	Thickness					
	Micrometer with Point			Micrometer with Plate		
	C_1 Min.	C_1 Max.	C_1 Mean	C_2 Min.	C_2 Max.	C_2 Mean
Bovine	0.75	1.05	0.91	1.10	1.50	1.35
Goat	0.85	1.15	0.98	1.10	1.50	1.39

Table 2 shows the score for damage to leather. Table 3 shows the sum of the scores for 12 tests on the elbow dummy and 7 tests on the shoulder. It can be seen that the difference in resistance to grinding and tearing between goatskin and bovine leather is small.

Wear and tear strength of different test pieces of leather was also tested as to penetration. The results of this test can be seen in Figure 1. The worse the wear and tear strength, the larger the diameter of the hole. Bovine leather Type I had a mean thickness of 0.64mm, Type II, 0.90mm, and Type IV, 1.14mm, measured with a pointed micrometer. Corresponding values measured with a

Table 2. Scores for different types of grinding and tearing damages to test pieces of leather

Type of Damage	Score	Description of Damage
Grinding damage	1	Superficial damage, superficial scratches
	2	Superficial damage, deep scratches
	3	Deep scratches, small scratch holes
	4	Deep scratches, long scratch holes
	5	Large scratch holes
Tearing damage	0	No damage
	1	Small damage
	2	Extensive damage

Table 3. Grinding and tearing damage on different pieces of leather

Body Area	Type of Leather	Grinding Damage	Tearing Damage
Elbow (12)	Goat	26	4
	Bovine	34	2
Shoulder (7)	Goat	13	0
	Bovine	15	2

micrometer with a plate were 1.03, 1.36, and 1.60mm. Goat leather had a mean thickness of 0.98mm measured with a pointed micrometer and 1.37mm with a micrometer with a plate.

Figure 1 shows that bovine leather Types I and IV had a lower resistance to penetration compared with Type II and goatskin. This means it is possible to distinguish between good and bad quality by using a penetration test.

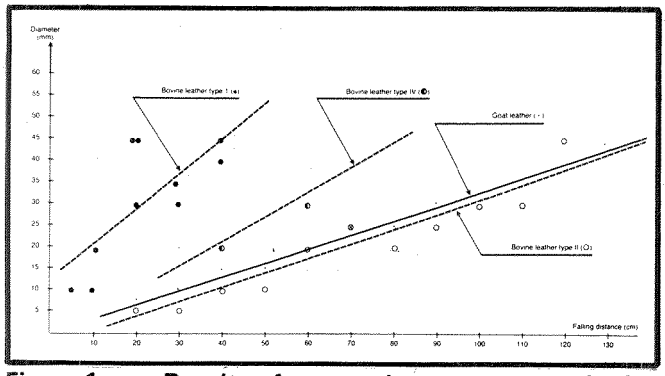

Figure 1. Results of penetration tests summarized by linear regression

Test of Shock-absorbing Material

Table 4 shows the temperature inside and on the inner and outer surface of the Confor Foam, measured in a real traffic situation for different air temperatures.

The mean temperature measured over the shock-absorbing material varies between +11.1° C and +26.3° C in the test situation at a temperature in the air of 0° C and +21° C when driving in urban traffic and at 110km/h. It is

Table 4. Temperature inside, on outer and inner surface of the shock-absorbing material measured in real traffic situations

	Air Temperature 0°C		21°C	
	Urban Traffic	110km/h	Urban Traffic	110km/h
Outer surface	9.4	5.4	24.3	22.6
Inside the confor foam	13.5	10.3	26.1	25.0
Inner surface	21.1	17.7	28.6	28.3
Mean	14.7	11.1	26.3	25.3

thus desirable that the shock-absorbing material keep its shock-absorbing ability between +10° C and +.30° C.

Figure 2 shows the shock-absorbing ability for Confor Foam at different temperatures inside the material. One plate of Confor Foam (15mm) was exposed to falling weights of 5kg and plane impact area (177cm^2). It can be seen that Confor Foam has good shock-absorbing properties between +.20° C and +30° C at which temperature a motorcycle is normally driven.

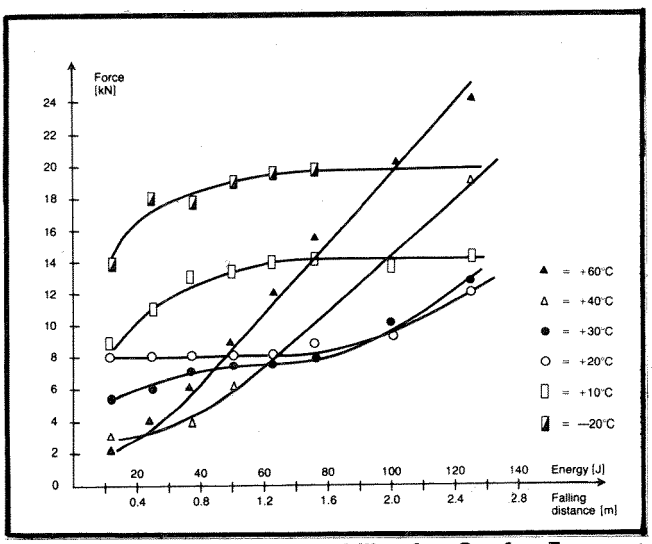

Figure 2. Shock-absorbing ability for Confor Foam at different temperatures

Figure 3 shows the shock-absorbing ability at different concentrations of water. Confor Foam loses its shock-absorbing ability at a low concentration of water.

Testing of the Shock-absorbing Ability in Different Motorcycle Suits

A suit with Confor Foam on knees, elbows, and shoulders was compared with a suit without any shock-absorbing material. The test was made on the knee area as to shock-absorbing ability.

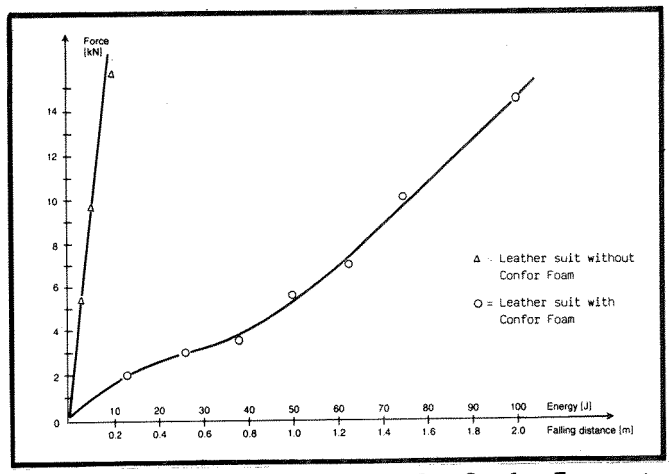

Figure 3. Shock-absorbing ability for Confor Foam at different concentrations of water

The knee areas of the two suits were exposed to two falling weights of 5kg of different shapes: one with a spherical impact area with a diameter of 45mm and the other with a plane surface with a diameter of 40mm. These two weights were dropped at different heights. The force directed toward the underlying surface was measured. The temperature was +20°, and the relative air humidity was 60 percent.

Figure 4 shows the force curves for a plane impact area and Figure 5 for a spherical one. It can be seen that a suit without shock-absorbing material has a linear force curve. The protective effect is thus very low (<5.0J) and cannot be measured in this study.

The suit with shock-absorbing material, on the other hand, can absorb energy. At energy levels between 10 and 30J, the curves are not linear, which means the shock-absorbing material will absorb energy until it touches the bottom and the relation between force and energy becomes linear.

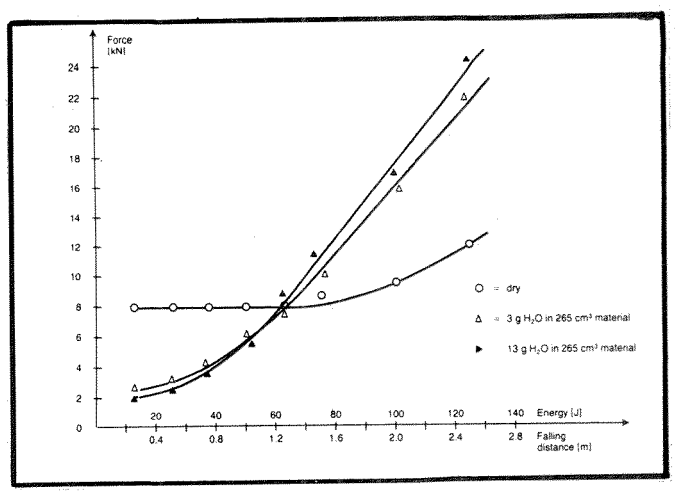

Figure 4. Force as a function of falling distance for two different suits with and without Confor Foam—plane impact area

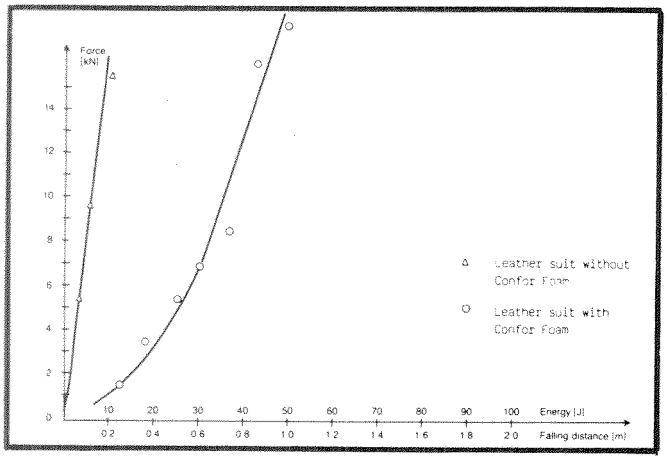

Figure 5. Force as a function of falling distance for two different suits with and without Confor Foam—spherical impact area

Evaluation of the Effect of the Constructed Suit on Bodily Injuries

Method and Material

Among policyholders having a motorcycle insured with the Folksam Group (about 35,000), several studies have been conducted.

- A sample of 1,001 motorcyclists, irrespective of their being involved in an accident or not
- A sample of motorcyclists injured in 1983 and 1984
- All motorcyclists that received a medical disability >10 percent from 1976 to 1982

Insurance records were completed with questionnaires on how the motorcyclists were dressed.

Results

Table 5 shows that 10.3 percent of the injured motorcyclists suffered a medical disability of >10 percent. The corresponding figure for car occupants was 6.2 percent.

Table 5. Relative frequency of permanent disability >10 percent for motorcyclists compared with car occupants

Type of Road User	Relative Frequency of Permanent Disability >10%
Motorcyclist	10.3%
Car occupant	6.2%

Table 6 shows contact areas for motorcyclists involved in accidents. Contact areas are defined as areas that came into contact with different surfaces during the accident and were recognized by the motorcyclist or could be seen on the clothing after the accident.

Table 6. Soft tissue injuries per contact area related to body region and type of clothing among motorcyclists involved in accidents for both injured and uninjured, head injuries omitted

Body Region	Not Covered by Leather	Covered by Leather	N
Knee, elbow shoulder	77.9%	24.4%	203
Other body regions	(4/17)	(5/21)	38

In Table 6, it can be seen that soft tissue injuries are less common among those wearing leather clothing compared to those wearing other types (significant). It is also shown that contact areas are concentrated on the joints of the extremities, e.g., knees, elbows, and shoulders.

Table 7 shows that contamination of soft tissue injuries is more uncommon to areas covered by leather compared to uncovered areas (significant). Table 8 shows 46 percent of all injuries that led to medical disability were located at shoulders, elbows, and knees. The most common location was the knee (32 percent).

Table 7. Soft tissue injuries; contaminated and not contaminated for areas covered and not covered by leather

Type of Clothing	Contaminated	Not Contaminated	All
Leather	4	34	38
Not leather	28	29	57
All	32	63	95

Table 8. Number of injuries causing medical disability >10 percent) among motorcyclists injured in 1976-1983. N = 93

Localization	Number	Localization	Number
Shoulder	7	Head (incl. face)	10
Elbow	5	Vertebrae	6
Soft tissue, leg	1	Spinal cord, nerves	4
Knee	30	Hands (incl. joints)	12
		Viscera	1
		Pelvis	2
		Ankle	14
Total	43		50

The suit with Confor Foam was introduced in 1983. During 1983 and 1984, about 12,000 safety suits were sold in Sweden. These suits fulfilled certain regulations according to Folksam specifications, built on the experimental studies described earlier.

Two studies in 1984 analyzed the injury-reducing effects of the safety suit. One was a sample among those wearing safety suits whether they were involved in an accident or not.

Table 9 shows a comparison between all kinds of clothing except safety suits. Contact areas were defined as described in Table 5. It can be seen there is a big difference between safety suits and other types of clothing. The difference is highly significant.

Table 9. Number of contacts between driver and any surface in an accident to areas protected by safety suit (knees, elbows, shoulders) and number of fractures to these areas

	No Safety Suits	Safety Suit
Number of contacts	187	78
Number of fractures	25 (13.4%)	1 (1.3%)

In the other study, a sample of injured motorcyclists was examined. All fractures were divided into two groups: fractures located in areas protected by the suit with shock-absorbing material and fractures located in other areas (except the head).

Table 10 shows the ratio between protected and unprotected areas is different for those wearing a safety suit compared to those not wearing one. The difference in distribution is highly significant.

Table 10. Number of fractures to areas protected by safety suit and other areas for injured motorcyclists wearing and not wearing a safety suit in an accident

Body Region	No Safety Suit	Safety Suit
Knees, elbows, shoulders	26	2
Other areas	22	15
Total	48	17

From Tables 9 and 10, it can be calculated the injury reduction to knees, elbows, and shoulders is more than 50 percent. To calculate with a higher precision, the research must be extended since the technique of relating different kinds of injuries to each other (affected versus unaffected injuries) requires further study.

Discussion

The number of motorcycles is increasing all over the world, and this results in an increase in the number of injured and killed. Efforts must be made to reduce this trend. Motorcycle helmets are compulsory in many countries, and this has decreased head injuries considerably. By studying disabling injuries, it is obvious that fractures near joints are important injuries to prevent.

In this study, the effects and properties of a specially designed suit have been evaluated in real-life situations as well as under laboratory conditions. When the movements of the motorcyclist involved in an accident are taken into consideration, it is obvious a layer of strong material should cover the body. During this type of sliding movement, there is great risk of wounds and contamination of these wounds. Contaminated wounds near a fracture lead to longer treatment periods and increase the risk of long-term consequences.

Leather is considered to be the best protective material. Prime and Woods(5) showed that synthetic materials cannot offer efficient protection.

What magnitude of forces produces fractures? Patric, Kroell, and Mertz(6) showed that a force of 6kN was the level for injuries to the knee. Injuries to patellae can occur at lower levels. A force of 5kN was chosen as a reference level for minor patella injuries. Powell(7) showed 80 percent patella fractures and 33 percent fractures of the condyles at a force of 10.5kN, and FMVSS 208 (1977) suggests a force of 10kN as a realistic limit for the risk of femur fractures.

Confor Foam protects from fractures. Experimentally it was shown that Confor Foam accumulates energy between 10 to 30J. The energy absorption for a suit with Confor Foam was 14.1 times higher than for a suit with no shock-absorbing material at a force of 10kN and with a plane impact area. The corresponding value for a spherical area was 6.5.

Tests on the suit with shock-absorbing material show that the suit seems to give satisfactory protection, and experimental tests appear useful to test the effect of different materials and suits.

Conclusion

Studies made in an insurance study have led to the following conclusions:

- Leather clothing diminishes the risk of wounds at least 50 percent in an impact between the body and the ground or other hard objects.
- Leather clothing diminishes the risk of the wounds becoming contaminated by at least 50 percent.
- Shock-absorbing material on knees, elbows, and shoulders diminishes the risk of fractures by at least 50 percent.
- Almost 50 percent of all disabling injuries were concentrated at knees, elbows, and shoulders.

The following conclusions could be drawn from the experimental studies made:

- The quality of leather varies, and it is important to have continuous tests when manufacturing motorcycle suits.
- A number of different shock-absorbing materials can probably be used.

- Confor Foam has been tested, used, and seems suitable.
- The quality of Confor Foam varies and must be tested at the manufacturer's facility before its use.
- Confor Foam is sensitive to dampness and should, therefore, be protected from water.
- Confor Foam is sensitive to temperature and has its optimal shock-absorbing effect at +10°C to +30°C, that is, at the temperature reigning during the motorcycle season in Sweden.

A Study of Motorcycle Leg Protection

Hidetoshi Tadokoro
Motorcycle Rider Protection Subcommittee,
Japan Automobile Manufacturers Association

Shigehisa Fukuda and
Kyoichi Miyazaki
Japan Automobile Research Institute

Abstract

Researchers concerned with motorcycle occupant protection have attempted to develop ways to protect the motorcycle occupant from injury. In the hope of finding a means to protect the motorcycle occupant's lower extremities, the authors have investigated past research, designed a device that incorporates an energy-absorbing component, tested the device in a series of collisions with automobiles, and performed an analysis of the test results to assess the merits of the new device. Results show that although the device may under certain circumstances reduce lower leg injuries, there may be increased potential for upper leg, chest, and head injuries.

Introduction

It has been generally recognized the most frequent injury, although not the most serious, to the motorcycle occupant involved in a multivehicle collision is injury to the lower extremities(1).

The inherent design of the motorcycle leaves the occupant exposed to the environment, in contrast with an automobile that fully encloses the occupant within a substantial structure. Such inherent characteristics present the researcher with a formidable task in attempting to increase motorcycle occupant protection from injury during vehicle collisions.

In the area of leg protection, studies by various organizations were begun in the 1960's and have continued to the present(2). The studies sought a means to preserve sufficient leg space for the motorcycle occupant when impacted by an automobile. However, all of the numerous devices tested to date, including those previously examined by the Japan Automobile Manufacturers Association (JAMA) during the mid-1970's(3), were found to be unsatisfactory. Such devices were either structurally inadequate to preserve the leg space(2) or, when of sufficient structural strength to preserve leg space during the collision, were found to pose a significant potential to

increase injury to the head and chest of the motorcycle occupant(4).

In the hope of finding a solution to this problem, JAMA developed a device possessing energy-absorbing properties. In conjunction with the Japan Automobile Research Institute (JARI), the effectiveness of the new device was analyzed by a series of vehicle collision tests.

Review of Past Studies Concerning Motorcycle Leg Protection Devices

The study of motorcycle occupant leg protection originated from the intent to prevent the legs from being trapped and crushed between the opposing automobile and the motorcycle. Initially, crash tests were performed in the late 1960's and early 1970's with tubular steel structures to determine their ability to preserve the necessary leg space(2). However, the studies concluded that such devices then available did not possess sufficient strength and failed, due to the loads placed on them by the opposing automobile.

Subsequently, greatly strengthened and variously configured devices were designed, fabricated, and tested during the mid-1970's by various researchers in Great Britain, the United States, and Japan(3,4,5,6).

Although the more substantial of the reinforced structures did at times succeed in preserving the necessary leg space when struck by automobiles at speeds up to 48km/h, the reported conclusions stated such a device could not be recommended for use because of the following findings:

- When the leg space is sufficiently preserved so that no leg trap occurred, the motorcycle occupant seemed to be more readily ejected from the motorcycle at the time of the impact, resulting in the potential of causing significant injury to the motorcycle occupant's head and chest. Since head and chest injuries present a danger to life, such potential was identified as a primary concern(3,4).
- Although the lower portion of the leg was generally protected from injury, it was found that at times even the reinforced device did not eliminate all leg injury. For example, serious upper leg injury occurred when the upper leg was subjected to a torsional moment, which may have been sufficient to cause injury to the pelvic joint. Such is an undesirable result(3).
- Other injury-producing causes were identified, such as leg fracture due to the leg impacting the leg protection structure itself(5).

In summary, although the substantial leg protection structures did at times preserve necessary leg space, such a device was identified as being the cause of potentially more serious injuries.

Considerations and Proposed Requirements for the Design of a Leg Protection Device

Due to the problems identified above and in the hope of discovering a solution, basic principles were first reassessed and in doing so the following considerations resulted:

- To reduce or eliminate head and chest injury caused by ejection into the opposing automobile, energy absorption was considered as an element in the design of the new leg protection device. A new crushable component was incorporated with the hope that such a device would sufficiently reduce the initial motorcycle acceleration, occupant ejection, and chest and head injury caused by preservation of the leg space.

  As alternatives, motorcycle occupant ejection prevention by utilizing restraint systems such as seatbelts or airbags were considered. However, such alternatives had been previously considered, tested, and rejected by other researchers for various reasons(7).
- To preserve necessary leg space, the leg protection device should possess sufficient strength so it would not permit the opposing automobile to intrude to the extent of causing the leg to be trapped and crushed between the automobile and motorcycle.

Table 1 sets forth the details of the application of these considerations.

Table 1. Considerations and requirements for the design of a leg protection device

Element	Proposed Requirements	Remarks
Energy-absorbing component	Energy-absorbing component is to be provided.	The energy-absorbing component is to be provided to reduce the acceleration of the motorcycle on impact. The size of the energy-absorbing component is such that its outer dimension is not so large as to create other safety problems.
Preservation of leg space	The leg space is to be preserved with the reinforced structure.	A reinforced structure which does not deform and thereby preserves leg space is to be installed as an inner portion of the device. The reinforced structure should be strong enough to endure a broadside collision at 48km/h with an automobile.
	The leg space is to be the minimum required.	Excessive leg space is not desirable because the occupant will be more readily ejected, resulting in greater injury.
Restraint of occupant	Restraining the occupant with restraint device is not recommended.	When restrained with the motorcycle, the occupant may be caught between motorcycle and opposing vehicle or road surface, resulting in greater injury(7).

The following items were also to be considered to reduce injury-inflicting potential:

- Direct leg impact against the reinforced structure
- Hyperextension of the knee
- Trapping of the leg by the reinforced structure
- Highsiding of the motorcycle

In the design of this device, the maximization of the protective effect of the Crushable Leg Protector (CLP) was sought; therefore, no consideration was given to aerodynamic effects, braking, lean angle, or other performance requirements.

Test Procedures

Currently, there are no formal standards that apply to motorcycle crash tests as there are for automobiles. For the purposes of this test program, the following requirements were considered appropriate for evaluation of the CLP:

- The program should permit an evaluation of the effects of the device on the occupant during an accident.
- The program should permit kinematic analysis of various collision modes.

Test Motorcycle

In view of the above, a Yamaha XS 400 SP motorcycle was selected for all tests. It is a medium-size motorcycle. The basis for the selection was, first, that accident statistical reports(1) have indicated the 50th percentile size is a medium-size motorcycle; second, to permit the kinematic analysis it was determined that the medium-sized motorcycle would be appropriate. Test motorcycle specifications are given in Table 2.

Table 2. Specifications of test motorcycle

Manufacturer	:	Yamaha
Model	:	XS400SP
Overall length	:	2,070mm
Overall width	:	870mm
Overall height	:	1,140mm
Weight	:	170kg (210kg for the CLP type)
Appearance	:	Figures 1 and 2

Crushable Leg Protector (CLP)

The CLP used in this test program consisted of a rigid understructure made of steel tubing covered by an energy-absorbing component constructed of aluminum honeycomb and urethane foam. The specifications for these materials can be found in Table 3 and Figure 3. The CLP was attached to the motorcycle as shown in Figure 4.

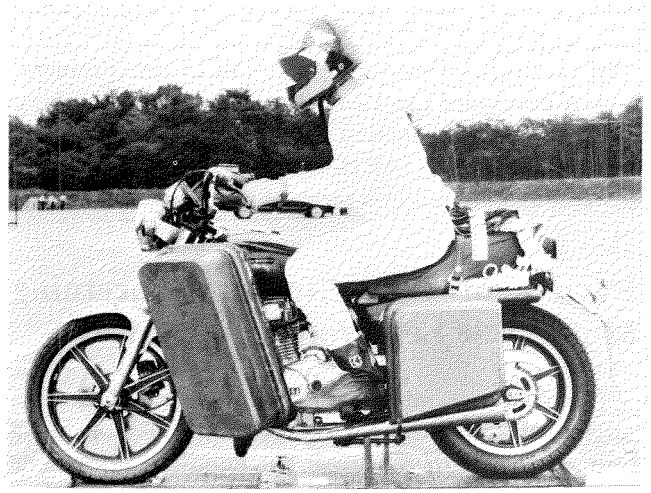

Figure 1. Side view of motorcycle with CLP

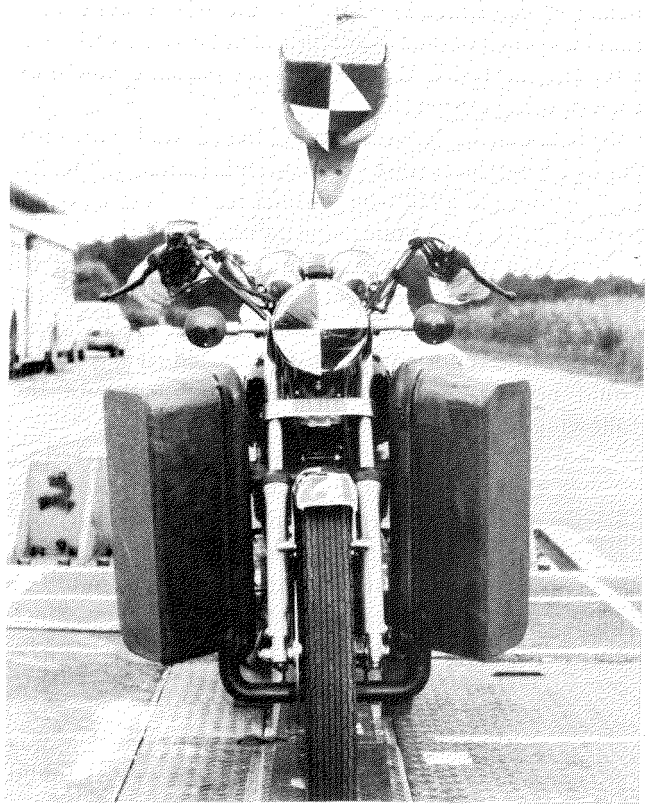

Figure 2. Front view of motorcycle with CLP

Opposing Automobile

The Toyota Crown automobile was selected for the test program. The basis for this selection was accident statistical studies that show that when motorcycles collide with opposing vehicles, approximately 80 percent of the opposing vehicles are identified as passenger automobiles(1). The Toyota Crown, which is representative of a medium-size automobile when viewed from a worldwide perspective, was believed to be appropriate

for the kinematic analysis. Its specifications are given in Table 4.

Collision Speed

To determine the effects of the device, the speeds for the collisions included 0, 24, 32, and 48km/h. It is notable that this speed range encompasses the speed of 34.4km/h, which one accident study found to be the mean collision speed(1).

Collision Configuration

In essence, three collision geometries were selected that the authors believed would satisfy the criteria. The three collision geometries are as follows:

- Angled Collision—The opposing automobile and motorcycle both in a moving configuration collide at a 45° angle with the motorcycle striking the front of the automobile.
- Broadside Collision—The opposing automobile strikes the motorcycle at a 90° angle.
- Offset Frontal Collision—The motorcycle traveling at a speed of 48km/h collides with the front corner of the opposing automobile in an offset mode.

	C-2	48	0	CLP

* STD—Denotes the standard motorcycle
** CLP—Denotes the motorcycle equipped with the crushable leg protector

Collision Test Facilities

The collision tests were performed at JARI's collision test facility. This is shown in Figure 8 wherein the facility specifications in terms of towing speeds, propulsion drive, tow system, and test capabilities are set forth.

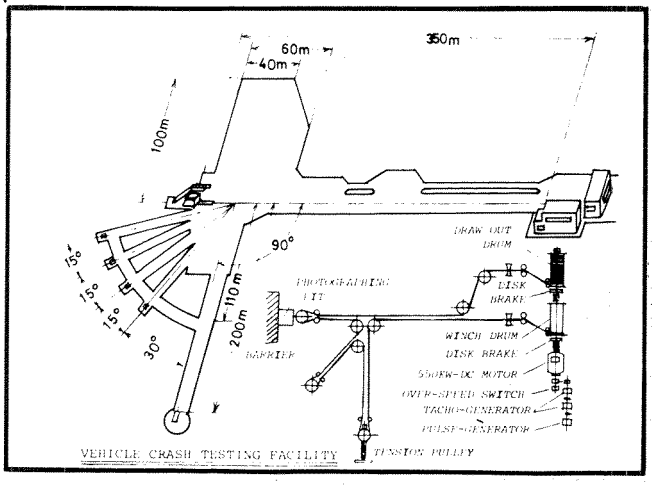

Figure 8. Specifications of JARI vehicle crash testing facility

The motorcycle was transported to the point of impact by the utilization of a four-wheeled trolley. The motorcycle was held in place by attachments at the handlebar, the lower section of the wheels, and the upper rear section of the motorcycle until its release just prior to impact. Figures 9 and 10 show from a frontal and side view the four-wheeled trolley used and the motorcycle mount system.

Measured Items

Leg Space and Fracture

The crushable leg protector device was evaluated for leg protection effectiveness by analyzing leg space preservation and leg fractures.

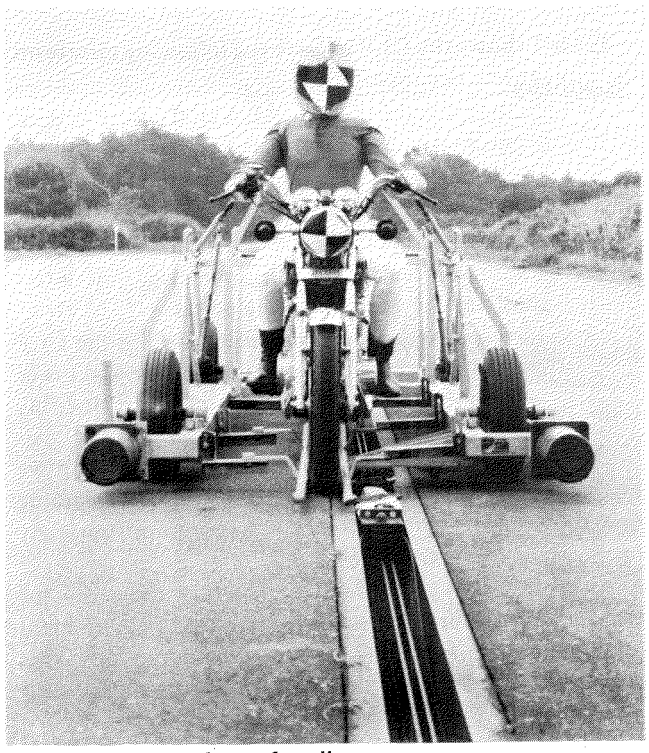

Figure 9. Front view of trolley

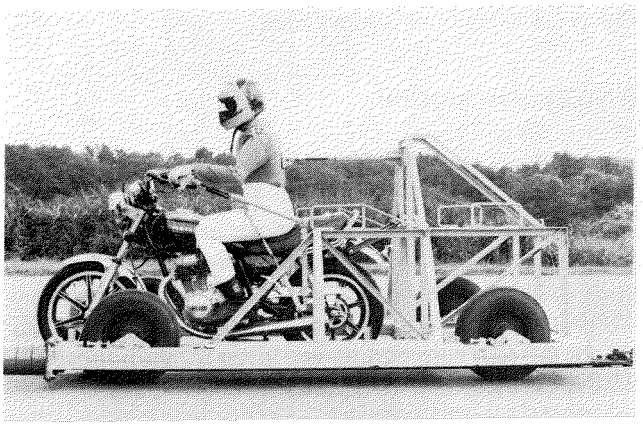

Figure 10. Side view of trolley

Energy Absorption

A triaxial accelerator was placed in the motorcycle at the point of its center of gravity. This was used to monitor the motorcycle acceleration and evaluate the effectiveness of the energy-absorbing component.

Head Velocity

As past studies indicated that reinforced-type leg protection structures possessed a potential to increase injury to the head and chest, the subject device was analyzed for such resultant effects. To evaluate these effects, a detailed head velocity and head travel analysis were performed, using photographic data.

Occupant Motion

In addition to the above, the dummy was further modified in that an accelerometer was placed at the hip. The lift of the hip was also measured to determine the tendency of the occupant to eject from the motorcycle.

Motorcycle Motion

Using film analysis, the motion of the motorcycle itself was observed.

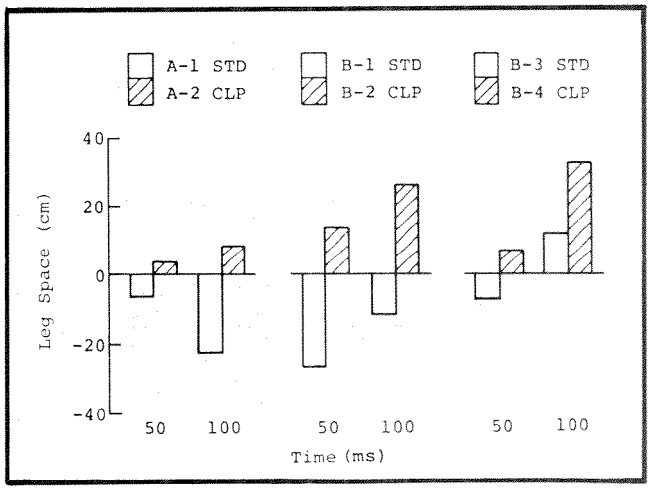
Test Results

Leg Protection Effect

Leg Space

It was difficult to measure directly how much space existed around the leg at the time of the collision. Accordingly, the leg space was estimated on the basis of how near a reference mark on the opposing automobile came to a reference mark on the motorcycle.

Figure 11 shows the comparison between CLP and STD. In all cases, the motorcycle with CLP did preserve the leg space better than STD. The leg space in this design seems to be the minimum required for the prevention of bone fracture for a broadside collision at 48km/h, as discussed below.



Note: Measurements were not obtained for A-3 and A-4 because of excessive deformation of vehicles

Figure 11. Comparison of estimated leg space

Leg Fracture

The state of the art of dummy technology for human injury analysis imposes some limits on the findings. The analysis of leg injuries was limited in scope because of the

lack of means of identifying the actual human injuries. Although it is believed the bakelite bone was a representative available means of identifying fracture modes in dummy analysis, it is also recognized there are limitations therein. Further research concerning the mechanisms of leg fractures is necessary.

For example, in the current test case, B-2, the bakelite bone did not fracture. It was found that the bakelite bone end experienced slippage at its connector; this was interpreted as a potential torsional fracture of the femur. To verify this, film analysis was used, and this showed that the enormous inertial loading would surely fracture the femur(9). Nevertheless, such experimental factors had to be addressed in interpreting the test results.

Note that in all tests, the leg of the dummy impacted against the front of the opposing automobile. Impacting of the leg resulted from the leg being caught between the motorcycle and opposing automobile or from the inertial force of the unrestrained leg itself. Figures 12 and 13 show examples of the bakelite leg bone fractures for tests A-3 and A-4, respectively.

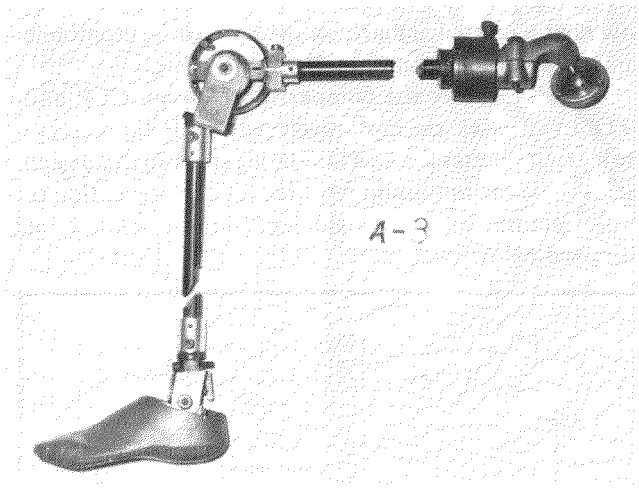


Figure 12. Example of bakelite leg fracture (test A-3)

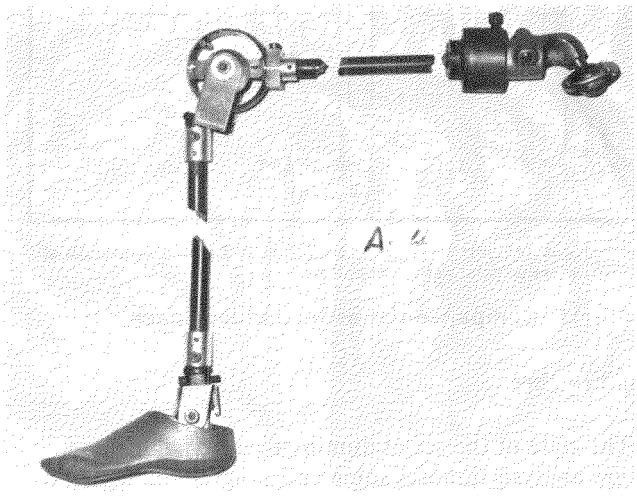

Figure 13. Example of bakelite leg fracture (test A-4)

Table 7 shows the CLP to have the following effects on the motorcycle occupant:

- In the angled collision (A1-A2), the CLP caused compression fracture in the upper leg that, in turn, may possibly extend to the pelvis.
- In the broadside collision (B1-B2), the CLP does reduce fracture of the lower leg and could cause a torsional fracture in the upper leg. The latter may possibly extend to the pelvis.
- In the offset frontal collision (C1-C2), the CLP caused transfer of bone fracture from the lower leg to the upper leg and such may possibly extend to the pelvis.

The fracture terminology shown is for descriptive purposes. It is recognized that generally both the bending and the compression fractures are more appropriately termed transverse fractures.

As used herein, the bending fracture describes the transverse fracture resulting from a bending moment applied to the bone. The compression fracture describes the transverse fracture that results from axial loading applied along the longitudinal axis of the bone.

Experimentally, such was determined by an examination of the shape of fracture point and film analysis of the motorcycle occupant's movement.

Energy Absorption

The object of the CLP was to reduce the motorcycle's acceleration due to impact by means of the energy-absorbing component. Therefore, the impact acceleration was measured for the broadside collision, which allows more accurate evaluation of the effect of the absorbing component. From the measurement, it was evident that the motorcycle acceleration was lower for the motorcycle with CLP than STD by approximately 10 percent.

Potential Head Injury

Head Velocity

The analysis of injury to the head and chest is necessarily incomplete. Not only is there lack of agreement in the medical field concerning injury criteria, but, in addition, appropriate dummy technology is lacking.

The potential for head and chest injury was evaluated by comparison of resultant head velocities relative to the opposing automobile after impact. A higher resultant head velocity indicated a higher potential for injury due to subsequent impact with the engine compartment, automobile roof, windshield, etc. For this study, velocity was chosen rather than acceleration because the latter is overly sensitive to impact angle, impact location, rigidity of objects, etc.

Table 7. Leg fracture data

STD	Test No.	A-1	A-3	B-1	B-3	C-1
	Upper Leg	Bending	Compression	Bending	Compression	None
	Lower Leg	Bending	Bending	Bending	Bending	Bending
CLP	Test No.	A-2	A-4	B-2	B-4	C-2
	Upper Leg	Compression	Compression	Torsional	Compression	Compression
	Lower Leg	Bending	Bending	None	None	None

Figure 14 shows the effect of CLP on resultant head velocity. In most cases, the motorcycle equipped with the CLP showed higher resultant head velocity than did the STD motorcycle. This shows potential for increased head and chest injuries due to CLP.

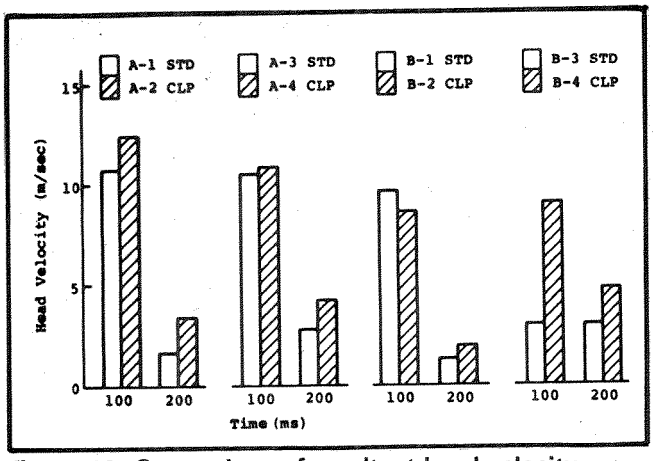

Figure 14. Comparison of resultant head velocity

Head Travel

Figure 15 shows the effect of CLP on horizontal head travel relative to the opposing automobile. More travel indicates more tendency for ejection. Ejection may result in the increased likelihood of impacting other vehicle structures.

In almost all cases, the CLP causes more travel across the opposing automotive engine compartment, meaning more ejection tendency.

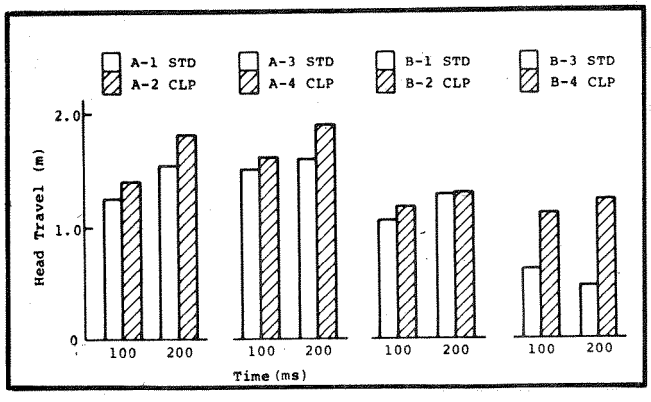

Figure 15. Comparison of horizontal head travel

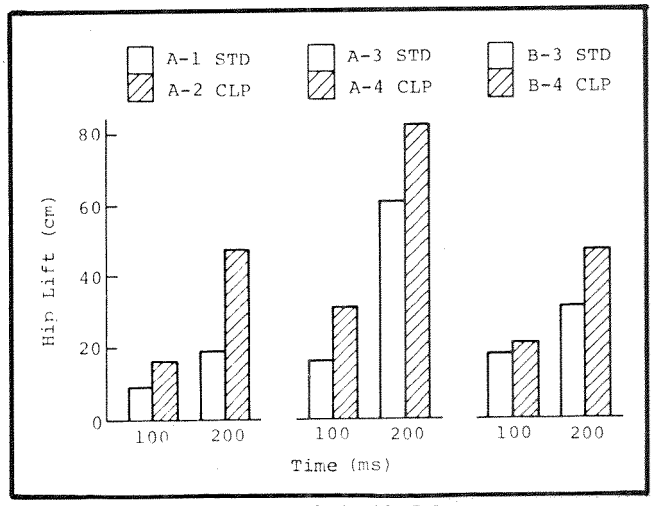
Occupant Motion

To determine the tendency of the occupant to eject from the motorcycle, the lift of the hip was measured.

The results in Figure 16 show that the motorcycle with the CLP has higher hip lift than STD, showing that the CLP allows ejection more readily.

In performing the overall evaluation of leg space, energy absorption, and occupant motion, it appears the effect of leg space is so great in contributing to increased velocity of the motorcycle occupant's ejection that the benefits of the energy-absorbing component are overcome. In other words, the CLP-equipped motorcycle possesses the potential for increased injury.



Note: Measurements were not obtained for B-2

Figure 16. Comparison of hip lift

Motorcycle Motion

An analysis of the film data showed that, at the time of collision, the STD overturns and comes to a halt after sliding for a short distance. The CLP exhibits a tumbling motion after impact, which may possibly involve third parties in the accident. In some conditions, this tumbling means the so-called highside phenomenon occurs.

Conclusion and Recommendations

The CLP was shown to be of generally sufficient structural strength for typical collision speeds and geo-

metries. In some cases, it did preserve leg space so the opposing automobile did not cause the leg to be trapped between the automobile and the motorcycle. In particular, the CLP prevented fracture to the lower leg in three of five cases. However, in at least one collision geometry, the CLP does seem to cause a torsional fracture of the upper leg, while with the standard motorcycle no torsional fracture circumstances were observed. This is a concern because it is believed the torsional fracture is a more serious injury. In summary, the CLP did not prevent injury to the motorcycle occupant's legs, but rather tended to move the site up into the upper leg and hip region.

Also, the energy-absorbing component appeared to function so the motorcycle's acceleration on impact was decreased to a degree.

However, the potential may still exist that the CLP may increase injury to the motorcycle occupant including the head and chest. As the velocity analysis shows, the motorcycle occupant in general had a higher ejection velocity when the motorcycle was equipped with the CLP. In one case, the velocity was significantly higher. This higher velocity produces a potential for more severe subsequent impact.

The motorcycle equipped with the CLP also tended to tumble for a long distance following the collision, while the standard motorcycle did not do so. The tumble condition could cause an accident or injury to third parties who were initially uninvolved in the motorcycle-automobile collision.

Based on the limited data, a fundamental problem appears to be the effectiveness of the CLP in preserving leg space may produce an undesirable increased velocity on ejection.

As there is a potential for the CLP that was presently tested to cause increased injury, the CLP device cannot be recommended for use on a motorcycle. Further study of human injuries in motorcycle collisions and of leg protection devices may be indicated.

Aspects of Motorcycle Braking

G.L. Donne and

Abstract

This paper discusses the problems inherent in the braking of motorcycles and other powered two-wheeled vehicles and suggests ways in which antilock brake systems and other engineering measures can assist riders. Evidence is presented of the failure of many motorcyclists to brake effectively, and it is suggested that advances in engineering will lead eventually to an improvement in braking behaviour. Results obtained by the antilock system installed in ESM-2 are compared with those obtained by a variety of riders.

Introduction

For many types of vehicle, incorrect or inappropriate brake application is not critical under most circumstances. With powered two-wheeled vehicles (PTWV), however, the situation is different. A mistake by the rider that leads to either wheel being overbraked will cause the machine to skid, become unstable, and capsize. The consequences can be serious, depending on surrounding traffic conditions and nearby obstacles. The incidence of skidding in personal-injury accidents has been higher for PTWV than other vehicles(1) for many years, and more recent data show no sign of this decreasing (Table 1).

The high incidence of skidding in PTWV accidents is an illustration of the difficulties faced by riders in braking such machines effectively. Motorcycles are inherently difficult to brake safely and efficiently because of a number of factors: a large load transfer from rear wheel to front wheel during braking, separate controls for front and rear brakes, and a wide variation in the proportion of front and rear brake effort required on different surfaces to give optimum performance.

The rider is faced with the almost impossible task of assessing these factors and applying correctly the necessary control inputs. Failure to do so is manifest in two main ways: simple misjudgment of brake application leading to the high incidence of skidding already mentioned and reluctance to apply high brake efforts because of the known skidding risk, which leads to unnecessarily long stopping distances. In addition, there are problems related to the design of particular machines, such as inadequate provision of brake power and susceptibility to the effects of water on the brake friction surfaces.

As in all aspects of riding a motorcycle, the experience and skill of the rider must play a considerable part in the effective and safe application of braking. Nevertheless, the task is so complex that it is beyond the abilities of the majority of riders, however experienced or well trained they are. Although training has a part to play, engineering measures applied to the machine appear to offer the greatest possibility of bringing about an improvement in PTWV braking generally. ESM-2 is equipped with antilock brakes that probably offer the greatest potential benefit of any such measures. The various factors involved in PTWV braking and the ways in which antilock systems and other measures can improve matters are now discussed.

Load Transfer During Braking

All vehicles are subject to the transfer of load from rear to front wheels as a result of the deceleration produced during braking. This effect produces changes in the levels of brake effort that can be safely applied, generally increasing those on front wheels and reducing those on rear wheels. In the case of cars and most commercial vehicles, which have wheelbases that are long in relation to the heights of their centres of gravity, the effect is less severe. A motorcycle with its rider has a centre of gravity that is very high in comparison with its wheelbase. This leads to considerable load transfer and produces a wide range of optimum brake distributions, which depend on the deceleration required and the road surface type. With PTWV, this effect is significant. For instance, it is

Table 1. Incidence of skidding in injury accidents in Great Britain—1983

	Dry			Wet			Ice/Snow			All Conditions		
	Skidded	Total	%	Skidded	Total	%	Skidded	Total	%	Skidded	Total	%
PTWV	6338	47375	13	5162	17471	34	695	1113	62	12195	65959	18
Other Vehicles	19024	197930	10	17976	106058	17	3650	7330	50	40650	311318	13

estimated that load transfer prevents a deceleration of more than about 0.36g when the rear wheel only is braked, even on a surface with a high friction coefficient(2). Simple measures such as a fixed relation between the brake efforts of the two wheels or valves that reduce rear brake effort are not sufficient to counter the difficulties caused. Because almost all PTWV have separate means of application for front and rear wheel brakes, it would be possible for the rider to make continuous adjustments to the levels of each. However, as already illustrated, the task is too difficult to permit even an approximation to optimum braking, particularly under adverse road surface conditions.

A braking system in which the brake effort is related to the behaviour of the braked wheel would overcome the problems caused by load transfer. The antilock system that is fitted to both brakes of ESM-2 does just this.

Each wheel is continuously monitored during braking, and brake effort is reduced if the level of wheel deceleration reaches a value at which the wheel locks. In this way, the maximum braking effort obtainable on any surface can be reached without danger of instability caused by wheels locking.

Braking While Cornering

It is not uncommon for a PTWV to brake while it is also changing direction. This situation can arise not only when it is necessary to reduce speed unexpectedly while negotiating a bend, but also during attempts to avoid an obstacle in an emergency. When a two-wheeled vehicle changes direction, the angle of inclination of the machine is adjusted to take account of the centrifugal force that is induced.

A reaction, in the form of a sideway force at the tyre contact area, is developed. This force is related to the mass of the machine and rider, the square of their tangential speed, and inversely to the radius of the curve traversed. Depending on the magnitude of these factors, it can be shown(1) is a minimum coefficient of friction that must exist to enable the cornering manoeuvre to be accomplished without braking. The frictional force between tyre and road must be divided between components for the sideways force required for cornering and the braking force. If grip is low and the cornering force requirement is high, there may be little left for braking.

This situation adds another variable to the rider's problems in achieving a balance between safe and effective braking. It means that instability will occur if either the cornering radius is reduced while hard braking is being undertaken or if brake force is increased while traversing a curve of fixed radius. However, if the level of braking applied to a wheel is controlled by a system that continuously monitors wheel behaviour, whatever component of the overall coefficient of friction between tyre and surface that remains after sideway force has been generated will be available for braking.

If, for instance, a rider has to make an abrupt change of direction while braking hard, there is no danger of wheel lock because the brake effort will be reduced to accommodate the side force requirement. The antilock system fitted to ESM-2 works in this way.

Braking in Wet Conditions

In addition to causing problems by acting as a lubricant between tyres and road surfaces, rainwater can affect the frictional properties of motorcycle brakes. It has been recognised for several years that disc brakes have been prone to problems in some wet weather conditions(3). Under these conditions, a laminar film of water exists between the brake pads and the disc and prevents dry contact. In extreme cases, it appears the only braking force generated between disc and pads is that due to the sheer strength of the water film(4). The motorcycle rider is thus faced with the possibility of extremely low brake power being available in wet conditions. The effect is, however, unpredictable and variable in its extent, which leads to considerable difficulty for the rider in judging the correct control input to give the required vehicle deceleration. It is reasonable to assume this effect has contributed to a considerable number of motorcycle accidents and is another factor that leads to the high incidence of skidding in two-wheeled vehicles.

An investigation of the factors involved in the performance of motorcycle disc brakes in wet conditions has been made by TRRL(5,6). This took the form of measuring the braking distance of an experimental motorcycle under controlled conditions.

The results obtained with a completely dry brake system were compared with those obtained when the brake friction surfaces were wetted at various rates from a supply of water carried on the machine. Many hundreds of test runs were made, using a variety of brake disc and pad materials with water applied over a considerable range of flow rates. As a method of quantifying the performance of a particular brake system, the term "wet retention" was used. This is the ratio of dry brake to wet brake stopping distances from the same test speed, expressed as a percentage. It was found in some cases that brake systems using standard pad materials were capable of a wet retention of only 15 to 20 percent, and it was uncommon to obtain a figure in excess of 60 to 70 percent even at very high levels of braking. (It is important to bear in mind that wet brake problems are most likely to occur under circumstances in which the available tyre/road adhesion is low and high braking forces are not appropriate.)

Although variations were found in the performance of brake systems depending on disc material, the most

significant factor was the selection of the pad material; sintered metal compositions were found to exhibit very little deterioration when wet, whereas some conventional organic materials were very poor and could not reach an acceptable standard. As a result of this work, a type approval test for wet brake performance has been incorporated into ECE Regulation 13. This specifies a minimum wet retention of 60 percent, based on a dry brake deceleration of $3m/S^2$ with water applied to the brake at 15 litre/h. Although the conditions are not particularly stringent, the advent of the type approval test and the interest generated by the research programme results have led to the use of friction materials that are better than those of recent years, and a range of sintered metal pads is commercially available for the majority of motorcycles. It is hoped this use of suitable friction materials will, in due course, eliminate the problems of inconsistent braking in wet conditions.

Antilock systems have a secondary role in overcoming wet brake inconsistency. Clearly they can do nothing to restore normal friction between brake discs and pads that are wet. They can, however, prevent wheel lock that might result from excessive brake torque becoming suddenly available when the water film is penetrated during a braking stop. However, the prime requirement is that motorcycles be equipped with brake systems that offer a consistent performance whether or not the friction surfaces are wet, thereby presenting riders with a less complex task. There seems to be scope to increase the requirements of the ECE test eventually, for example, either by increasing the wet retention requirement or by reducing the dry brake deceleration on which the test is based. This latter change would be an additional step toward consistency.

Antilock Braking

The high incidence of skidding in accidents that involve motorcycles has been mentioned already along with some of the factors that lead to it. This problem has been recognised for many years, and an experimental antilock installation on the front wheel of a motorcycle was produced at TRRL more than 20 years ago. This demonstrated the effectiveness of the principle of antilock on a two-wheeled vehicle in that riders were able to retain control of the machine in adverse conditions and, in some cases, braking distances were shorter using the system than when riders braked without it. A version of the Dunlop Maxaret system, which was used on aircraft, formed the basis of this experimental installation. This employed a flywheel overrun device to control the brake effort applied to the roadwheel. A system that could have been developed into a commercially acceptable unit was fitted to the first TRRL experimental safety motorcycle, ESM-1(1,7). This sensed wheel behaviour electronically and produced excellent results on machines ranging from a $200cm^3$ lightweight to one of the largest and heaviest motorcycles produced.

ESM-2 is fitted with an antilock system developed by Lucas Girling to both front and rear wheels. Wheel behaviour is sensed by a small flywheel driven via a toothed belt from the roadwheel hub. Under braking, the flywheel follows the deceleration of the roadwheel unless the latter reaches an unsafe level (equivalent to a vehicle deceleration of about 1.2g). At this point, the inertia of the flywheel is such that it cannot respond to the roadwheel deceleration, and it overruns. As it does so, it operates a valve that reduces the hydraulic pressure applied to the brake and allows the wheel to regain a safe level of deceleration. This causes the control flywheel to return to the state of following the roadwheel acceleration, and full braking is reapplied. This cycle of events continues until the vehicle comes to rest. The system on ESM-2 is similar to the Lucas Girling Stop Control System, which is to be made available for cars(8,9)

Many hundreds of experimental braking distance measurements have been made with the various antilock systems that have been developed for motorcycle use. In this way, considerable experience has been gained in the ways in which such systems might be of benefit and their performance relative to that of test riders. Limited results have also been obtained with a small number of riders with a range of limited experience(1). However, there are no data available either on the performance of antilock systems on motorcycles that are in service or from performance measurements obtained with a large number of riders. To provide this information, two trials have been conducted.

The Field Trial

A number of machines have been equipped with the Lucas Girling system, as on ESM-2, and issued to police forces to be used in their patrol vehicle fleets. The first of these, a BMW K100, was handed over to Gwent police in May 1985. During the course of 2 to 3 years' use, the performance of the system from the point of view of effectiveness, reliability, and rider reaction will be monitored.

Each machine will be fitted with counters that will record the number of cycles of operation of the antilock installations. The information obtained from this trial is of great importance. For instance, little is known about the question of reliability in a system likely to operate only very infrequently. In experimental use, there has been no reliability problem, but in these circumstances the frequency of operation of the system is high. It will also be of interest to note the reaction of riders, particularly with regard to the amount of use they make of its braking capability.

Comparison Between Riders

In terms of system performance, comparison of braking distances achieved with the system operating with those obtained by riders with the system immobilised is valid. Twenty-one riders, ranging widely in experience and ability, were asked to achieve, using their normal technique, braking distances shorter than those obtained with the antilock system working. (Although the experimental machine was equipped with skids to prevent capsize, the locking of the rear wheel can cause a sideway skid, which could throw the rider from the machine. As a safety measure, the rear wheel antilock system was left operative throughout these tests.) The tests were conducted at the TRRL track on a wet, slippery surface (Bridport gravel macadam). Note was taken of the number of occasions on which riders locked the front wheel and caused the machine to fall onto the safety skid and any obvious cycling of the rear wheel antilock system.

Measurements were made from a nominal speed of 50km/h (30mi/h), and five runs were made by each rider using both brakes. In addition, a sixth measurement was obtained with the rider using only the front brake. Table 2 presents the complete results. As there was some variation in test speed between riders and within each rider's set of runs, the braking performance is expressed as average deceleration.

The results show that five riders were able to consistently equal or exceed the deceleration obtained by the antilock system. Of these, one is familiar with the characteristics of the TRRL surfaces and has been involved in the development of antilock systems. Two others are regular riders with long experience and two are occasional riders. Five riders achieved average decelerations that were at least 80 percent of those obtained by the antilock system. However, one of these, with over 30 years' experience, lost and regained control during three runs and two others had at least one run that resulted in the motorcycle falling on a skid. The remaining eleven riders comprised three who were unable to achieve decelerations of 50 percent of that reached by the antilock system and eight who obtained values between 50 percent and 80 percent. In the former group was a rider of 30 years' experience who locked the front wheel in four of his runs and lost control.

Under the conditions of this trial where riders brake in a situation of no danger from losing control of the machine or of striking an obstacle, it is to be expected that those with skill and a degree of familiarity with the test surface will achieve results comparable with those of the antilock system. However, a number of riders were consistently unable to avoid losing control because they misjudged braking effort and locked a wheel. This failing seemed not to be related to experience. It is interesting that a number of riders were successful in completing five runs using both brakes but failed when asked to use only the front brake. This suggests they were unable to adjust quickly to the greatly reduced deceleration that was

possible and indicates that, when confronted with a strange situation, many riders commit errors. As mentioned, attempts were made to record cycling of the rear brake antilock system so that runs in which it was present could be counted as rider failures. It is likely there were occasions on which riders were able to obtain more braking from the rear wheel because of the antilock system than they would have if the system had been immobilised.

While the antilock system produced shorter braking distances than did many of the riders in this trial, it is the stability that it confers, particularly in an emergency, that is more likely to lead to a reduction in skidding accidents than any improvement in overall braking distances. However, if reliable and effective systems become common in the motorcycle population, there will undoubtedly be such an improvement as riders gain confidence in their operation and brake accordingly.

Antilock Systems for Small Machines

All the antilock systems mentioned above are applicable only to machines equipped with hydraulically actuated brakes. Disc brakes actuated by this means are now common on motorcycles. However, in the United Kingdom about 60 percent of the PTWV are lightweight machines with a capacity of 150cm^3 or less and mopeds. Many of these are fitted with mechanically operated disc brakes or drum brakes. It is, of course, technically impossible to equip such machines with the Lucas Girling antilock system unless their brake systems are redesigned and, additionally, such cheap machines would be unlikely to stand the cost imposed by such an addition.

A purely mechanical system has been devised and is under development for machines fitted with any type of brake that acts on the roadwheel hub. This system is illustrated schematically in Figure 1, and its method of operation is as follows.

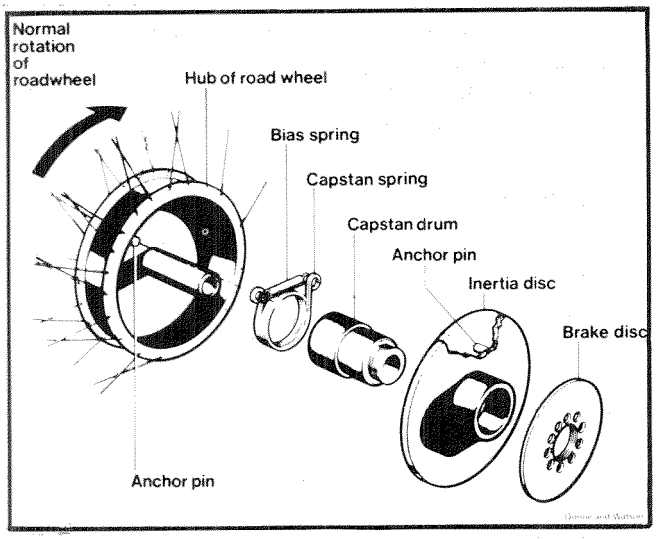

Figure 1. Capstan antilock brake system

The hub of the roadwheel carries a capstan drum that is free to rotate independently. Around the drum is wrapped a spring, one end of which is pinned to the roadwheel and the other is attached by a pin to a flywheel, itself free to rotate through a limited angle independently of all other components. A brake disc (or drum) is attached to the capstan drum. The flywheel is held at one end of its rotational travel by a light spring. In normal conditions, all parts of the device rotate together and, under braking, the wrapped spring connects the brake disc to the roadwheel. If, however, the wheel decelerates at a high rate, the flywheel overruns against the force of its bias spring and partially unwraps the spring from the capstan drum via the end that is pinned to it. This disconnects the brake disc and roadwheel, thus removing the brake torque and allowing the wheel to regain speed. When it reaches the speed of the flywheel, the spring is again tightly wrapped and brake torque is reapplied to the wheel. This sequence is repeated until the vehicle comes to rest.

It is unlikely this system will have the finesse of those with electronic wheel speed sensing or those that employ overrunning flywheels for sensing alone. (The flywheel in the capstan spring system provides the modulating force in addition to sensing wheel deceleration, hence it needs relatively high inertia.) However, if a satisfactory overall performance is attainable, this system should be relatively cheap to produce and could be fitted to almost any cycle, moped, or motorcycle, whatever the mode of brake operation.

Effect of Suspension Movement on Operation of Antilock Systems

Telescopic front forks are fitted to the majority of motorcycles for several reasons. They are simple and economical to manufacture, keep unsprung weight to a minimum, are aesthetically acceptable, and may be replaced as a unit in the event of minor machine damage. However, there is evidence(10) that such a suspension arrangement can not only lead to instability but is mechanically inadequate in some circumstances, particularly if antilock braking is applied to the front wheel. This is brought about by the cyclic behaviour of the antilock installation and the fact that such systems operate at a level of brake force near the maximum available. Study of high-speed cine film of a BMW R100, similar to ESM-2, braking using the Lucas Girling antilock system has revealed several aspects of suspension behaviour, which need more study to assess their implications. For instance, when using the front brake (either alone or with the rear) on a high-grip surface, the initial effect is for the front suspension travel to be fully used followed by considerable rearward bending of the fork legs. This reaches a maximum as wheel lock approaches. As brake force is reduced by the antilock system, a partial recovery of the forks occurs, and this cycle continues until the machine comes to rest. Perhaps the most important effect is the modification of the behaviour of the front wheel caused by fork flexing and suspension movement. In both circumstances, the wheelbase of the motorcycle changes, generally becoming shorter than in the static state. The result is that an acceleration is imparted to the front wheel in addition to that caused by braking torque alone. In the case of the R100, a rearward deflection of 65mm at the wheel spindle was noted when braking from a speed of 50km/h with the antilock system operative. This alone produces an apparent wheel acceleration of nearly 10 percent of the deceleration due to braking. This lasts for about 80ms; during shorter time periods, it is possible that larger accelerations occur. A film speed higher than the 200 frame/s used would be necessary to obtain

sufficient resolution to estimate these effects. The superimposed acceleration of the wheel could, depending on its sign, inhibit a necessary operating cycle of an antilock system or lead to an unnecessary one. In either case, the antilock system would operate in a less than fully effective manner.

TRRL is examining front suspension systems other than those based on telescopic forks and is fitting a centre hub-steered design to a BMW R80, similar to ESM-2, for evaluation. Such suspension designs are inherently stiffer than telescopic forks and should result in less interference to the operation of antilock systems.

Rider Behaviour

It is clear from the above there are many aspects of the PTWV that make safe and effective braking difficult to achieve even if the rider is aware of the problems and behaves accordingly. There is evidence to suggest that, in addition to the practical difficulties, riders do not even attempt to brake in an effective manner in many cases(11).

To obtain short braking distances, it is essential that both brakes be used; this is the method advocated officially(12). However, Sheppard(11) suggests that among many motorcyclists there is the view that the front brake should not be used at all, almost certainly based on fear of a skid caused by locking a front wheel. In Sheppard's study, driving test records were examined, roadside observations of braking behaviour were made, and riders were interviewed regarding their braking technique. It was found in about one-quarter of the driving test reports studied mention was made of a fault of some severity during the emergency stop, particularly "omits use of front brake." A similar incidence of poor braking technique was not found in car test candidates(13). From roadside observation of braking behaviour, it was noted that only in about half of the 5,410 cases did riders use both brakes under normal conditions, and even in emergency conditions only about one-third did so.

Clearly there is a considerable amount of incorrect and potentially ineffective braking by motorcyclists. There is obvious scope for improvement in rider training with more emphasis placed on braking technique in the driving test than at present. However, entrenched attitudes and beliefs are difficult to change. It is possible that machine improvements such as the widespread fitting of antilock brakes eventually will produce a motorcyclist population that will have less fear of locking a wheel than is the case at present. It will then be likely that brakes will be used correctly. One control to apply both brakes would prevent riders from using only one brake; this would be most effective when used in conjunction with antilock systems on both wheels.

Conclusion

Accident statistics show that PTWV's are more prone to skidding than are other vehicles, particularly in adverse conditions. This is a result of features of the vehicles themselves and of incorrect techniques applied by riders. It is likely the former have led to the latter during the history of motorcycling and produced, for instance, a widespread fear of the use of the front brake.

Education and rider training have a part to play in leading to improvement in rider techniques, but the most direct approach to the PTWV braking problem is to adopt engineering measures that simplify the demands placed on riders.

The availability of effective wet-weather brake pads has reduced the problems of wet fade, but most other adverse features are inherent in the design of motorcycles. The effects of load transfer, cornering, and road surface coefficient on brake effort proportioning can be overcome only by the use of antilock systems that respond to the behaviour of the wheel as it is braked. Widespread use of such systems will eventually eliminate the effects of poor rider technique and will lead to an overall improvement in motorcycle braking performance generally.

Motorcycle Rider Protection in Frontal Impacts

B.P. Chinn,
G.L. Donne, and
P.D. Hopes
Transport and Road Research Laboratory, Crowthorne, Berkshire, United Kingdom

Abstract

The problem of motorcycle rider injuries in frontal impacts is discussed in relation to the trajectory of the rider. Possible methods for reducing injury severity are also considered. A system is described that provides partial restraint to the rider in frontal impact and is combined with devices intended to reduce rider injury in other accident situations. Results are given of checks on this system by means of tests on a dynamic impact rig and in controlled vehicle-to-vehicle impacts.

Introduction

It is well established that powered two-wheel vehicles suffer an accident rate that is disproportionately high when compared with that for other vehicles on any basis. The results from general and detailed(1,2) investigations of accidents that involve motorcycles indicate that by far the most common vehicle conflict causing injury to motorcyclists is the frontal collision. About two-thirds of all collisions occur at an angle within 15° of head-on for the motorcycle. In many cases, the motorcycle is travelling at a normal traffic speed at the time of impact, and injuries are caused to the rider when he hits obstacles after being thrown from the machine. Studies of simulated impacts show that as little as 15 percent of a rider's kinetic energy is absorbed during the vehicle impact, leaving considerable potential for serious injury when an object is struck by his body. Clearly some form of energy-absorbing system must be incorporated into the motorcycle if any reduction is to be achieved in the injuries caused by frontal impact.

Various investigations into the mechanics of frontal impacts and possible rider restraint methods have been made. Severy(3) described a series of controlled impacts of motorcycles into stationary cars and concluded that the space between the rider and the impacted obstacle is wasted from the point of view of the absorption of rider energy, the characteristics of the motorcycle front provide a deceleration pulse for use with a rider-restraint system, and the rider moves forward in his seated position after impact until an obstacle is struck. Bothwell(4) examined a number of variables in a series of frontal impact experiments, including various restraint systems. Several researchers(5,6) commented on the problem of pitching of the motorcycle and suggested a rigid projection at a level above the centre of gravity to counteract this. Whitaker(7) investigated the trajectory of riders after frontal impact and examined the effects of a number of possible restraint devices. These were a chest pad, an airbag, and a block of energy-absorbing foam mounted on the fuel tank. TRRL produced prototype chest pad installations(7,8), but the acceptability problems of such devices are considerable.

Airbag installations can be envisaged that would intrude little into the traditional character of the motorcycle. Considerable research into the use of airbags for car occupant restraint systems has been conducted in the United States and elsewhere, and it appears possible that such devices will be used widely, at least in North America. Problems posed by the use of airbags in cars (sudden inflation in confined space, spurious inflation) either do not exist or may be easily overcome in motorcycle applications. The installation of an airbag

restraint system in conjunction with measures to protect against leg injuries(9,10) in the TRRL experimental safety motorcycle ESM-2 is described in this paper. The effectiveness of this system has been assessed in a programme of controlled impacts both on a dynamic test rig and with a free-running motorcycle into cars and barriers. In both cases, instrumented dummy riders are used and provide data on the decelerations and loads likely to be applied to critical areas of the human body. Results obtained with the restraint system in use are compared with those from tests using similar but unmodified motorcycles.

The Restraint System

In the form exhibited on ESM-2, this consists of a strengthened and modified version of the BMW RT fairing as fitted to twin-cylinder BMW motorcycles of 850 and 1,000cm^3 capacity. In addition, an energy-absorbing knee restraint is provided, and an airbag is mounted above the steering head on a bracket attached to the front fork assembly (Figure 1).

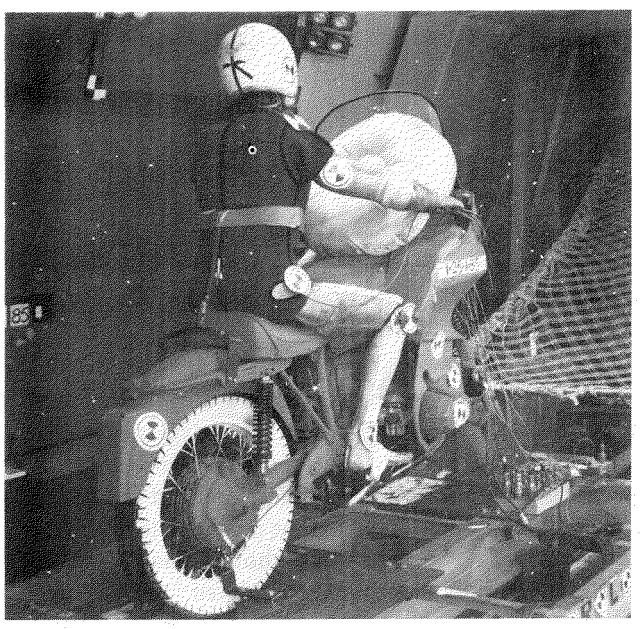

Figure 1. Airbag installed on impact rig test frame

The modifications to the fairing are a strengthened and extended bracket in the nose surrounding the headlamp to prevent pitching, a sheet metal instrument panel below the windscreen to provide increased stiffness and a reaction surface for the airbag, and a tubular steel internal structure to support the outer shell and provide lower limb protection in oblique impact(9,10). This last supports energy-absorbing knee restraints, which are present both to reduce knee injury and to modify the trajectory of the rider to induce rotation of the torso so load is applied to the inflated airbag in a substantially vertical direction.

The airbag itself is a prototype unit manufactured by Talley Industries in the United States and is of disc form, approximately 700mm in diameter and 250mm thick, with a volume of 70 litres when inflated. A pyrotechnic inflator assembly, 100mm in diameter and 50mm thick, is mounted on the front fork assembly and discharges directly into the bag, which is folded around it when not deployed. On inflation, the bag is at an angle of approximately 45° to the horizontal in side elevation and is supported by the handlebars, the front of the fuel tank, and the upper surface of the fairing with its strengthened areas.

One of the major problems with airbag installations in cars has been spurious deployment due to various causes such as high-intensity electromagnetic radiation from radar stations. This affects the deceleration-sensitive switches used to fire the bag inflators. In the ESM-2 installation, the bag inflator is fired by a switch activated by the seat of the motorcycle. This is mounted in such a way that it is able to slide forward under the effects of vehicle deceleration in an impact. In normal use, the seat is held in place by a section of aluminum honeycomb material, the dimensions of which determine the load at which the seat will move. Obviously it is essential that the actuating load level is set sufficiently high to prevent bag deployment in normal conditions of use. In calculating the dimensions of the seat assembly, it was assumed there would be at least some interaction between rider and seat during the bag initiation phase of the impact. Results from simulated impacts on the dynamic test rig(11) show it is possible to achieve reliable bag actuation with this system while maintaining sufficiently high seat sliding loads to prevent the possibility of accidental bag deployment.

As already stated, it is generally accepted by those in the field of motorcycle impact testing that a rider continues in his seated position after impact until an obstacle is struck. This does not provide the ideal situation for a practical airbag installation. It is essential the bag be well supported to withstand the loads applied to it by the rider. On a standard motorcycle, there is little possibility of providing this support for withstanding horizontally applied loads; in the ESM-2 installation, the rider trajectory is modified to cause rotation of the torso so a large proportion of the load is applied vertically. In this case, it is possible to provide support for the bag by means of the upper surface of the fairing, the instrument panel, and the fuel tank without markedly changing the character of the motorcycle. Rotation of the rider's torso is induced by the provision of energy-absorbing knee restraints attached to the rear of the fairing structure. After impact and as the rider moves forward in the sliding seat, his knees make contact with these restraints. The lower body is then decelerated, causing rotation about

the pelvis, which leads to his torso striking the inflated airbag.

Performance Tests

Two main methods of testing have been used to develop and assess the restraint system. First is the dynamic test rig(11) in which either a complete motorcycle or a simulation frame is mounted on a trolley that is subjected to an appropriate controlled deceleration from the test speed. The level of deceleration is chosen to simulate an impact. The second is controlled impacts on a test track, in which a complete motorcycle collides with a fixed barrier or part of another vehicle(10). In both cases, the motorcycle carries an anthropometric dummy to represent its rider. This carries instruments to record accelerations in the head, chest, and pelvis, and loads applied to the femur. In addition, all tests were recorded using high-speed cine cameras to enable analyses to be made of vehicle and rider trajectory and velocity.

Results

In the case of simulated impact on the test rig, there is no crushing of the motorcycle, such as would occur in a real vehicle-to-vehicle collision. Consequently, a Hypothetical Vertical Barrier (HVB) was used as a datum to enable comparisons to be made of rider velocity and energy between the various test conditions. The HVB was placed ahead of the test motorcycle by a distance that depended on the recorded deceleration achieved. In the analysis of high-speed film records, the dummy rider was assumed to have struck the HVB, which simulated an obstacle struck by the motorcycle. Figure 2 gives the kinetic energy of the rider on striking the HVB in three tests: using an unmodified motorcycle, with two pre-inflated airbags, and with one impact-actuated airbag. The energies were calculated using the rider linear and angular velocity and the mass and inertia of the torso. The test with two airbags (one mounted on the steering head and one on the petrol tank) was conducted to assess the effects of a large airbag installation.

It is clear that modifications to the motorcycle impart more rotational energy but greatly reduced linear energy to the rider compared with the standard machine. In the case of the double airbag installation, the rider's linear kinetic energy was zero at the HVB and reduced by 30 percent with the single impact-actuated airbag. The total kinetic energy of the rider was reduced by 78 percent for the double airbag and by 30 percent with the single airbag in comparison with the standard machine.

Discussion and Conclusion

The work described is at an early stage. The airbags used were standard items, and no attempt was made to optimise their size or shape. Despite this, a 30 percent reduction in kinetic energy of the rider has been obtained when using one airbag. The use of an airbag designed specifically for motorcycle applications and the careful design of other components of the motorcycle to provide suitable crush characteristics should enable greater reductions in rider energy to be achieved.

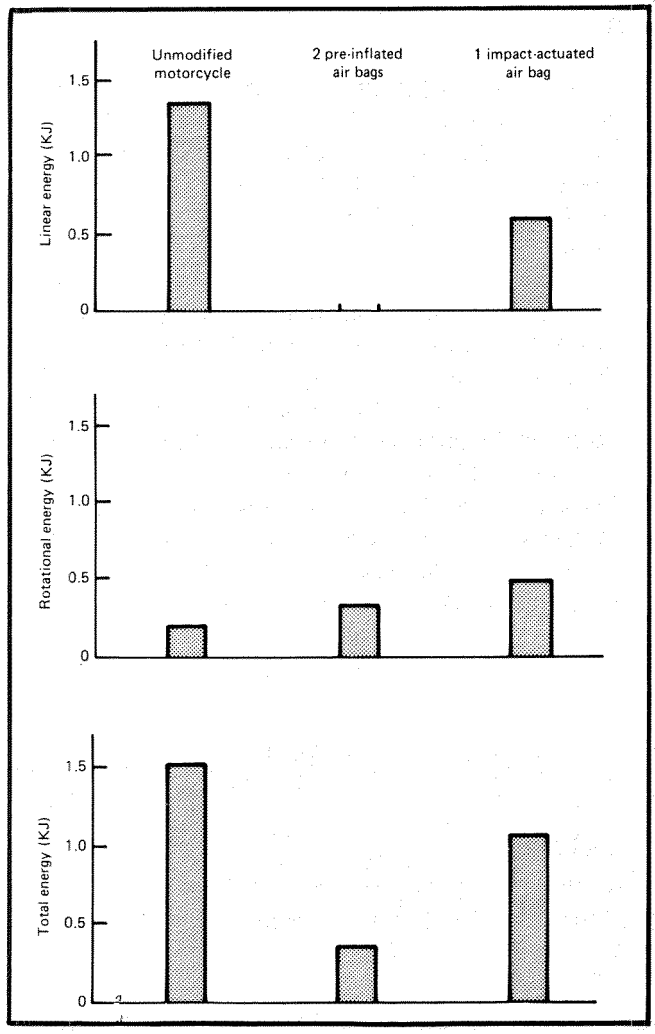

Figure 2. Rider torso kinetic energy at hypothetical vertical barrier

Preliminary analysis of a vehicle-to-vehicle impact indicates that a machine equipped with a single airbag provides a reduction in rider energy of 55 percent in comparison with a standard machine as he reaches a hypothetical point of impact of the motorcycle (the HVB).

Motorcycle Conspicuity in Daylight

G.L. Donne
Transport and Road Research Laboratory, Crowthorne, United Kingdom

E.J. Fulton
Institute for Consumer Ergonomics, United Kingdom

P.G. Stroud
Loughborough University of Technology, United Kingdom

Abstract

In recent years, a series of studies has been conducted by the Institute for Consumer Ergonomics for the Transport and Road Research Laboratory concerned with finding effective and acceptable ways of improving the conspicuity of motorcycles in daylight. The relative effectiveness of clothing for riders, lighting, and other treatments for motorcycles was examined. Results from these studies have shown there are ways of effectively increasing motorcycle conspicuity in a wide range of daylight situations. Pairs of daytime running lamps, large dipped headlamps, or clothing displaying a large fluorescent area are all effective. Small headlamps on low-powered machines or small areas of fluorescent treatment are not effective.

Introduction

Detailed investigation conducted by the Transport and Road Research Laboratory into accidents between motorcycles and other vehicles concluded that, in almost one-third of the accidents, another vehicle driver had not seen the motorcycle prior to the collision(1,2). The accidents occurred principally at junctions in urban areas, and many involved manoeuvres in which other vehicles infringed on the motorcycle's right-of-way. Using 1983 data, it is estimated that approximately 18,000 motorcycle accidents are of this type each year in Great Britain(3). There appeared to be several reasons why people might fail to see motorcycles. Because of their small size, they can be obscured easily and are able to travel in positions on the road where other road users do not expect or search for traffic. Also, because of their irregular outline and the dark colour of much specialist motorcycle clothing, they do not readily stand out. Some of these qualities are inherent in the nature of motorcycles themselves, but it seemed likely that accident numbers could be reduced if the conspicuity (i.e., ability to attract attention) of motorcycles was improved.

A programme of work was conducted(4,5) to examine ways of achieving this. Treatments to the motorcycle, such as the use of various types of lights and fluorescent materials, and the use of special clothing for riders were considered.

There were thought to be advantages in machine-based options over those affecting riders because they are

permanent features and the motorcycle itself is already subject to vehicle legislation that could be readily adapted if necessary.

Options Assessed

Several different types of aids to conspicuity were examined.

Fluorescent Materials

These were applied to both rider and machine-based items, such as legshields, headlamp cover, sleeves, waistcoat, jacket, and helmet. The items of clothing conformed to BS 4610:1970, specification for high-visibility clothing.

Headlamps

Standard headlamps with a dipped beam were used and ranged in size from 100 to 180mm in diameter and in power from 18 to 55W. The effects of modulating the output of such lamps and the use of high-intensity bulbs in the parking light position were also assessed.

Running Lamps

These are specially designed lamps, measuring 100 by 80mm, fitted with a multiprism lens. They were used either in pairs, mounted on the motorcycle handlebar approximately 1000mm above the ground and 410mm apart, or singly, centrally mounted below the headlamp (Figure 1). They were assessed with a variety of bulbs, ranging in power from 6W tungsten to 15W glass-halogen. Luminous intensity along the central axis of each lamp varied from less than 100 to 825cd depending on the bulb fitted.

Methods

Several assessment methods were used at different stages in the investigation to compare the effectiveness of the proposed conspicuity aids. The measure of effectiveness used by all methods was based on judgments by numbers of people about the presence or otherwise of motorcycles with and without the test options. In all cases, the control condition comprised a motorcyclist in dark clothing on a motorcycle with its lights switched off and with no special conspicuity treatment. This type of measure was used because conspicuity is not only a matter of physically measured properties of an object but also of the physiological and psychological characteristics of observers.

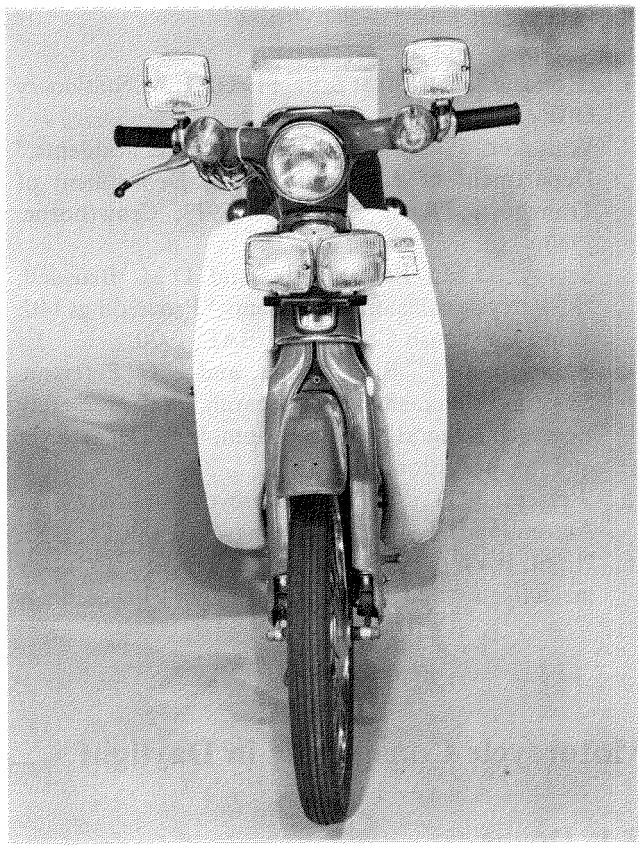

Figure 1. Experimental motorcycle fitted with a pair of running lamps and double running lamps

First, as a rough sorting procedure, a laboratory-based tachistoscopic experiment was conducted using slides of street scenes that included motorcycles. The mean time taken by subjects to detect the motorcycle using each of the test options was used as a measure of its effectiveness compared with the control condition. A short detection time indicates a conspicuous option.

Second, using those options that had offered improvements over the control condition in the first experiment, a field trial was conducted. A motorcycle and rider were positioned in a side street, and pedestrians who crossed the street at its junction with the main road were questioned to determine whether or not they had seen the motorcycle. This method enabled data to be collected from a large number of people. To avoid influencing subjects' responses, it was found to be essential they were unaware of the nature of the experiment. In this case, the percentage of subjects who detected the motorcycle was used as the measure of the effectiveness of each option as a conspicuity aid. The higher the percentage of detection, the more effective the option. This method has the advantage that large amounts of data can be gathered economically and from people who are unaware of the purpose of the experiment and their own part in it. However, it differs from the driving situation in important respects: subjects are pedestrians, and the motorcycle is stationary.

A third method was developed that used drivers as subjects and in which the test motorcycle was moving. Subjects, seated in the driving position in a car, were allowed brief glimpses through a shutter along the road ahead of them. The road might not contain any traffic or there might be just the vehicles that were incidentally present, but sometimes there would be the test motorcycle. The measure of conspicuity was based on the frequency with which experimental options were detected, compared with the control condition of the motorcycle.

Results

Results for the three methods are presented separately below.

Method 1—Laboratory Trial

Table 1 shows the mean detection times for 100 subjects. It was apparent that small areas of fluorescent material (e.g., sleeves and headlamp covers) provided no significant improvement over the control.

Table 1. Mean detection times for options using fluorescent material—laboratory method

Experimental Option	Mean Detection Time (seconds)
Control-not fluorescent	1.090
Legshields-fluorescent from front	1.048
Jacket-completely fluorescent	0.896*
Headlamp Cover-fluorescent from front	1.070
Helmet-covered in fluorescent material	1.008
Waistcoat-completely fluorescent	0.880*
Sleeves-completely fluorescent	1.116

* Denotes significantly better than control ($p < 0.05$)

Large areas of fluorescent material (e.g., jackets and waistcoats) were detected more quickly than the control condition.

Method 2—Pedestrian Field Trials

Pedestrian field trials were conducted at several sites on many separate occasions. There was a wide range of overall detection rates between sites, and Table 2 shows the range of detection rates for each option. In all, 18,596 subjects were involved.

Table 3. Mean values of ranks—road glimpse trials

Experimental Option	Mean Values of Ranks †
Control	2.68
40W, 180mm diameter headlamp	3.22*
1x15W Daytime running lamp-glass-halogen	2.90
2x15W Daytime running lamp-tungsten	3.11*
Fluorescent Jacket	2.99*

* Denotes significantly better than control ($p < 0.05$)

† Denotes always seen, 0 denotes never seen

Method 3—Road Glimpse Trials

For each subject, five sets of data were collected in the form of a seen (designated 1) or not seen (designated 0) response for each of the five motorcycle conditions. The five conspicuity aids were put into a rank order on a scale of 5 to 0 with 5 denoting the most seen. Table 3 shows the means of these scores obtained with 197 subjects at three experimental sites.

Table 2. Summary of results from pedestrian field trials

Experimental option	Range of Detection Rate %	Level of Performance Compared with Control
Control	7.1—26.5	—
Fluorescent helmet	15.2	No significant benefit
Fluorescent jacket/waistcoat	22.5	Significantly better
Small dipped headlamp. 100mm dia. 18W tungsten	17.3	No significant benefit
Small dipped headlamp. 100mm dia. 40W tungsten	3.9—29.5	No significant benefit
Small dipped headlamp. 100mm dia. 40W tungsten (flashing)	11.2—20.7	No significant benefit
Large dipped headlamp. 180mm dia. 24W and 40W tungsten	21.5—29.7	Significantly better in some trials
Large dipped headlamp. 180mm dia. 40W tungsten (flashing)	13.2—26.0	Significantly better at 1 site only
Large dipped headlamp. 180mm dia. 55W halogen	8.1—34.2	Significantly better at 2 sites only
1 x daytime running lamp. 10W tungsten	21.0—28.4	Significantly better in some trials
1 x daytime running lamp. 15W halogen	12.1—33.3	Significantly better at 1 site only
2 x daytime running lamp. 6W tungsten	30.8—38.0	Significantly better
2 x daytime running lamp. 10W tungsten	14.2—31.9	Significantly better
2 x daytime running lamp. 15W tungsten	18.7—44.7	Significantly better
Double daytime running lamp. 15W tungsten (2 running lamps mounted centrally, side by side)	11.5—37.7	Significantly better at 2 sites only
Small parking lamp—100mm dia. 15W halogen	12.5—28.8	No significant benefit
Large parking lamp—180mm dia. 15W halogen (high-intensity halogen bulb in parking light position of headlamp).	15.5—30.5	Significantly better at 1 site only

The results from field trials show that the use of small single lamps (including headlamps) provided no improvement in detection compared with the control condition.

All pairs of daytime running lamps, fluorescent jackets, and waistcoats performed significantly better than the control condition.

Results for large headlamps (i.e., those of 180mm diameter and 40W, or greater, power) were inconsistent but, in most cases, were an effective improvement over the control condition.

Conclusion and Discussion

The major conclusion from this work is that it is possible to improve the conspicuity of motorcyclists. Results show the most effective machine-based option assessed was a pair of daytime running lamps.

The use of headlamps has considerable appeal because they are machine-based and fitted to all machines. However, whereas the use of large, powerful headlamps was shown to confer benefits in some circumstances, small headlamps had no beneficial effect. In the motorcycle population of Great Britain, over 50 percent of machines have a capacity of $150cm^3$ or less(6) and are neither required to nor likely to have headlamps of adequate dimensions to be an aid to daytime conspicuity. Consequently, a requirement to use headlamps in daylight would be unlikely to be of benefit to machines of all sizes. It would enhance the conspicuity of large machines but would be of no benefit to the riders of the majority of motorcycles in use.

Of all the rider-based options assessed, a fluorescent jacket or waistcoat was found to be more conspicuous than the control condition. This conspicuity aid is available to all motorcyclists but has two disadvantages when compared with running lamps. Its effectiveness depends on riders' choosing to wear it, and fluorescence decays with exposure to light. So, to be effective, jackets must be stored away from light and replaced every few months if in frequent use.

The experimental safety motorcycle ESM-2 is equipped with a pair of running lamps of the type assessed in this work.

A Feedback Control Method for Antilock Brake Design

John W. Zellner and
Dean P. Chiang
Dynamic Research, Inc.

Abstract

An analysis of antilock brake system dynamics—based on nonlinear control theory—was performed. Results were used to define initial performance and design requirements for a prototype fluidic motorcycle antilock system. The analysis emphasized the frequency response of system components and effects on stopping performance and stability. Results showed wheel angular acceleration provides a feasible single loop feedback for antilock control; wheel angular jerk is probably not a desirable primary feedback variable; nominal design requirements for modulator and controller exist that represent a compromise among high and low μ performance, stability, roughness, and signal-to-noise ratio; net time delay between modulator and brake caliper is a key design parameter and should be investigated more thoroughly.

Introduction

Since the 1930's, antilock brake technology has been developed and applied to a variety of vehicles, including railcars, aircraft, automobiles, commercial vehicles, and more recently motorcycles(1). The advantages of antilock for each vehicle category tend to be different: reduction of damage to wheels and tires has been a main goal for rail and aircraft systems; improved steerability and yaw stability are the goals of automotive systems. Motorcycle antilock examples—all in prototype versions only—have attempted to reduce the capsize tendencies of two-wheelers encountered under limit braking conditions. So, over the years, the antilock trend has been increasingly toward the role of stability and control augmentation and also toward applications involving smaller, lighter, more quickly responding vehicles. For motorcycles, these factors have combined to produce challenging prospects for antilock developers.

Motorcycle antilock prototypes have included perhaps a dozen well-known examples since the 1960's, as reviewed in (1). Many of these evolved from Experimental Safety Vehicle (ESV) programs in the United States, Europe, and Japan, begun in the 1970's, as well as proprietary development efforts. To date, all of the documented versions would have required additional development to make them viable, practical, and reliable production brake systems.

Historically, antilocks are usually developed empirically, supported by conventional design and test techniques. This process is made especially challenging by the complexities of tire/roadway friction and dynamic behavior of vehicles and brake systems. To date, not much insight has been provided by theoretical approaches, and the development process remains mostly empirical, with accompanying costs, time, and risks.

Recently, other technologies are being brought to bear in the antilock area. These include, to mention a few, digital- and microprocessor-based systems, all mechanical antilock systems, and fluidic sensing and control. As these new technologies join the several dozen antilock systems in various stages of development and use, the need for analytical input continues.

As part of such development—specifically of a fluidic antilock system for motorcycles(2,3)—an effort to treat antilock analytically was undertaken and is reported here in part.

The objective of this portion of the development was to analyze antilock dynamics in a preliminary way and to determine desirable and feasible feedback control structures (i.e., which variable to use as a feedback). A complementary goal was to identify antilock component response requirements and an initial configuration. The approach used was largely analytical, based on nonlinear control systems analysis.

This paper focuses on the analysis method used. An example preliminary design for a motorcycle antilock is used to illustrate the approach and typical results.

Analytical Approach

The antilock design task involves sensing the rotational motion of the braked wheel or wheels and using this information to modulate the brake fluid pressure applied to the wheel to avoid overbraking and lockup. The main motion variables, as shown in Figure 1, are the wheel angular velocity and acceleration, the linear velocity and acceleration of the vehicle itself, and the relative velocity or slip ratio at the tire/road interface. The design goal is to keep the wheel tangential velocity somewhat less than the vehicle velocity. This does two things. It retains most of the sideforce capability of the tire needed for vehicle stability and control, and it allows the vehicle to be decelerated at near the limit of available tire/road friction. Generally speaking, this involves a design tradeoff between maximizing wheel rotational stability versus stopping performance.

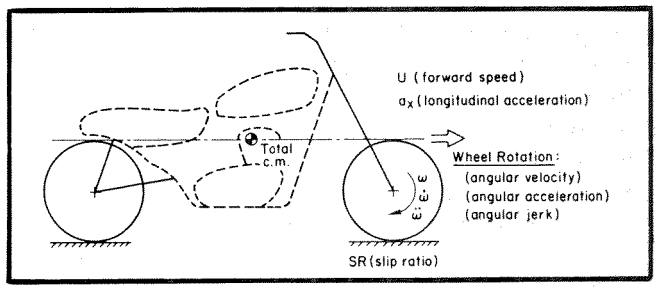

Figure 1. Primary motion variables for antilock dynamics

The interaction between stability and stopping performance is shown schematically in Figure 2. During normal forward operation, the rider uses steer torque to control motorcycle roll angle, thereby also effecting heading and path control(4). Brake force is used to control stopping distance (i.e., forward velocity). With conventional brakes, if a wheel is overbraked and locked, the motorcycle can be rapidly destabilized in roll, resulting in a potential capsize. A goal of motorcycle antilock is to automatically sense wheel speed and control brake force to maintain both stopping performance and attitude stability.

Past analytical studies of antilock have commonly involved developing a mathematical model of the vehicle and antilock components. Such models are typically analyzed in the time domain to produce time responses of the system. Once constructed, such models can be used as paper prototypes, where the antilock design can be modified and adjusted—much like a real vehicle—until satisfactory results are obtained. Such an approach was used in (5), for example.

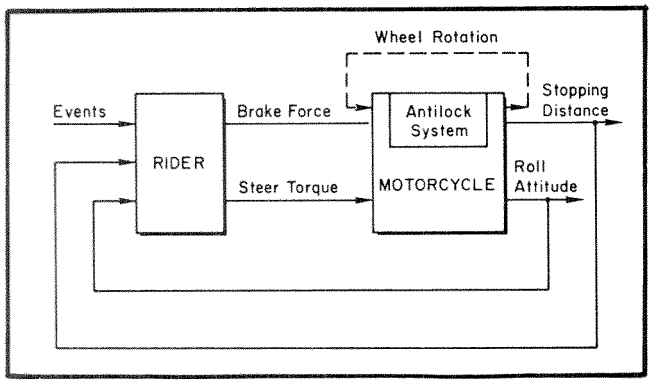

Figure 2. Schematic of rider/motorcycle/antilock control system

The next step could involve using control theory methods to determine the antilock design analytically (i.e., as opposed to by trial and error). Two methods are generally available: time domain and frequency domain.

A fundamental aspect of antilock that must be addressed by such theoretical methods is the nonlinear behavior of the vehicle and candidate antilock components. Such nonlinearities (e.g., tire/road friction) limit the range of analytical tools available to the designer.

In the time domain, antilock has been examined using external (or nonlinear optimal) control techniques, as, for example, GM used in the 1960's(6). Such approaches typically involve assuming a fixed form of control and numerical solution.

A somewhat more general approach is available in the frequency domain, involving describing functions and gain-phase techniques(7,8). Applying these methods to antilock design is described in the balance of this paper.

Feedback Control Formulation

Feedback control theory suggests that the controller and controlled element of a system be tailored to one another in order to result in a system that has a balance among such things as—

- Stability
- Rapid, well-damped response to commands
- Insensitivity to disturbances
- Insensitivity to small changes in controlled element or controller parameters.

For linear systems, a crossover model of a feedback control system includes the above considerations and can be used to determine requirements for feedback design. Zellner(9) provides an example of the crossover method applied to antilock design. One difficulty, as mentioned above, is the presence of amplitude nonlinearities. This can be partially handled with families of describing functions (i.e., frequency response curves). From a practical standpoint, the multidimensional nature of such curves makes a conventional graphical solution inconvenient.

An alternative technique also used in linear servo analysis(7,8) is the gain-phase plot method. The gain-phase plot provides a convenient tool for determining conditions for limit cycles in quasi-linear systems. If the linear portion of the transfer function is plotted on the gain-phase plot, together with the negative inverse describing function of the nonlinear portion, intersections of the two curves will illustrate the conditions for sustained oscillation. The frequency and amplitude of the limit cycle, if any, will appear directly; the plot can also be used to determine whether the limit cycle is stable, that is, whether the limit cycle will sustain itself in the face of disturbances.

Formally, in a manner similar to the basic stability condition that underlies the theory of constant-coefficient linear systems, the basic condition for stationary oscillations in quasi-linear closed-loop systems can be expressed as follows (see Figure 3):

$$1 + \mu\beta = 0$$

or

$$\mu\beta = -1 \qquad (1)$$

where

μ = forward path transfer function
β = feedback path transfer function

If any part of either μ or β is the describing function of a nonlinearity, N, and the remainder of the open-loop frequency response function is the linear term $G(j\omega)$, the stability condition is:

$$NG(j\omega) = -1$$

or

$$G(j\omega) = -1/N \qquad (2)$$

The solution of Equation (2) can be carried out graphically. Equation (2) indicates that, if $G(j\omega)$ and $-1/N$ are plotted together on the gain-phase plane, intersections of the two curves will satisfy the equation. Intersections, therefore, will show the conditions for neutral oscillatory stability, where the describing function, N, is a function of amplitude only, as it is for all simple nonlinearities in first approximation quasi-linear systems, the construction is especially convenient. $-1/N$ is then an amplitude variant function, and $G(j\omega)$ is a frequency variant function. Each curve can be plotted as a function of a single parameter.

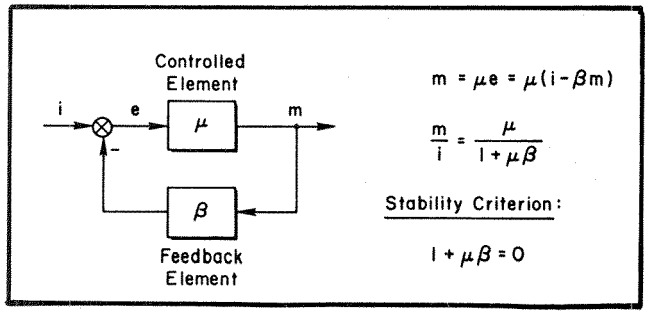

Figure 3. Generalized stability condition for single closed-loop control system

The gain-phase design method can be summarized as follows:

- Determine the time responses of system components (i.e., measure actual hardware or use a computer simulation)
- Calculate the corresponding component describing functions (i.e., Fourier transform the time histories) at a range of frequencies and amplitudes
- Identify the frequency dependent (linear) components and the amplitude dependent (quasi-linear) components, from the describing function data
- Plot the gain-phase characteristics of the frequency and amplitude dependent parts of the system
- Note characteristics of the intersection point (i.e., the limit cycle point)
- Modify the response curves to adjust the quality of the intersection

The quality of the gain-phase intersection (i.e., limit cycle) is determined by several criteria, including—

- Limit cycle existence is indicated by intersection existence.
- Limit cycle stability is indicated by the direction of the intersection (amplitude dependent curve crossing the frequency dependent curve from left to right is stable).
- Sensitivity to parameter changes is indicated by the angle of intersection (90° is least sensitive).
- Stability margin is indicated by the intersection's proximity to the end points of either the frequency or amplitude dependent curve.

Examples of the gain-phase approach are discussed next.

Example: Antilock Gain-Phase Analysis

For purpose of control system analysis, antilock systems can be broken down into four main components, as shown in Figure 4. These are the—

- Vehicle dynamics
- Sensor
- Controller
- Modulator

In general, each of these contain potentially significant nonlinearities. Yet, dynamic measurement of typical components, as well as simulation results, reported in (9) and elsewhere have shown that, to a first approximation, only the controller is fundamentally nonlinear (the other components are essentially linear). This means the frequency responses of the modulator, vehicle, and sensor can be combined and plotted and then compared to the response curve of the controller.

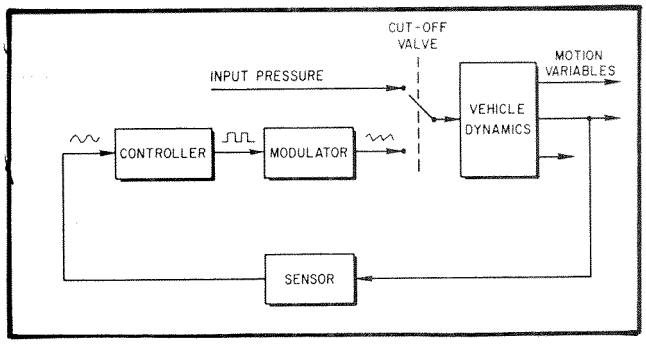

Figure 4. Generalized schematic of antilock control system

Figure 5 shows an example gain-phase plot. This is for an idealized acceleration sensor, a typical dump/reapply modulator (including time delay), and a dump/reapply switch controller. The latter can be referred to as a toggle, and in this case the toggle trigger values are 2g (i.e., ±1g) apart. Figure 5 shows that a limit cycle—

- Exists, at a frequency of 5Hz
- Is stable (left to right crossover)
- Is fairly insensitive to changes in vehicle or modulator gain (nonparallel curves)
- Has a fair stability margin (i.e., the limit cycle must decrease to less than 1g amplitude at 90° phase lag to destabilize the antilock)

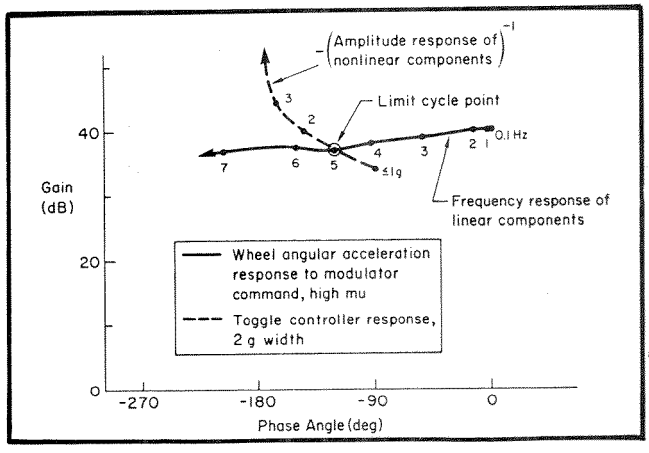

Figure 5. Example gain-phase plot for angular acceleration feedback, with 2g toggle

Another example is shown in Figure 6. The only difference from Figure 5 is that the toggle is set at ±2g, resulting in an unstable system (i.e., the wheel never decelerates enough to trigger the 2g dump condition; therefore, the wheel locks up).

Some of the fundamental difficulties inherent in using angular jerk as a feedback are shown in Figure 7. Since the linear and nonlinear response curves are fairly parallel (above 7Hz), small changes in any component will result in relatively large changes in limit cycle stability and stopping performance (i.e., it is an overly sensitive system). In particular, the potential limit cycle

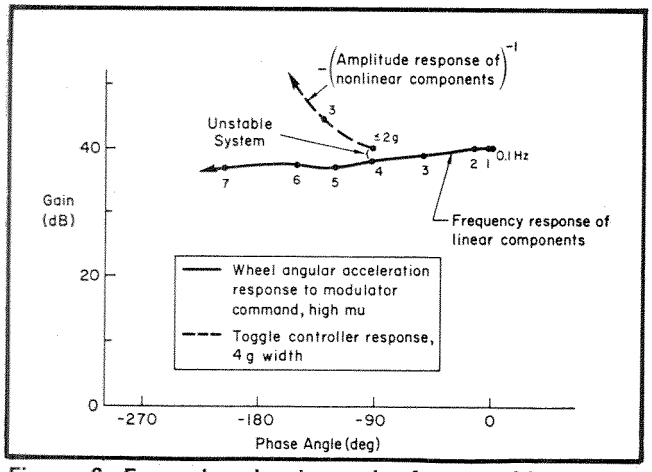

Figure 6. Example gain-phase plot for unstable system, angular acceleration feedback, with 4g toggle

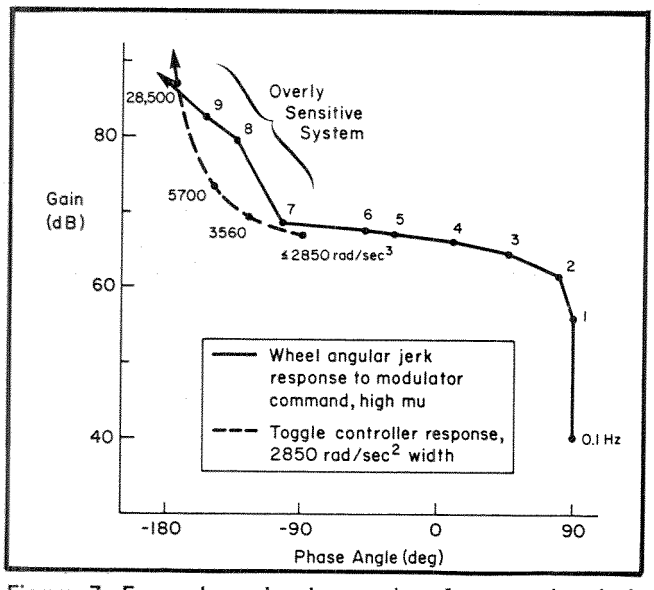

Figure 7. Example gain-phase plot for angular jerk feedback

near 7Hz is very close to the lockup boundary (i.e., 90° phase lag, as above), and the limit cycle near 10Hz is near the no-brake boundary where the system merely chatters, with little deceleration (i.e., 180° phase lag). Both of these adverse conditions can exist with jerk feedback, and a relatively small reduction in vehicle gain (e.g., about 10dB) could result in a completely unstable system. For these and other reasons, angular jerk feedback cannot be recommended.

An overall summary plot of antilock gain-phase results for acceleration feedback is shown in Figure 8. As can be seen, a feasible region of stable designs exists, bounded by a lockup region (at lower phase lags) and a no-braking region (at higher phase lags). Within the feasible region, higher intersections (or crossovers) result in rougher antilock cycling (the gain is logrhythmically related to limit cycle amplitude), while excessively low ones suggest oscillations so small they might become confused with

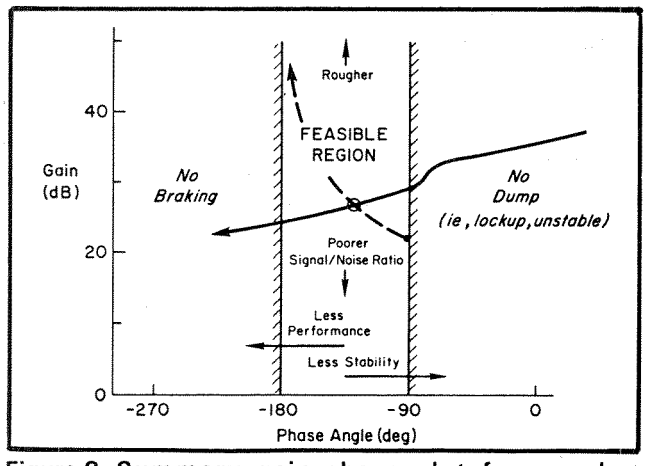

Figure 8. Summary gain-phase plot for angular acceleration feedback, with toggle controller

noise sources in the system. Again, stability decreases toward the right, and braking decreases toward the left.

Figure 8 is also significant in that it illustrates the relationships among antilock stability, performance, roughness, and noise, as well as the relative contributions of the controller's other system components. As an evaluation or design tool, it seems applicable to most single loop (and, with extension, possibly multiloop) antilock systems.

Preliminary Antilock Design

A combination of simulation, full-scale measurement, and gain-phase analyses was used to help define an initial feedback design and component requirements for the motorcycle fluidic antilock system. The analyses considered the effects of—

- Various feedback structures
- Controller (toggle) characteristics
- Modulator and vehicle responses
- High and low μ road friction characteristics

The basic design parameters are shown in Figure 9. Primarily these were modulator dump and reapply pressure rates, toggle (trigger) width and bias, and modulator-to-caliper net time delay.

A feasible front wheel antilock design for an example touring motorcycle (for both high and low μ surfaces) was defined as follows:

Feedback:	Wheel angular acceleration (assumed to have no sensor dynamics)
Dump rate:	-3600 psi/s
Reapply rate:	2000 psi/s
Toggle width:	3.0g
Toggle bias:	-1.5g
Modulator to caliper delay:	20ms

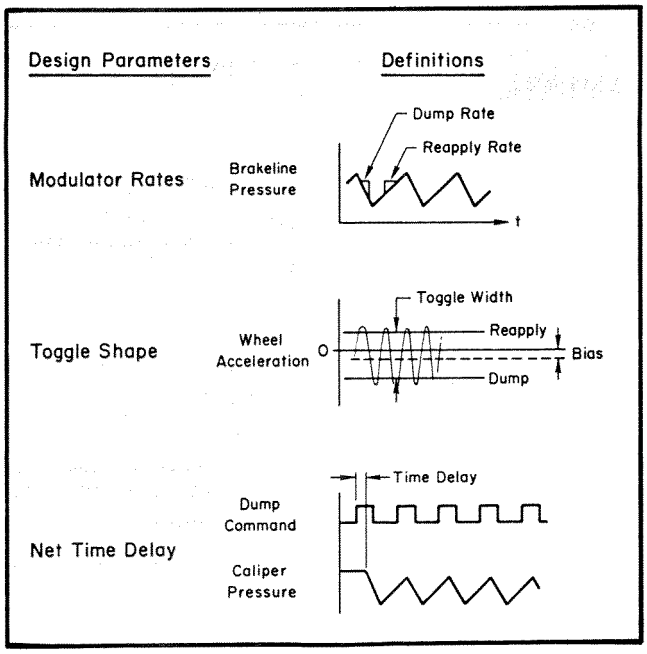

Figure 9. Design parameters varied in sensitivity analysis

This gave low μ stops of -0.23g at 13Hz, and high μ stops of -0.54g at 13Hz (subjectively, these were felt to be reasonable performance levels for an initial design; these are not intended to imply minimum acceptable levels or maximum attainable levels).

In addition, the initial design parameter values were perturbed ±50 percent to confirm that the design was not overly sensitive. Results are shown in Figures 10 and 11.

Effects of modulator pressure rates on vehicle deceleration and wheel speed roughness (peak to peak) are shown in Figure 10. The effects on high and low μ are seen to be quite different; not surprisingly, low μ is more sensitive to modulator response properties. For low μ, smaller reapply rates are better, as has been reported in the industry, while for high μ, higher reapply rates are better. The opposite preferences seem to apply to dump rates.

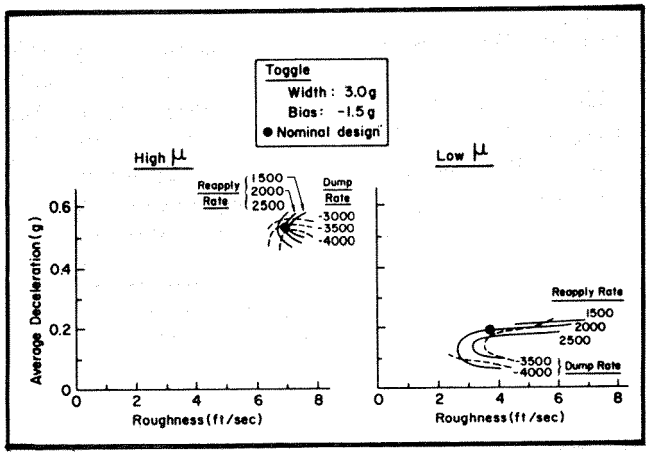

Figure 10. Effects of modulator dump and reapply rates on antilock performance

Effects of toggle (i.e., trigger) shape are shown in Figure 11. Here, fairly large effects are seen in both high and low μ performance. Greater toggle width, within limits, improves both high and low μ performance. On the other hand, greater toggle bias improves high μ performance but can considerably degrade low μ performance.

Of course, in general, somewhat larger changes in modulator or toggle design values than those listed here can result in exceeding the feasible design region or the subjectively acceptable region (related to roughness and noise).

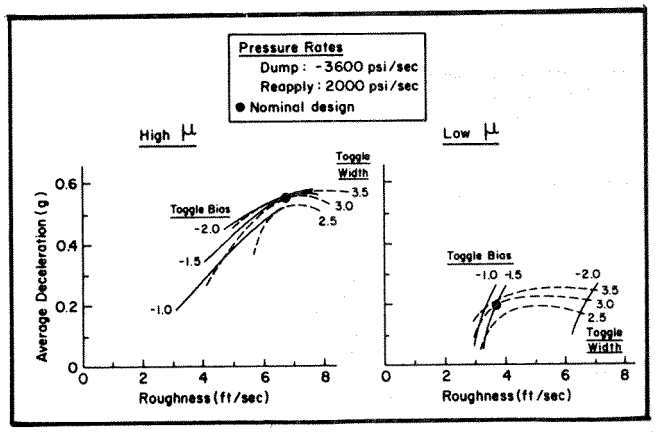

Figure 11. Effects of toggle width and bias on antilock performance

Preliminary results of the effects of time delay on high μ performance are shown in Figure 12. This shows a fairly high level of performance (-0.52g) at 20ms and considerably less performance (-0.36g) at 120ms. Currently it is unknown how the intermediate ranges of time delay compare to these more extreme values (i.e., whether there is a sharp or gradual reduction above 20ms). This seems to be a key design parameter variation for future antilock development, and a more complete analysis would be useful.

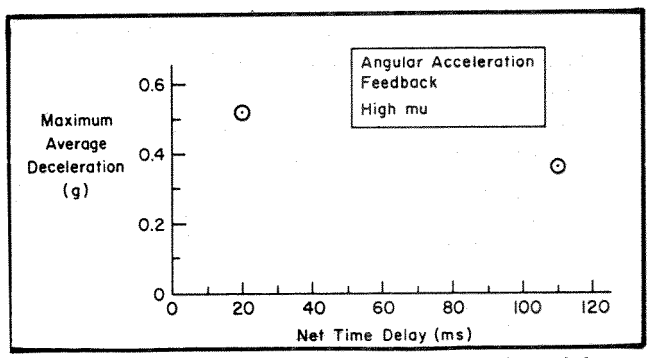

Figure 12. Effect of modulator-to-caliper time delay on antilock performance

Examples of resultant antilock time responses are shown in Figures 13 and 14 for 110 and 20ms delay times, respectively. Note that in these cases, the toggle and modulator parameters have been adjusted to give a balance among stability, performance, and roughness for

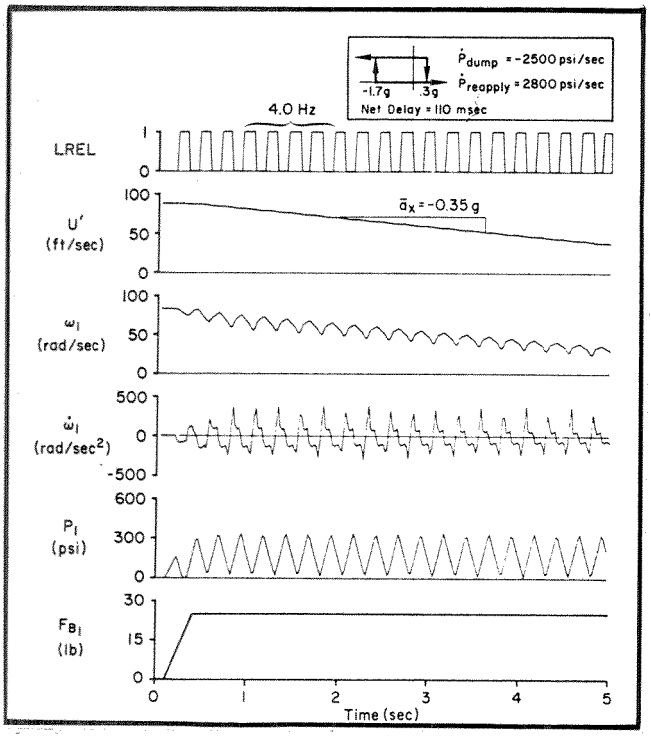

Figure 13. Example simulated antilock closed-loop response, 110ms time delay

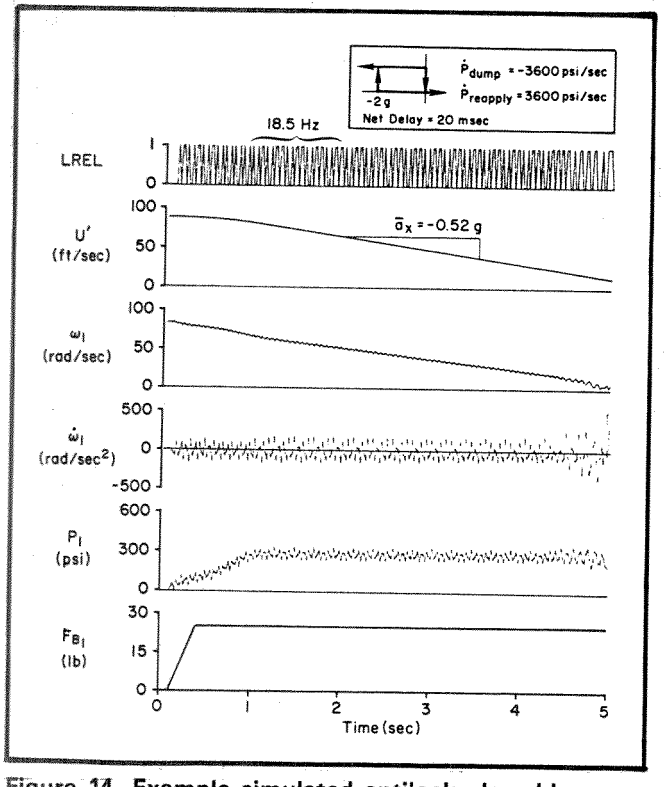

Figure 14. Example simulated antilock closed-loop response, 20ms time delay

high μ limit braking. Figure 13 (110ms delay) shows a relatively low (4Hz) cycling rate and deceleration level, with a fair amount of wheel speed roughness. Figure 14 shows a very smooth, high (18.5Hz) cycling rate similar to some aircraft systems and also a fairly high deceleration rate. Again, this suggests the importance of net time delay to overall antilock performance.

Conclusion and Recommendations

A generalized analysis of motorcycle antilock brake system dynamics—based on nonlinear control theory—was performed. Overall, the gain-phase analysis approach involved transforming antilock time responses to frequency responses and determining conditions necessary for existence of a stable limit cycle. The method was found to provide a generalized method for antilock analysis and to provide some possible insight into antilock dynamics and design effects and requirements.

In particular, preliminary design requirements were determined for example modulator, toggle, and sensor components. These indicated that—

- Wheel angular acceleration feedback provides a feasible single loop feedback design.
- Wheel angular jerk feedback is not desirable as a primary feedback control variable, in part because it results in excessive sensitivity to small variations in vehicle and systems parameters.
- A set of controller and modulator characteristics was found that gave a reasonable balance among performance, stability, and stability margin on both high and low μ surfaces.
- One way to achieve potentially higher performance stability levels on both high and low μ surfaces could involve use of μ dependent, adaptive controller or modulator, as may be found on some existing antilock systems.
- Net time delay between the modulator and caliper seems to be a key design parameter affecting performance and stability and should be evaluated more completely to assess fluidic and other antilock design requirements.

Measurement of Motorcycle Riders' Eye Locations

Masanori Motoki and
Tsutomu Asah
Japan Automobile Research Institute, Inc.

Abstract

In this study, with a final objective of obtaining such data necessary for the international standardization of eye ranges of motorcycle riders in the future, we selected five different models of motorcycles (with engine capacities ranging from 250cc class to 1,000cc class) comprising four typical motorcycle types and measured the eye locations and riding positions of 456 Japanese and American motorcycle riders mounted on those motorcycles.

As a result, we found that when the shoulder location is adopted as the origin, four items—namely, distances between shoulder and handle grip, shoulder and hip, shoulder and eye, and the angle formed by the locations of eye, shoulder, and hip—are nearly constant, regardless of differences in vehicle frame dimensions. Therefore, the eye range of motorcycle riders can be located from the relative positions between the handle grip and hip point.

Furthermore, through comparison of anthropometric data between Europeans and Americans, the actually measured eye locations of American riders can be used as representing European riders' eye locations.

Introduction

The statistical distribution (eye range) and the representative point (eye point) of motorcycle riders' eye locations are not only indispensable as reference points for the study of the indirect field of view by means of rear view mirrors, but also those data will be useful as reference points for the study of the direct field of view.

The eye locations of automobile (four-wheeled motor vehicle) drivers have been standardized internationally by ISO 4513(1), while, as for the eye locations of motorcycle riders, only the reference eye point is specified in VDTUV Leaflet 736(2) and no standard exists that specifies eye ranges indicating statistical distribution of eye locations.

This study, with a final objective of obtaining data necessary for the international standardization of eye ranges of motorcycle riders, was started in 1981 as a 2-year program. In the study program, three research items were adopted: comparing anthropometric data among Japanese, American, and European riders; establishing eye ranges of Japanese, American, and European riders; and obtaining the correct formula for eye locations.

Mopeds were excluded from this study because moped riders were clearly different in category from the riders of such motorcycles as were used for this study, and their riding positions were also quite different from those of motorcycle riders.

Comparisons of Anthropometric Data Among Japanese, American, and European Riders

Purpose

The purpose of this portion of the study was to obtain statistical anthropometric data of Japanese and American

riders through actual measurement of their physical members and to gather the necessary data for the estimation of eye locations of European riders by comparing the anthropometric data with those collected from studies concerning Japanese, American, and European people.

Method

Anthropometry

(1) Anthropometric instruments: Anthropometers and a sliding caliper were used for the measurement.

(2) Measurement points: Before the measurement, well-trained measuring staff manually located such measurement points as were difficult to locate visually—namely, cervical, left, and right acromions, right radiale, left and right trochanterions, and sphyrion, as illustrated in Figure 1—and marked them.

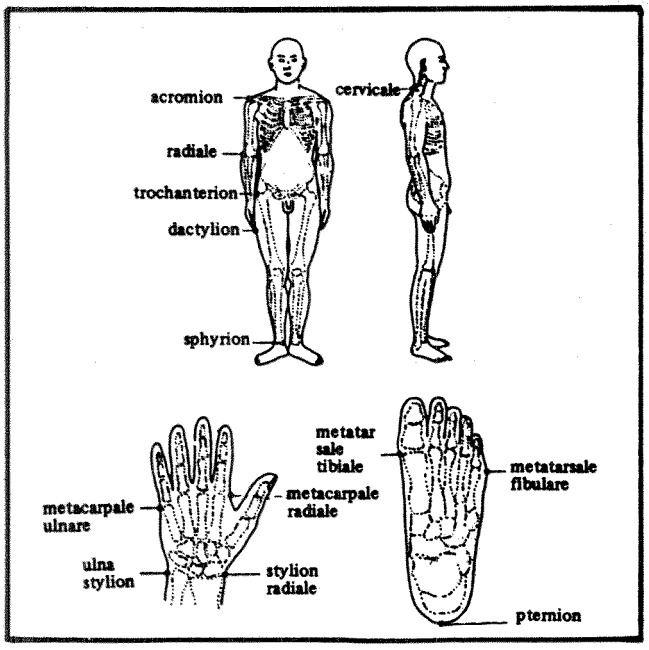

Figure 1. Measurement points

(3) Anthropometry items and physical members for measurement: The anthropometry items and physical members for the measurement are shown in Figure 2.

For the measurement in a standing posture, the riders took a natural standing posture with straight-ahead viewing so both left and right tragions and right orbitale were kept in a horizontal plane, and both arms were hanging down with their hand palms lightly contacting the side surfaces of the body except for the measurement of armreach from back.

For the measurement in a sitting posture, the riders took a natural sitting posture so that by adjusting the height of the chair, both thighs were nearly horizontal and both knees were about at a right angle to the thighs, both hands were placed on the thighs, and the head position was similar to that in a standing posture.

The riders measured wore jogging trunks only.

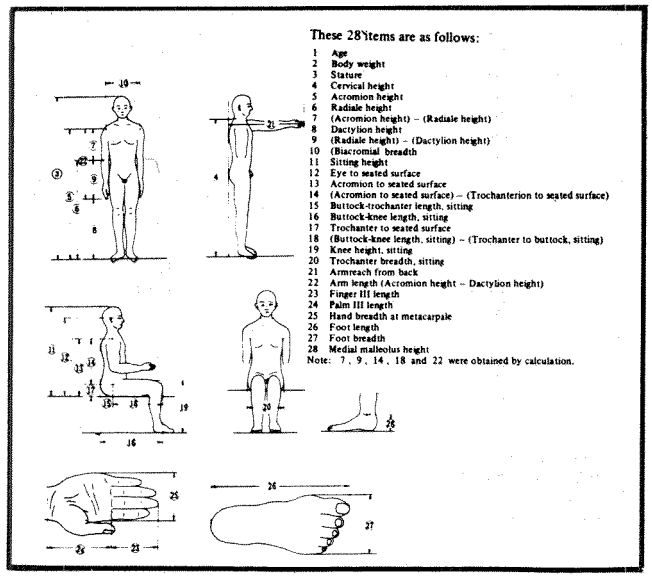

Figure 2. Anthropometry items and physical members for measurement

References Concerning Anthropometric Data

A Handbook of Anthropometric Data (3) published by the National Aeronautics and Space Administration (NASA) as the data to be used for the human engineering designs of space shuttles, space suits, and other space equipment contains rearranged data of anthropometry of various nations collected from 91 sources. In this handbook, 26 kinds of anthropometric data of male Americans and 5 kinds of those concerning Frenchmen, male Germans, and Englishmen, respectively, are included. NASA adopted one kind of data for the people of each nation from the above-mentioned data to determine the size of space suits(4).

In this study, the NASA-adopted data were used for the estimation of eye location of European riders.

Results

Anthropometric Data of Japanese and American Riders

The anthropometric data of Japanese riders are listed in Table 1 and those of American riders in Table 2. In these tables, statistical data of 28 items consisting of percentile values, maximum value, minimum value, mean value, and standard deviation are included as a result of calculation, although actual measurements were made with regard to 23 items.

Comparisons Among Dimensions and Proportions of Physical Members

The anthropometric data are apt to differ from one another according to the reference sources even within a nation. In Tables 3 and 4, three kinds of representative data published in each nation are shown for the purpose of comparison. These data were published in 1965 or later, and measurements were made with regard to the male.

The NASA-adopted data are printed in thick line numerals in the tables and used chiefly for comparison with Japanese riders.

(1) Stature: Japanese riders are 90mm lower in stature than American riders, 71mm lower than Frenchmen, 82mm lower than Germans, and 89mm lower than Englishmen. The statures of American riders are nearly equal to the data adopted by NASA. The difference between the maximum and the minimum data in a nation is about 30mm.

(2) Arm length: Japanese riders are 70mm shorter in arm length than American riders and ordinary Americans' reference literature data, 66mm shorter than Frenchmen, and about 90mm shorter than Germans and Englishmen. American and European people are generally long in arm length and large in the ratio of arm length to stature.

(3) Armreach from back: There are few actual measurement data concerning armreach from back of American and European people. From the few actual measurement data, it was found the differences between armreach from back and arm length are 49mm in Englishmen, 73mm in Germans, and 115mm in American riders. The large deviations in armreach from back data are supposed to be caused by the differences in the measuring positions or arm-stretching positions which differ remarkably from one another among these nations. In the case of arm length, on the contrary, as it was measured in such a position that both arms are drawn downward, this measuring position resulted in smaller errors due to measuring position or arm-stretching position.

Accordingly, actual measurement data of arm length are adopted instead of armreach from back for the estimation of eye locations for European riders because the data of armreach from back are larger in errors and, in addition, few data can be obtained.

(4) Sitting height: As for the ratio of sitting height to stature, riders are about 1 percent smaller than ordinary people in Japanese and Americans. This is considered to

Unit: mm

* : Estimated values
— : Data not available
() : Ratios against data of ordinary Americans

be due to the difference in physical positions in the measurement; in the measurement of sitting height, riders were somewhat relaxed.

(5) Eye to seated surface: American riders are 12mm longer in eye to seated surface than Japanese riders, while ordinary Americans as reported in reference literature are 36mm longer than Japanese riders.

Frenchmen are 60mm longer, Germans are 26mm longer, and Englishmen are 46mm longer in eye to seated surface than Japanese riders. Frenchmen especially show the longest eye to seated surface for all their shortest statures among European people, and the ratio of eye to seated surface to sitting height is about 2 percent larger than that of other European people.

(6) Acromion to seated surface: American riders are 31mm longer in acromion to seated surface than Japanese riders, ordinary Americans are 40mm longer than Japanese riders, and European people are 42 ~ 47mm longer than Japanese riders.

(7) Difference between eye to seated surface and acromion to seated surface: American riders are 19mm smaller in this value than Japanese riders, ordinary Americans are 4mm smaller than Japanese riders, and Germans are 17mm smaller than Japanese riders; Frenchmen are 13mm larger than Japanese riders, and Englishmen are 4mm larger than Japanese riders.

Deviation Range of Anthropometric Data

As an index to indicate the deviations in the measurement values in each nation, the ratios between the

measurement data of various physical members and statures are obtained. These ratios deviate by 1.0 percent in sitting height in Germans, 0.8 percent in arm length in Frenchmen, and about 0.5 percent in other items. Regarding sitting height, a 0.9 percent difference is found between Japanese riders and JASDF (Japanese Air Self Defense Force) members and a 1.1 percent difference between American riders and ordinary Americans.

These deviations found among the measured values within a nation are supposed to be caused by the differences in the positions taken for the measurement or the inaccuracy in making the measurement points and not by the variety in the specimens. Consequently, it is necessary to consider deviations of about 1 percent (18mm) of the values of statures for adopting anthropometric data.

Eye Ranges of Japanese, American, and European Riders

Purpose

The purpose of this segment of the study was to obtain the statistical distribution of eye locations (eye ranges) by means of the measurement of Japanese and American riders' eye locations and also to study the relation between the reference points on the test motorcycles (seat, handle grip, and footrest) and the eye range centroids after obtaining their riding positions from the locations of their eyes, shoulders, and hips.

An additional objective was to estimate the eye ranges of European riders from the anthropometric data of European and American peoples found in reference literature as well as the measurement data on eye locations of American riders.

Method

Measurement of Eye Locations of Japanese and American Riders

(1) Coordinates system: Three-dimensional indications of data in this paper are made in accordance with the orthogonal coordinates system with the seat reference point (a point located on the upper surface of the seat, and 200mm backward from the seat front end, and on the vehicle median plane) as the origin (Figure 3). When it is stated that the handle grip or footrest is adopted as the origin of the coordinates system, the center point of the upper surface of handle grip or footrest is to be the origin, respectively.

(2) Test motorcycles: Test motorcycles included five kinds of motorcycles whose engine capacities ranged

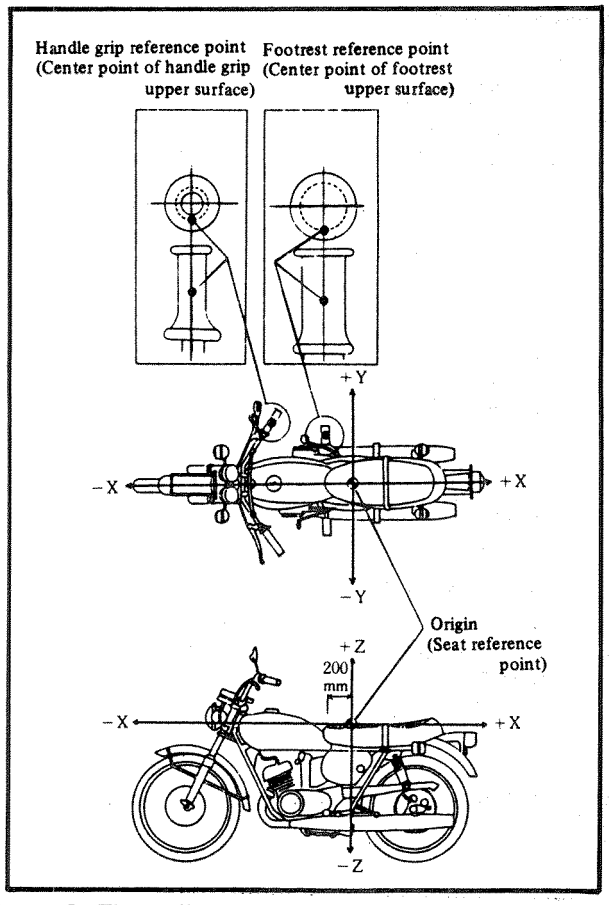

Figure 3. Three-dimensional orthogonal system and reference points

from 250cc class to 1,000cc class. They were divided into four types as follows:

- European-type motorcycles (handlebars located at the most forward position)—Yamaha RZ350, Honda CB750F
- Standard-type motorcycle (handlebar located at medium position)—Kawasaki Z1000J
- On-off-road-type motorcycle (bar-type handle, flat seat)—Suzuki TS250
- American-type motorcycle (chopper-type handlebar, stepped shape seat)—Honda CB750K

Dimensions of the test motorcycles regarding the seat reference point, shown in Figure 4, suggest that the test motorcycles can be divided into the following two groups:

- No. 1 Group: Distance between seat reference point and handle grip is long, thus the riding positions are inclined forward. (Hereinafter referred to as forward-inclined type. An example is shown in Figure 5.)
- No. 2 Group: Distance between seat reference point and handle grip is short, thus the riding positions are upright. (Hereinafter referred to as upright type. An example is shown in Figure 6.)

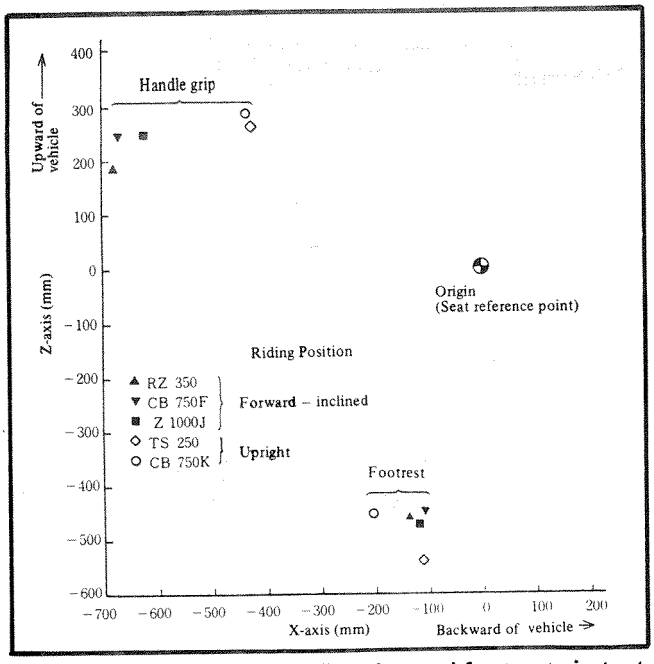

Figure 4. Locations of handle grips and footrests in test motorcycles

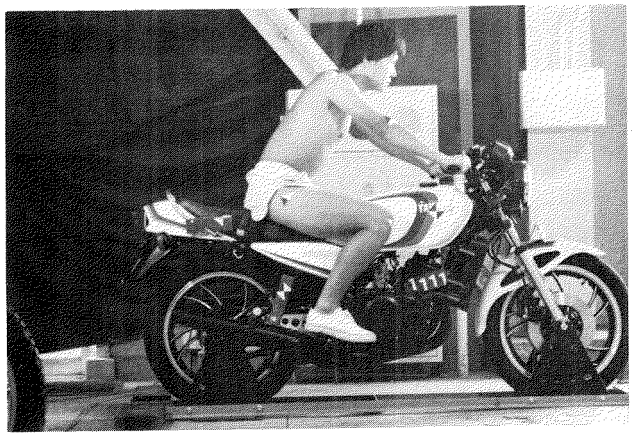

Figure 5. Example of test motorcycle showing forward-inclined riding position (RZ350)

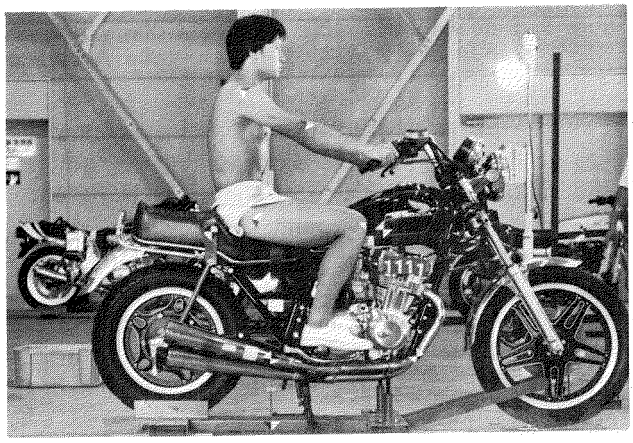

Figure 6. Example of test motorcycle showing upright riding position (CB750K)

(3) Locations of test motorcycle and cameras: The relative locations between the test motorcycle and cameras are illustrated in Figure 7. The test motorcycles were equipped with fixing jigs at the design attitude when one rider was mounting. The cameras were set at the same height as the seat reference point of the test motorcycle and located at 7.0m from the seat reference point.

(4) Measurement procedures: After the anthropometry was finished, the riders were affixed with the marks required for the data analysis at their shoulders and hips. The mark points (acromion and trochanterion) were located by means of manipulation of riders' shoulders and hips in nearly ordinary driving positions (both arms stretched horizontally and forward in a sitting position) and used as shoulder and hip reference points.

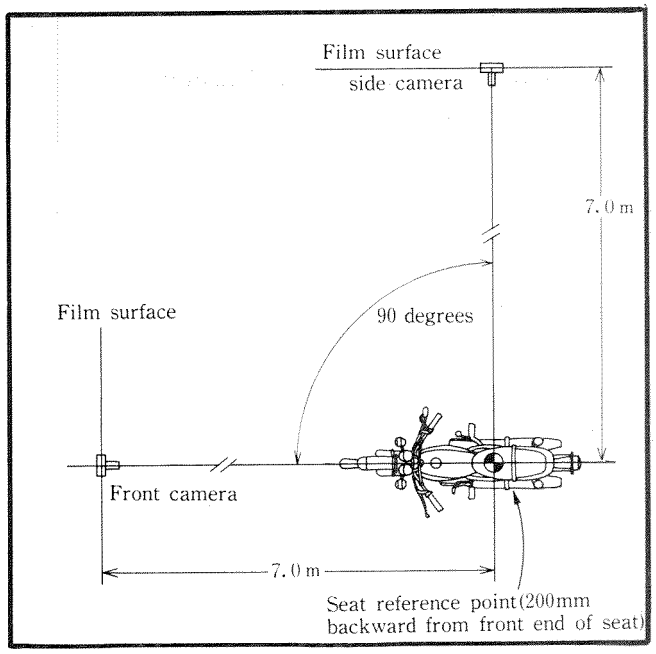

Figure 7. Locations of test motorcycle and cameras

As the next procedure, the riders taking such driving positions on the test motorcycles that correspond to ordinary driving at 50km/h were photographed synchronously by the front and side cameras.

(5) Data processing: The photographed 35mm films were read by a film analyzer with regard to the following items, and the data were collected as an output:

- Side view film (X and Z coordinates): Right eye, right shoulder, right hip, and frame marks for analysis
- Front view film (Y and Z coordinates): Right eye, left eye, and frame marks for analysis

The film analysis data were input into a computer to obtain the actual location of eyes, shoulders, and hips of the riders as well as their statistical distributions. As the locations in Y direction of the riders' acromion and trochanterion could not be photographed by the front camera, half values of biacromial breadth and tro-

chanterion breadth in a sitting position obtained by the anthropometry were used as substitutes for the calculation.

(6) Riders measured: A total of 456 motorcycle riders, comprising 301 Japanese riders and 155 American riders, were measured. All of them possessed motorcycle operation licenses and used motorcycles every day.

Estimation of European Riders' Eye Locations

Estimation was performed with the drawing method. Factors necessary for drawing were obtained by proportional calculations using the anthropometric data (ratios against the data of ordinary Americans listed in Tables 3 and 4) and the data of American riders' riding positions, assuming that the distance between shoulder and handle grip, shoulder and hip, and shoulder and eye are proportional to arm length, acromion to seated surface, and the difference between acromion to seated surface and eye to seated surface, respectively, in each nation.

In this estimation, the angles formed by eye-shoulder-hip and the location of hips of European riders were assumed to be the same as those of American riders.

Results and Consideration

Eye Range, Shoulder Range, and Hip Range of Japanese and American Riders

Eye ranges, shoulder ranges, and hip ranges of American riders on each test motorcycle, as well as the differences between those of American riders and Japanese riders, are shown in Table 5.

(1) Eye range: The sizes of side view eye ranges of American riders are similar for most test motorcycles. Eye ranges of 95th percentile values are ellipses with the major axes about 170mm long and the minor axes about 100mm long.

The inclination angles of the major axes in these eye range ellipses are about 30° in European-type motorcycles (Figure 8, for example) and 25° in standard-type motorcycles. No particular difference is found between these two types, while the inclination angles in on-off-road-type motorcycles and American-type motorcycles (Figure 9) are 14° and 8°, respectively, and are comparatively smaller than those in European- and standard-type motorcycles. When correcting by reducing the forward-inclined angles (the angles formed by the straight lines—one is drawn between the hip and shoulder, and the other is vertical) in riding positions, the inclination angles of the major axes of eye range ellipses, however, are nearly the same (10° ~ 13°) for all test motorcycles.

When compared with the side view eye ranges of Japanese riders, those of American riders are similar in

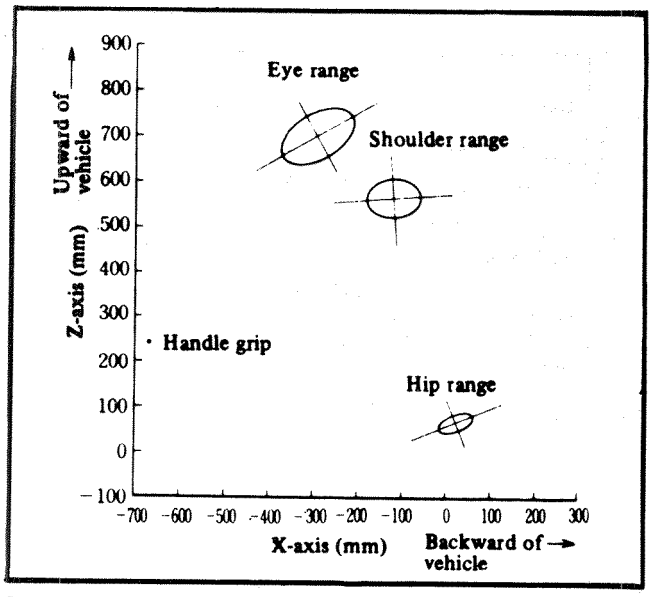

Figure 8. Side view eye range, shoulder range, and hip range of CB750F (95th percentile American riders)

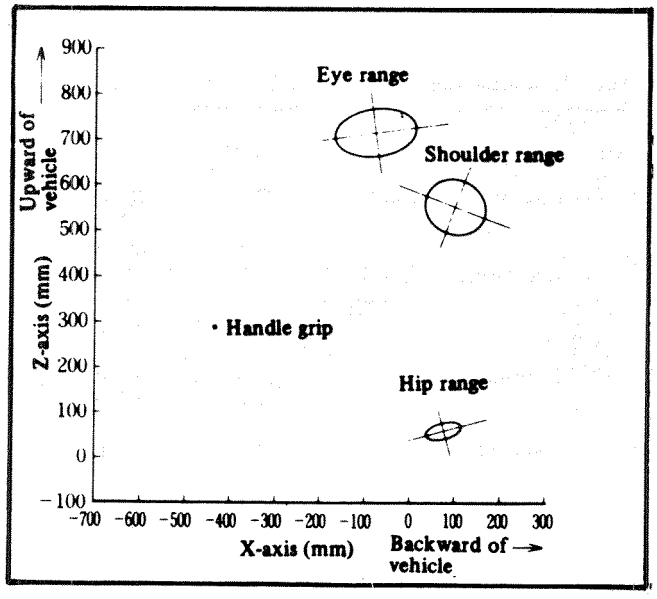

Figure 9. Side view eye range, shoulder range, and hip range of CB750K (95th percentile American riders)

the shape (the major axes of the ellipses are about 1.09 times as large as those of Japanese riders), but the inclination angles are smaller by about 20°.

The sizes of plan view eye ranges of American riders, in 95th percentile values, are a little larger and the major axes are 178mm long in American-type motorcycles (Figure 11) but nearly the same at about 160mm long in motorcycles of other types. (An example is shown in Figure 10.) The minor axes are about 35mm long in all test motorcycles.

The major axes of the plan view ellipses in American riders are somewhat larger (1.23 times) than those in

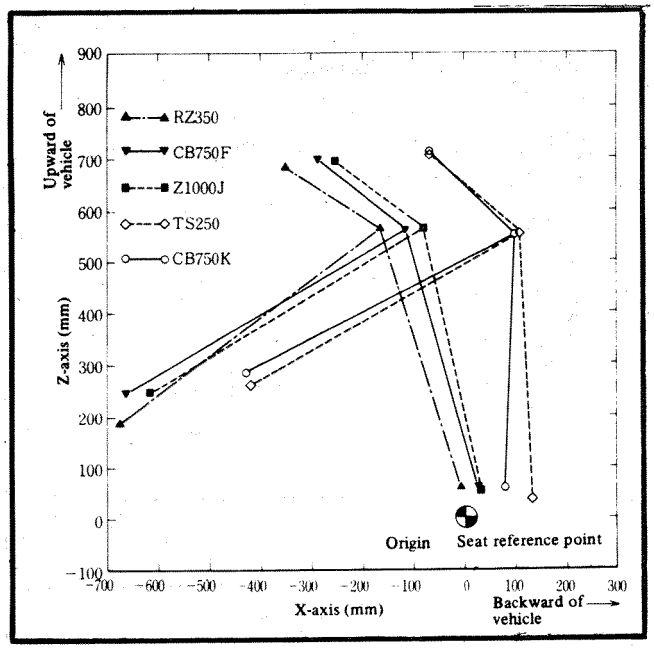

Figure 12. Locations of centroids with seat reference point as origin (American riders)

The differences in the locations of centroids between American and Japanese riders are—

- — Eye range centroids: 65 ~ 70mm in the longitudinal direction in the forward-inclined riding positions and 34 ~ 46mm in the upright riding positions, while 30 ~ 53mm in the vertical direction in the forward-inclined riding positions and 15 ~ 19mm in the upright riding positions
- — Shoulder range centroids: About 40mm in both directions
- — Hip range centroids: About 40mm in the longitudinal direction in most test motorcycles except for on-off-road-type motorcycles where the difference is 73mm owing to ample freedom in selecting seating positions on the seat

- With footrest reference point as origin: With the footrest reference point as the origin, centroids of eye ranges, shoulder ranges, and hip ranges of American riders are distributed in wide areas. (In the longitudinal direction, eye range centroids

On X-axis, "+" means American riders are located backward than Japanese riders.
On Z-axis, "+" means American riders are located upward than Japanese riders

are distributed for 183mm range, shoulder range centroids for 336mm range, and hip range centroids for 155mm range.)

With hande grip reference point as origin: With the handle grip reference point as the origin, the distribution of centroids of eye ranges, shoulder ranges, and hip ranges show different tendencies from those in other cases where the seat reference point or the footrest reference point is adopted to be the origin.

Namely, the hip range centroids of American riders are distributed in a wider area (185mm range in longitudinal direction), and their eye range and shoulder range centroids are distributed in a relatively narrow area. (Eye range centroid distribution is 56mm range in longitudinal direction and 72mm range in vertical direction. Shoulder range centroid distribution is 40mm range in longitudinal direction and 113mm range in vertical direction.)

Accordingly, the handle grip reference point is more suitable as a frame reference point than the seat or footrest reference points.

With shoulder range centroid as origin: With the shoulder range centroid as the origin, the locations of eye range centroids, hip range centroids, and handle grip reference points are shown in Figure 13.

In every test motorcycle, the distances from the shoulder range centroid to the handle grip reference point, to the hip range centroid, and to the eye range centroid are nearly constant, and the angles formed with the locations of eye-shoulder-hip also scarcely differ from one another.

Therefore, as illustrated in Figure 14, with the shoulder range centroid as the origin, the following items are obtained and compared among various types and models (Table 7).

Distance (A)	Distance between the shoulder range centroid and the handle grip reference point
Distance (B)	Distance between the shoulder range centroid and the hip range centroid
Distance (C)	Distance between the shoulder range centroid and the eye range centroid
Angle (α)	Angle formed with the locations of handle-shoulder-hip
Angle (β)	Angle formed between the straight line (shoulder-hip) and the vertical line
Angle (γ)	Angle formed with the locations of eye-shoulder-hip

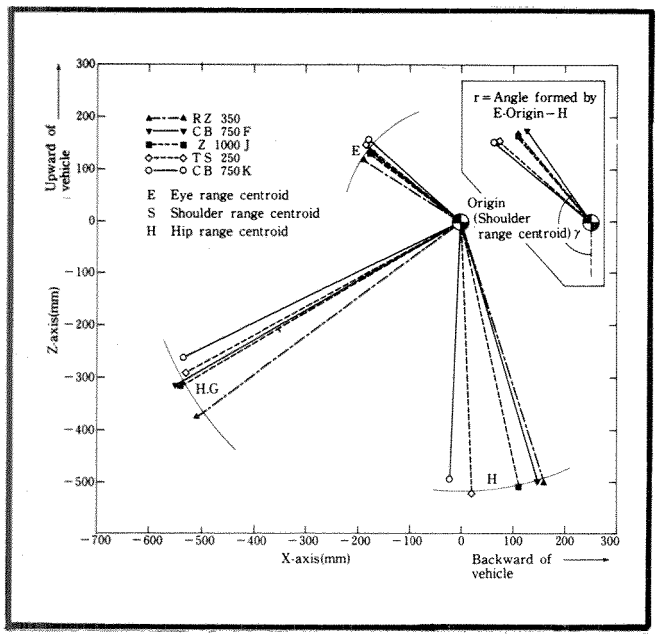

Figure 13. Locations of centroids with shoulder range centroid as origin (American riders)

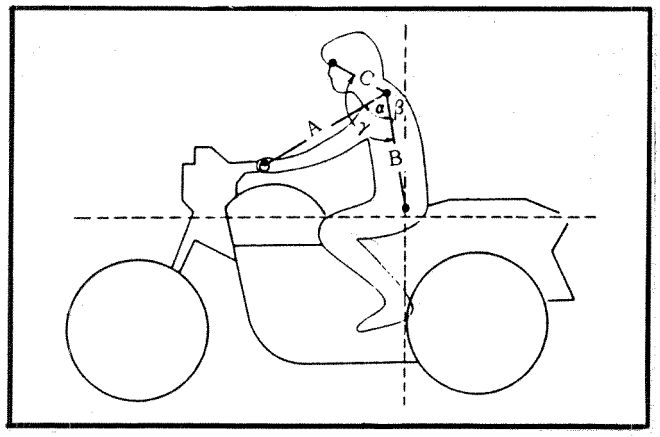

Figure 14. Indication of riding position with shoulder range centroid as origin

Distance (A) is about 630mm in European-type and standard-type motorcycles, 603mm in on-off-road-type motorcycles, and 593mm in American-type motorcycles. European-type and standard-type motorcycles are 30 ~ 40mm longer in distance (A) than on-off-road-type or American-type motorcycles.

Distance (B) is about 520mm and nearly the same in motorcycles of all types, except for American-type motorcycles in which distance (B) is 494mm.

Distance (C) in the forward-inclined-type motorcycles (European-type and standard-type motorcycles) is about 20mm shorter than that of the upright-type motorcycles (on-off-road-type and American-type motorcycles).

Unit: Major and minor axes: mm
Inclination angle: degree

(): Difference between American and Japanese riders "+" means American riders are larger than Japanese in an item. "-" means American riders are smaller than Japanese in an item.

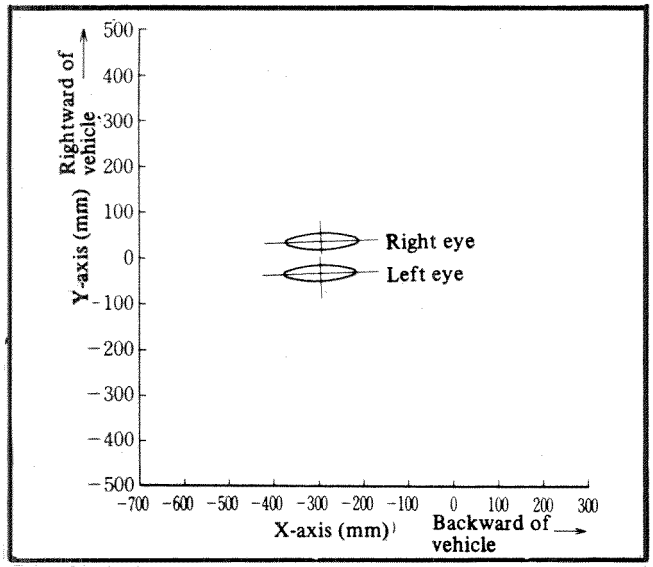

Figure 10. Plan view eye range of CB750F (95th percentile American riders)

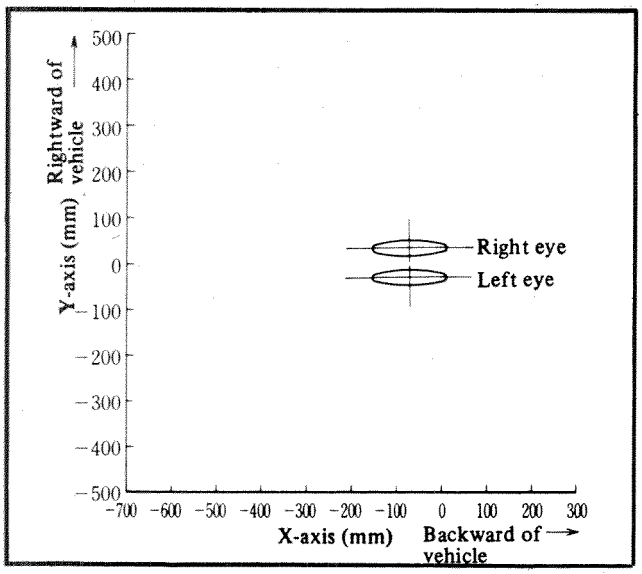

Figure 11. Plan view eye range of CB750K (95th percentile American riders)

Japanese riders. This is because the side view eye ranges of American riders are somewhat larger than those of Japanese riders, and the inclination angles of the major axes in the side view ranges are about 20° smaller than those of Japanese riders.

(2) Shoulder range: The sizes of shoulder ranges of American riders are nearly the same for all test motorcycles, and, in 95th percentile values, the shoulder ranges are ellipses with the major axes about 120mm long and the minor axes about 100mm long. The shapes of shoulder ranges are nearly circles.

The shoulder ranges in American riders are somewhat larger than those in Japanese riders. (The major axes are about 1.25 times as large as those in Japanese riders and the minor axes are 1.11 times.)

(3) Hip range: The sizes of hip ranges of American riders, in 95th percentile values, are nearly the same with the major axes about 95mm long in most European- and standard-type motorcycles, but are large (153mm in the major axes length) in American-type motorcycles and small (78mm in the major axes lengths) in American-type motorcycles. The minor axes are about 38mm long for all test motorcycles, and the inclination angles (of the major axes) are about 20° in European and standard types, 10° in on-off-road-type, and 15° in American-type motorcycles.

As for the sizes of hip ranges, American riders are similar to Japanese riders in all test motorcycles except for American-type motorcycles where American riders are a little smaller (0.78 times as large as Japanese riders).

(4) Relation between dimensions of test motorcycles and locations of eyes, shoulders, and hips of riders: The locations of eye range centroids, shoulder range centroids, and hip range centroids of American riders, as well as the differences between those of American riders and Japanese riders, are shown in Table 6, where the locations of those centroids are shown relatively in each test motorcycle with the seat reference point, the footrest reference point, and the handle grip reference point as the origins, respectively.

- With seat reference point as origin: The location of eyes, shoulders, and hips (eye range centroids, shoulder range centroids, and hip range centroids) of American riders on all test motorcycles with the seat reference point as the origin and the riding positions indicated by the lines drawn between these three centroids are shown in Figure 12.

  With the seat reference point as the origin, the locations of centroids of eye ranges, shoulder ranges, and hip ranges are distributed in wide areas. (In the longitudinal direction, eye range centroids are distributed for 280mm range, shoulder range centroids for 276mm range, and hip range centroids for 137mm range.)

  As the locations of hip range centroids of riders do not coincide with the seat reference points and are distributed in wide longitudinal ranges of 137mm, it is inappropriate that the seat reference point is adopted for setting H-point (hip point) or R-point (a design reference point corresponding to H-point). Accordingly, the actual measurements using a three-dimensional or two-dimensional manikin for motorcycles are considered necessary.

  When compared with Japanese riders, the locations of centroids of eye ranges, shoulder ranges, and hip ranges of American riders are more upward and rearward by a few centimeters than those of Japanese riders (Table 6).

Table 7. Relations among locations of eyes, shoulders, hips and handlegrip in American riders (factors for drawing)

Unit: Distance: mm

() Shows difference between American and Japanese riders.
"+" Means American riders are larger than Japanese in an item.
"-" Means American riders are smaller than Japanese in an item.

s = Shoulder hi = Hip H = Handle grip
e = Eye d = Distance a = Angle

Angle (α) of the forward-inclined-type motorcycles is larger than that of the upright-type motorcycles, and the angle formed with arm and back are closer to a right angle in the former type motorcycles than the latter.

Angle (β), which indicates the extent of the forward inclination in riding positions, is largest in European-type motorcycles. The average forward-inclination angle in European and standard types is 15.4°. On the contrary, in the upright-type motorcycles, this angle is 2.2° ~ -2.5°, which means nearly upright riding positions.

Angle (γ), formed with the location of eyes, shoulders, and hips, in the forward-inclined-type motorcycle is about 11° larger than that in the upright-type motorcycle, but the deviation of its value from the mean value in each type of test motorcycle is 3.1° maximum and in a stable condition.

It is found that riders adjust their riding positions to the differences in the dimensions of motorcycle frames chiefly by changing the angle (α) formed with arm and back and the forward-inclination angle (β).

It is also found that, with the increase in the forward-inclined angle, they would raise their head.

Distance (A) of American riders is about 50mm longer and distance (B) is 10 ~ 20mm longer than Japanese riders, while distance (C) of American riders is 20mm shorter than Japanese riders.

This tendency agrees with the fact that American riders are 70mm longer in arm length, 31mm longer in acromion to seated surface, and 19mm shorter in the distance between eye to seated surface—acromion to seated surface than Japanese riders (see Tables 3 and 4).

Angle (β), the forward-inclination angle of riders' torsos, of American riders on European-type motorcycles is about 2° smaller and on standard-type motorcycles 1° smaller than Japanese riders. This is because American riders have physical margins for the distance between shoulder and handle, which enables them to assume slightly forward-inclined riding positions.

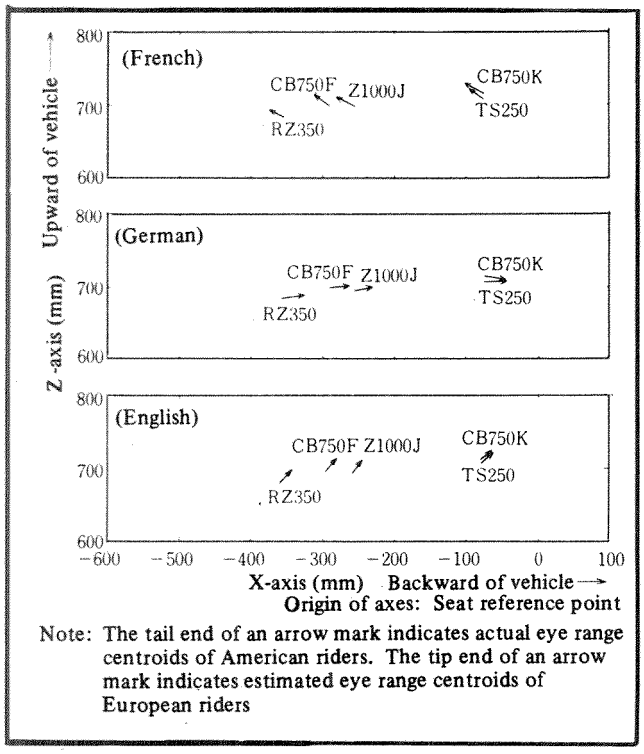
Angle (γ), formed with the locations of eye-shoulder-hip, is about 3° larger in American riders on European-type motorcycles and is 2.6° smaller in American riders on American-type motorcycles than Japanese riders.

- Correction of eye locations in accordance with test motorcycle dimensions: As stated in the foregoing, with the shoulder range centroid as the origin, four factors—namely, distances (A), (B), (C), and angle (γ)—hardly vary with the dimensions of test motorcycles within each riding position type. (But distance (B) in on-off-road-type motorcycles is similar to that in the forward-inclined riding position types.)

  Therefore, for an American rider, eye location can be determined with regard to any motorcycle by describing a drawing with these four factors, if the positional relations between the handle grip reference point and H-point of the rider are known (see Figure 14).

Estimation of European Riders' Eye Locations

With the handle grip reference point and the hip range centroid as the origin, the locations of eye range centroids of European riders were estimated by the drawing method as shown in Figure 14, and the differences in eye range centroid locations between American and European riders are shown in Figure 15. In this figure, arrow marks show the differences in eye range centroid locations from



Note: The tail end of an arrow mark indicates actual eye range centroids of American riders. The tip end of an arrow mark indicates estimated eye range centroids of European riders

Figure 15. Differences between estimated eye range centroids of European riders and actual measured eye range centroids of American riders

those of American riders. (Base end points of arrow marks show actually measured locations of eye range centroids of American riders, and front end points indicate the estimated eye range centroid locations of European riders.)

The locations of French riders' eye range centroids are estimated to be 20 ~ 25mm forward and 15mm upward more than those in American riders. This is because French riders are somewhat longer in acromion to seated surface than American riders (acromion to seated surface in French riders is 7mm longer than in American riders), and they are also larger in the difference between eye to seated surface and acromion to seated surface than American riders. (This difference in French riders is 17mm larger than in ordinary Americans.)

The location of German riders' eye range centroids are estimated to be 24 ~ 30mm more backward than those of American riders. This is because German riders are longer in arm length (21mm longer than American riders) and the difference between eye to seated surface and acromion to seated surface in German riders is shorter (by 13mm) than in American riders.

The locations of English riders' eye range centroids are estimated to be 15 ~ 20mm backward and 10 ~ 20mm upward more than those of American riders. This is because English riders are longer in arm length (by 22mm)than American riders and are also somewhat larger in the difference between eye to seated surface and acromion to seated surface (by 8mm) than American riders.

As stated above, the differences between the estimated location of eye range centroids for European riders and the location of eye range centroids in American riders are not so large and are about 30mm maximum. The differences in anthropometric data used for the estimation of eye range centroid locations between Europeans and Americans are maximum 22mm and are nearly the similar values to the tolerances on the anthropometric literature references (18mm maximum).

Accordingly, until such time when actually measured data of eye ranges in European riders are obtained, eye ranges of actual measurement in American riders should be adopted instead of the estimated locations of eye range centroids for European riders as the representative eye range for European riders. Figure 16 shows an example of comparison in eye ranges, shoulder ranges, and hip ranges among Japanese, American, and German riders.

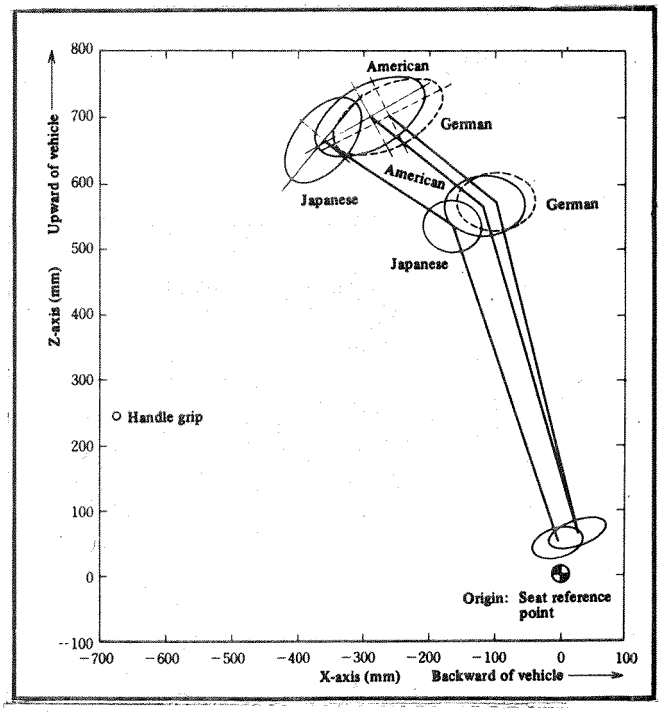


Figure 16. Comparisons of eye ranges, shoulder ranges, and hip ranges among Japanese, American, and German riders (CB750F)

Correction Formula for Eye Locations

Purpose

The purpose of this portion of the study was to establish a correction formula for eye ranges in consideration of vehicle dimensions and running speeds that affect riders' eye locations.

Method

Measurement of Variation in Eye Locations in Accordance With Vehicle Dimensions

(1) Mock-up: A mock-up for motorcycles was used. The locations of its handlebar and footrests could be changed in both longitudinal and vertical directions. In this study, the mock-up could cover the specifications of three types of test motorcycles (CB750F, TS250, and CB750K, Figure 17). In the mock-up, the standard locations of handle grip and footrest with the seat reference point as the origin coincided with those of each test motorcycle (see Figure 4).

(2) Measurement conditions: In each test motorcycle, either handle grip or footrest was fixed at the standard location and the location of the other was changed.

(3) Riders measured: Eleven motorcycle riders from Japanese manufacturers were measured. Their statures were averaged to be 1,679mm, which was nearly equal to the average of all Japanese riders' statures (1,685mm). The locations of test motorcycles and cameras, the measurement procedures, and the data processing were the same as stated before.

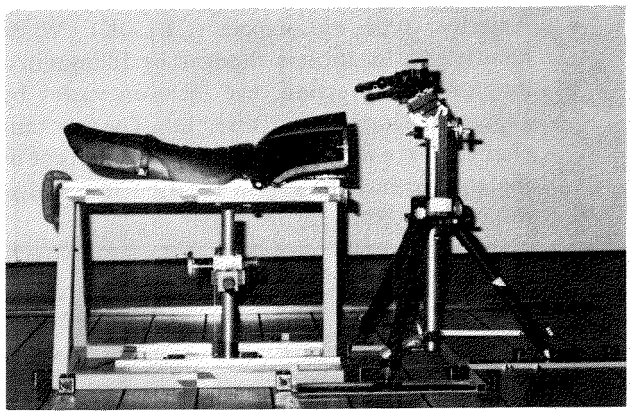

Figure 17. Motorcycle mock-up (European type)

Measurement of Variation in Eye Locations in Accordance With Vehicle Running Speed

(1) Test motorcycles: Two European-type motorcycles (Honda CB750F) with engines of 750cc piston displacement were used as the test motorcycles. One was equipped with a fairing and the other was not. The location of the fairing upper edge was 868mm forward and 534mm upward on the longitudinal median plane with the seat reference point as the origin.

(2) Photographing method: Side views of motorcycle riders running on a test course were photographed with a high-speed camera. The photographing rate was 500 frames/s, and the photographing distance was 15m.

As the riders wore full-face protective helmets, the locations of eyes were not photographed directly; therefore, the analysis marks for the indications of eye location were affixed on the surface of the helmets. (Intersections of those marks represent eye locations.)

Furthermore, the analysis marks representing locations of shoulder and hip were affixed on the riding wears for the identification of locations of acromion and trochanterion of the riders when they took riding positions adequate to various driving speeds.

(3) Running speed: Six running speeds in a range between 50 and 180km/h were selected for the testing. Each rider ran at a speed checked by a calibrated speedometer and passed through the front of the camera maintaining a steady and specified speed by assuming a natural riding position (Figure 18). The difference between the actual running speed obtained from the timing marks of the photographed films and the specified running speed was within about 2km/h in every running condition.

(4) Riders measured: Twelve riders from Japanese manufacturers participated in this test. Their statures were averaged to be 1,692mm, which was nearly equal to the averaged stature of all Japanese riders (1,685mm). The data obtained were processed in the same procedures as stated before.

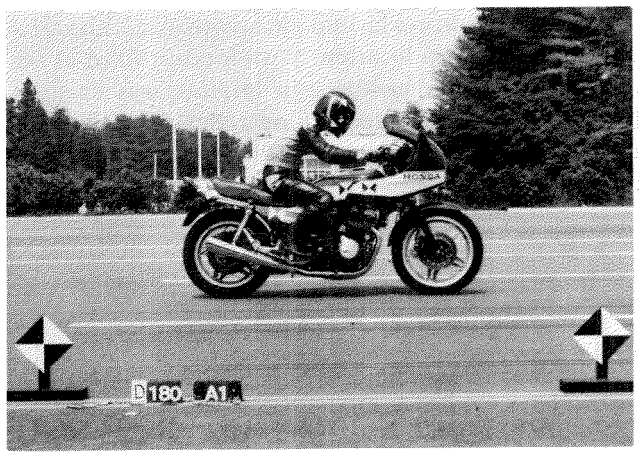

Figure 18. Riding position in actual running

Results and Considerations

Variation in Eye Locations in Accordance With Variation in Vehicle Dimensions

(1) Variation in eye locations in accordance with variation in footrest location: With handle grip fixed at the standard location, footrest location was changed from its standard location. Under this condition, the mean values of eye locations of 11 riders were obtained and studied.

- European-type motorcycle (CB750F): When footrest location is changed by 100mm in a

longitudinal direction, eye location varies by 18mm maximum in a longitudinal direction. When footrest location is changed backward, eye location shows a tendency to move somewhat forward. When footrest location is changed by 115mm in a vertical direction, eye location varies by 13mm maximum in a longitudinal direction, but no generally acceptable tendency is found.

- On-off-road-type motorcycle (TS250): When footrest location is changed by 100mm in a longitudinal direction, eye location varies by 10mm maximum in a longitudinal direction. When footrest location is changed by 115mm in a vertical direction, eye location varies by 19mm maximum in a longitudinal direction, but no generally acceptable tendency is found.
- American-type motorcycle (CB750K): Even if footrest location is changed by 100mm in a longitudinal direction, eye location hardly varies. When footrest location is changed by 75mm in a vertical direction, eye location varies by 11mm maximum in a longitudinal direction, but no generally acceptable tendency is found. It has become clear that the rider's eye location is scarcely influenced by the change in footrest location.

(2) Variation in eye location in accordance with variation in handle grip location: With footrest fixed at the standard location, handle grip location was changed from its standard location. Under this condition, the mean values of eye locations of all 11 riders were obtained and studied.

- European-type motorcycle (CB750F): When handle grip location is changed by 200mm in a longitudinal direction, eye location varies by 173mm in a longitudinal direction. The resultant change in eye location (179mm) is 90 percent of the change in handle grip location in a longitudinal direction (Figure 19).

  When handle grip location is changed by 125mm in a vertical direction, eye location varies by 89mm in a longitudinal direction. The resultant change in eye location (99mm) is 79 percent of the change in handle grip location in a vertical direction (Figure 20).
- On-off-road-type motorcycle (TS250): When handle grip location is changed by 125mm in a longitudinal direction, eye location varies by 82mm in a longitudinal direction. The resultant change in eye location (83mm) is 66 percent of the change in handle grip location in a longitudinal direction (Figure 21).

  When handle grip location is changed by 100mm in a vertical direction, eye location varies by 24mm in a longitudinal direction. The resultant change in eye location (25mm) is 25 percent of the change in handle grip location in a vertical direction (Figure 22).
- American-type motorcycle (CB750K): When handle grip location is changed by 187mm in a longitudinal direction, eye location varies by 145mm in a longitudinal direction. The resultant change in eye location (146mm) is 78 percent of the change in handle grip location in a longitudinal direction (Figure 23).

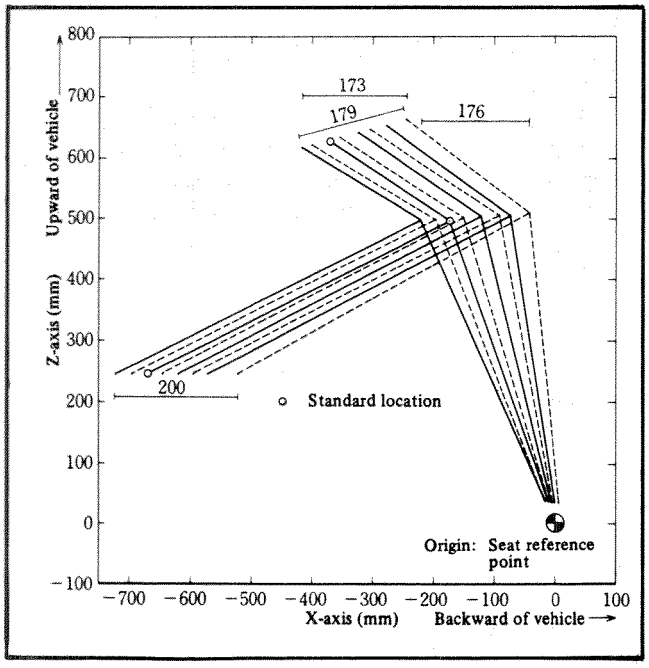

Figure 19. Riding position variation according to variation in handle grip location in longitudinal direction (European type)

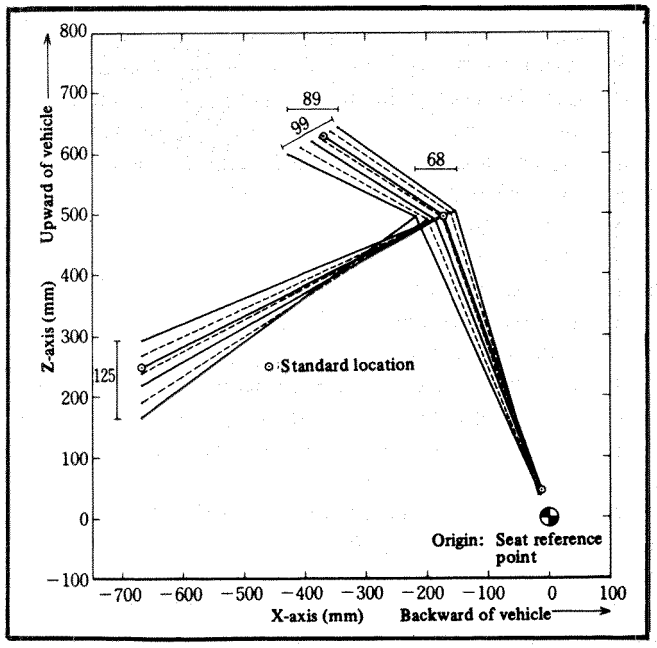

Figure 20. Riding position variation according to variation in handle grip location in vertical direction (European type)

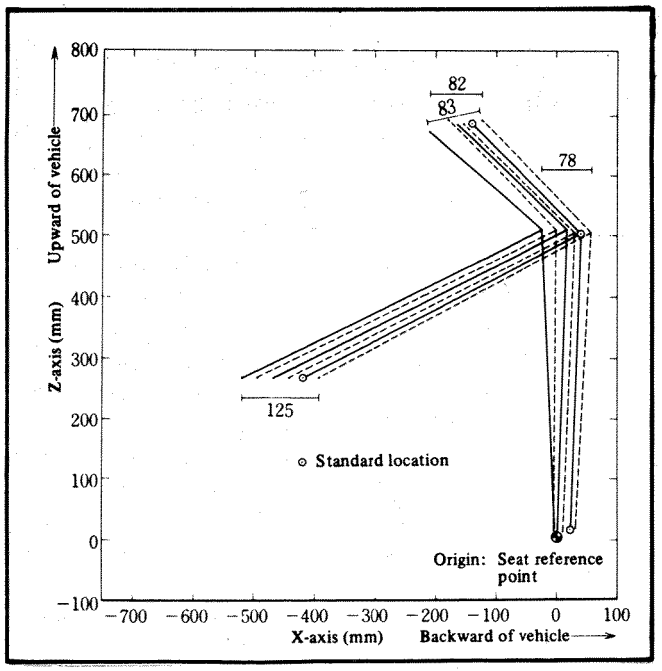

Figure 21. Riding position variation according to variation in handle grip location in longitudinal direction (on-off-road type)

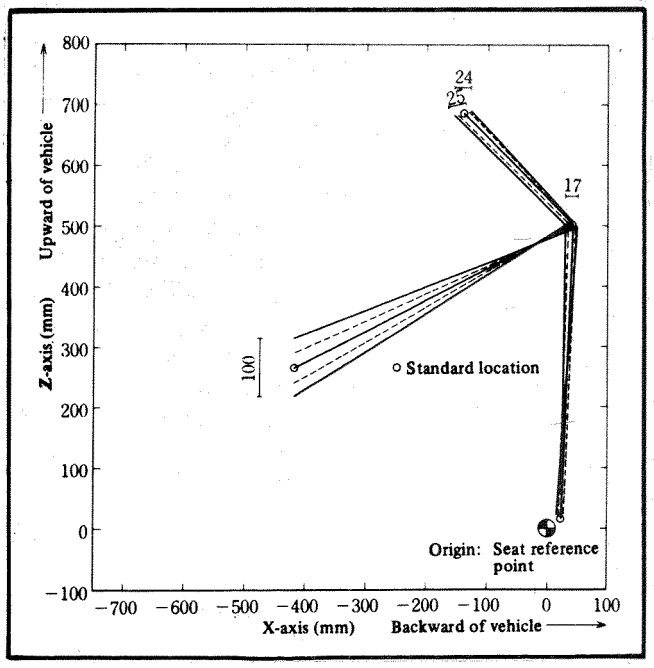

Figure 22. Riding position variation according to variation in handle grip location in vertical direction (on-off-road type)

When handle grip location is changed by 75mm in a vertical direction, eye location varies by 25mm in a longitudinal direction. The resultant change in eye location (26mm) is 35 percent of the change in handle grip location in a vertical direction (Figure 24).

As stated above, it is found that in any type of motorcycle with variation in handle grip location in a forward or downward direction, riding position is changed to forward inclined and eye location changes forward and downward.

The resultant change in eye location depends on the conditions. The longer the distance between the seat and the handle grip, the larger the variation in eye location. However, the variation in handle grip location in a longitudinal direction exerts a larger effect on the change in eye location than that in a vertical direction.

(3) Relation between handle grip location and riding position: The relation between the rider's forward-inclination angle (β) and four factors—namely, distance (A) (distance from shoulder to handle grip), distance (B) (distance from shoulder to hip), distance (C) (distance from shoulder to eye), and angle (γ) (formed with location of eyes, shoulders, and hips)—are shown in Figure 25.

Distance (A) is constant when angle (β) is 5° or more but is reduced when angle (β) is less than 5°, where riding position is near an upright position. (Distance (A) is reduced at a rate of about 30mm per 5° in the variation of angle (β).) This shows that the rider's arm is extended in a common manner in motorcycles of a forward-inclined riding position type irrespective of vehicle dimensions and that the arm-bending angle is increased with the decrease of angle (β) in an upright riding position type.

Distance (B) is a little decreased with the decrease of angle (β) in any type of motorcycle (about 6mm per 5° of variation in angle (β)) except for on-off-road type. In on-off-road-type motorcycles, distance (B) is constant irrespective of the forward-inclination angle. The value of distance (B) in on-off-road type is more similar to that in a European type than in an American type.

Distance (C), on the contrary, has a tendency to increase with the decrease of angle (β) (about 4mm per 5° of the variation in angle (β)).

Angle (γ) varies for some range even though angle (β) is constant, owing to other conditions, and shows a tendency to vary in such a manner as to be proportional to angle (β) (about 2.5° per 5° of the variation in angle (β) corresponding to about 10mm of the variation in eye location).

Variation in Eye Location in Accordance With Vehicle Running Speed

The riding positions at various running speeds are shown in Figures 26 and 27 by using mean values of 12 riders.

When a fairing was not equipped on the test motorcycle, with the increase in running speed, the forward-inclination angle in a riding position increased (hip location changed backward and shoulder location changed forward and downward), and eye location changed forward and downward (Figure 26).

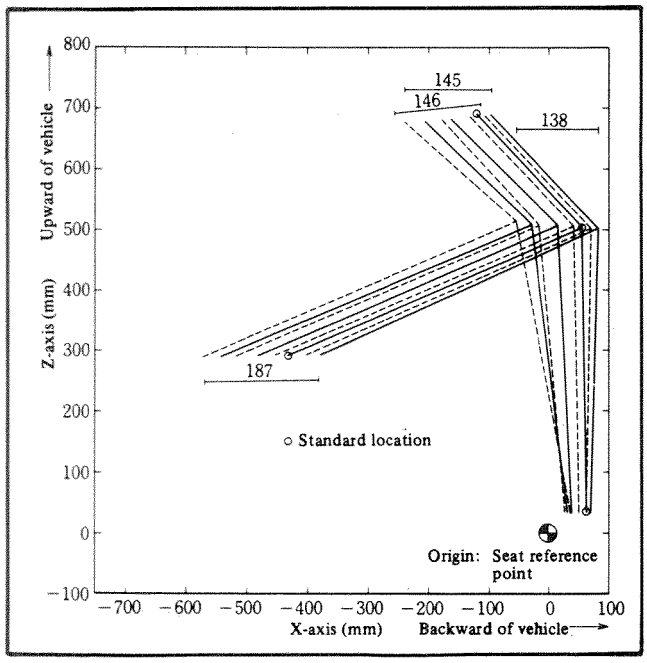

Figure 23. Riding position variation according to variation in handle grip location in longitudinal direction (American type)

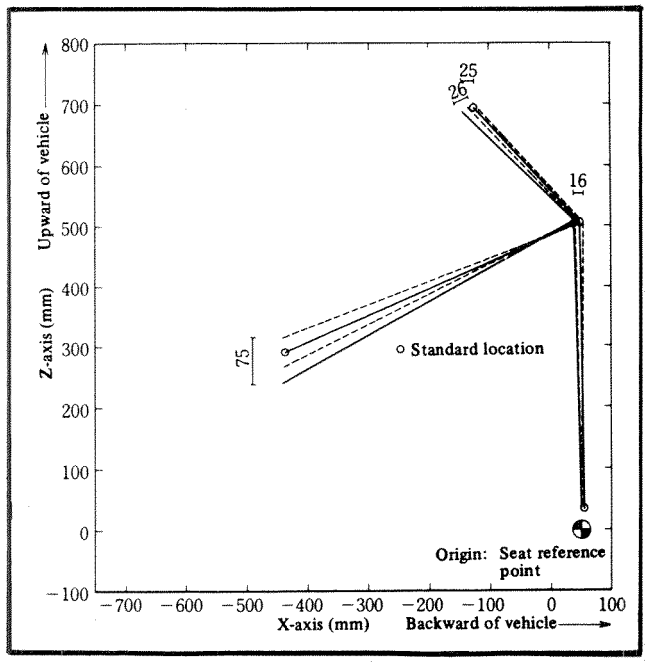

Figure 24. Riding position variation according to variation in handle grip location in vertical direction (American type)

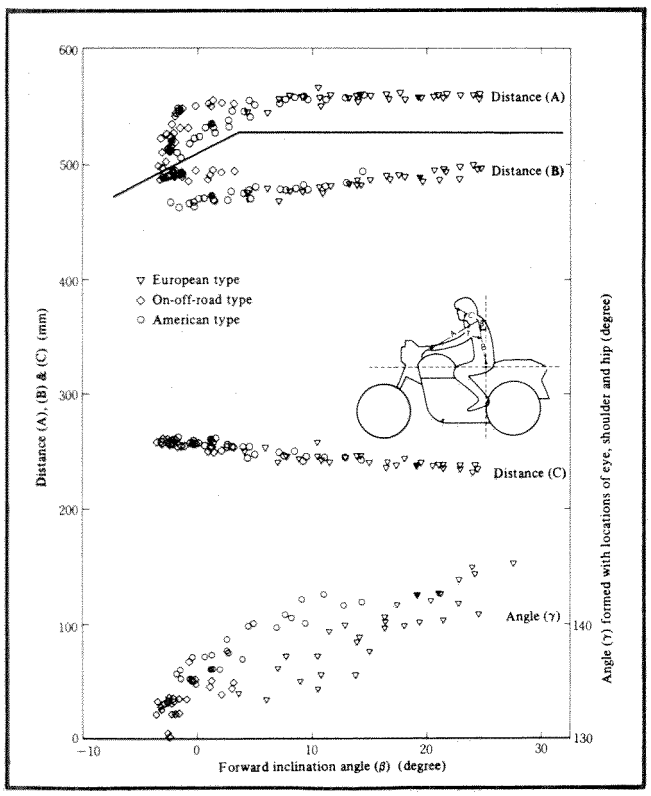

Figure 25. Factors (A), (B), (C), and (γ) for drawing in reference to forward-inclination angle (β)

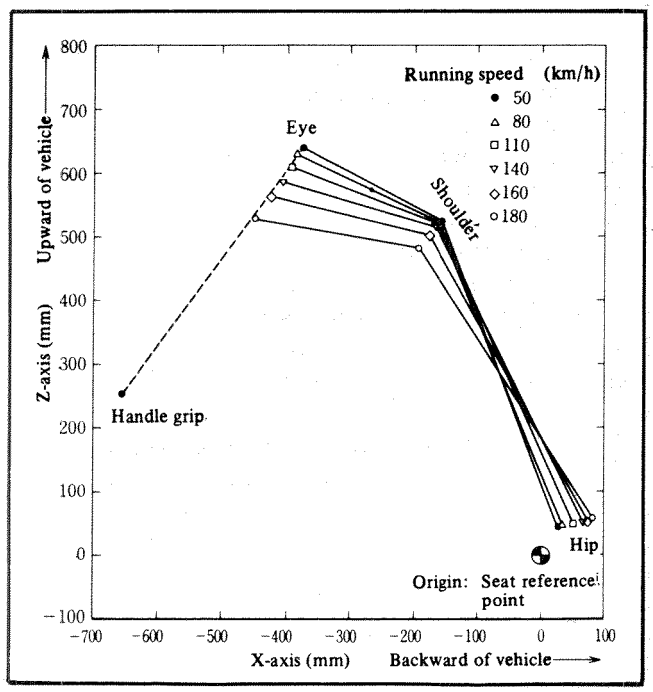

Figure 26. Variation of eye location according to running speed (without fairing)

When a fairing was equipped on the test motorcycle, the forward-inclination angle in a riding position also increased, and eye location changed forward and downward with the increase in running speed (Figure 27).

In addition to these tendencies, when eye location changed forward and downward, the downward view angle formed with a straight line drawn through the eye and the upper edge of fairing and the horizontal line

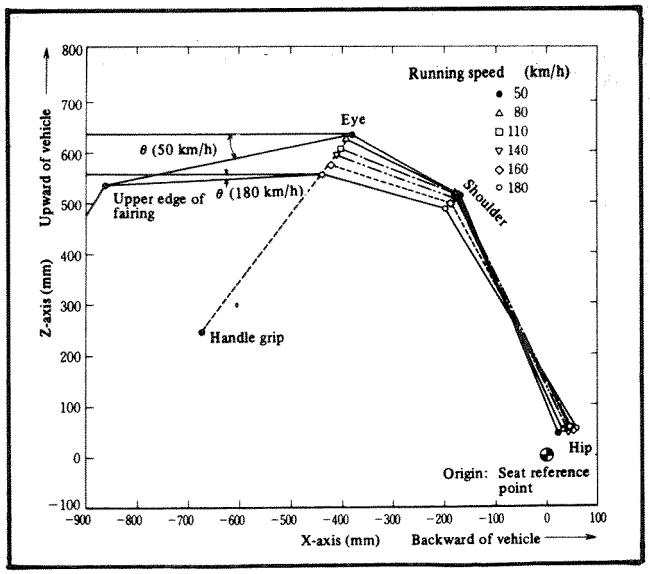

Figure 27. Variation of eye location according to running speed (with fairing)

(angle θ in Figure 27) decreased and was at a speed of 180km/h, about one-fourth of that at 50km/h.

In any case, with the change in running speed, eye location moved on a straight line drawn through the eye location at a running speed of 50km/h and the handle grip reference point. With location of eyes at a running speed of 50km/h as the standard location, resultant changes (distances) in eye location at various running speeds are shown in Figure 28.

If fairings are not equipped, the resultant changes in eye location are 37mm at a running speed of 110km/h and 65mm at a running speed of 140km/h. If fairings are equipped, the resultant change in eye location is 35mm at a running speed of 110km/h and 52mm at a running speed of 140km/h.

When compared with the former case, the difference is found to be negligible in change of eye locations between

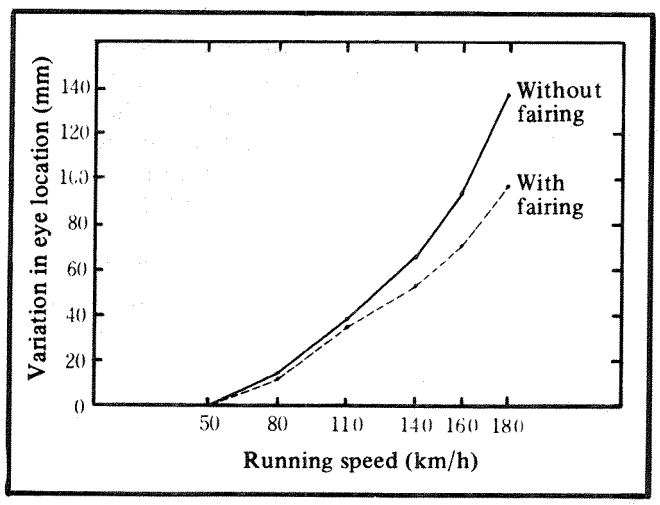

Figure 28. Resultant change of eye location according to running speed

this and the former cases until reaching a running speed of 110km/h, but, when reaching 140km/h or more, the eye location change in this case is smaller than that in the former case.

This shows that fairings will have no effect on the riding position until reaching high running speeds.

Method for Establishment of Eye Ranges

The Working Group for Motorcycle Rider's Eye Range of the Society of Automotive Engineers of Japan, Inc. (JSAE) worked to develop a standard based on the data obtained by this study and completed its work in establishing JASO T005(5), "Motorcycle Rider's Eye Range" under the approval of the Japan Automobile Standard Organization in March 1984.

The purpose of this standard is to specify the method for determining the rider's eye range that will be used as the origin in the study of the indirect field of view in motorcycles. Accordingly, this standard specifies the eye range of a motorcycle rider when seated on the motorcycle in the ordinary riding position and the method to determine it.

For assessment of the direct field of view in the motorcycle equipped with a fairing, this standard recommends considering also the eye location (estimated from the anthropometric data) of the rider taking a stretched riding position as the origin in addition to that of the ordinary riding position.

The factors for drawing prescribed in the standard for establishing eye range have been standardized in accordance with data of the ISO manikin and by using data of American riders obtained in this study. This method for the establishment of eye range of the motorcycle rider specified in JASO T005 is outlined in the following.

Selection of Factors for Drawing

Select the following items from Tables 8 and 9 corresponding to the design position angle β. (This angle corresponds to the forward-inclination angle β as shown in Figure 14. Plus-minus mark is in reverse between this angle and the forward-inclination angle β.):

- Factors for drawing
- Major and minor axes lengths of eyellipse
- Inclination angle of eyellipse

(Note: Eyellipse has nearly the same meaning as eye range. Eyellipse is the plan view and side view of eye range ellipse.)

Establishment of Eyellipse in Side View Drawing

Eyellipse is established by the side view drawing as follows (see Figures 29 and 30):

1. Describe a circle of radius A with G-point (center of the upper surface of handle grip) as the

Table 8. Factors for drawing

Design Position Angle β(°)		-45	-7	5
Item	Riding Position	Inclined Forward		Upright
	Distance A (mm)	630		598
	Distance B (mm)	514		486 (514)
	Distance C (mm)	219		238
	Angle γ (°)		131-0.67 β	

Remark: Use the value in parentheses in the case of on-off-road type motorcycles. (The value of distance B is corrected by 8mm in accordance with the difference between the height of "H-point to seated surface" in the three-dimensional manikin for motorcyles and that of "trochanterion to seated surface" in American riders, see Table 7.)

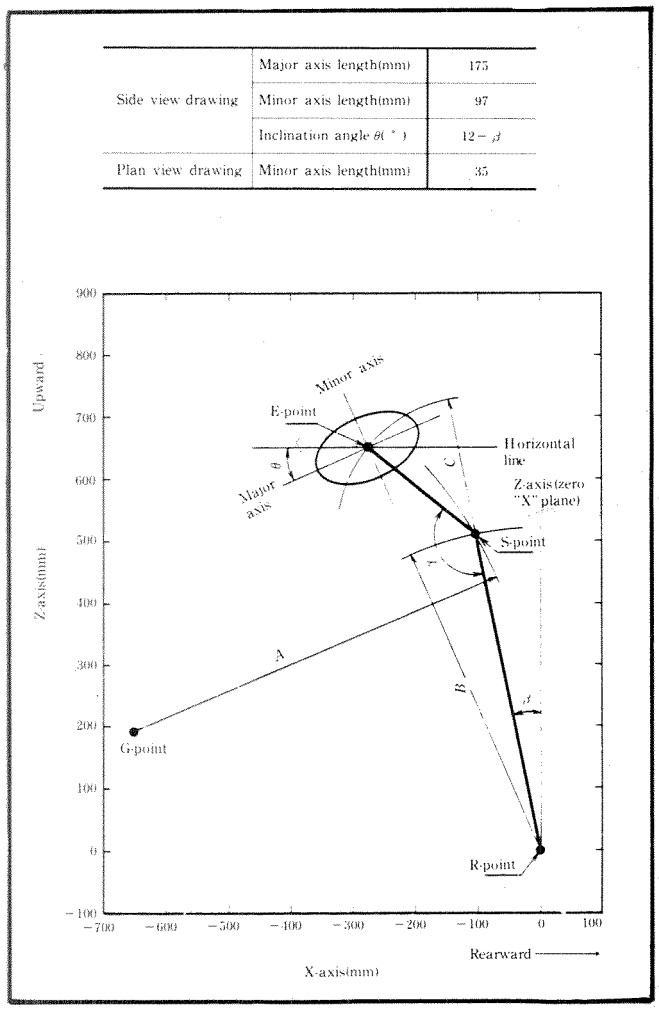

Figure 29. Method for the establishment of eyellipse

Table 9. Major and minor axis length and inclination angle of eyellipse

Side view drawing	Major axis length(mm)	175
	Minor axis length(mm)	97
	Inclination angle θ(°)	12-β
Plan view drawing	Minor axis length(mm)	35

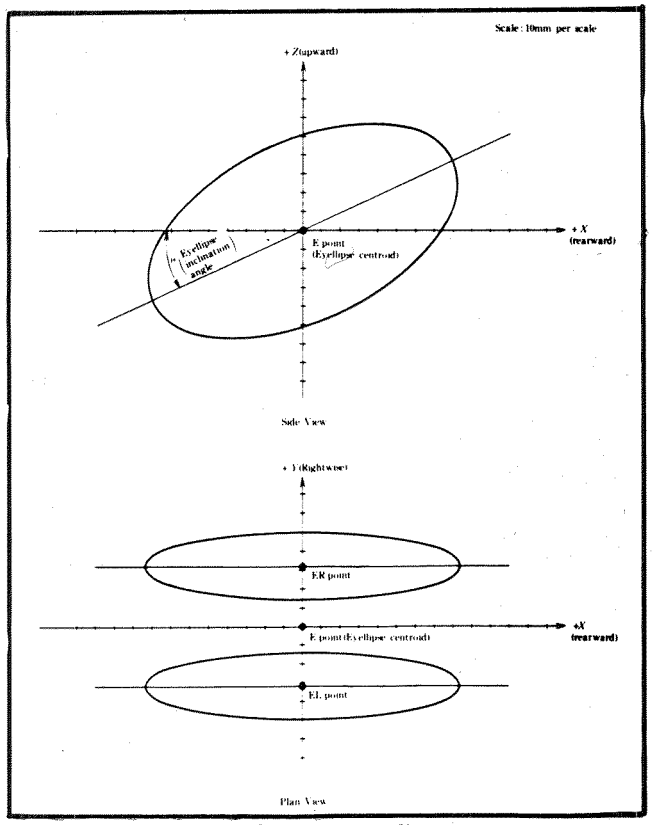

Figure 30. Eyellipse (95th percentile)

center. Describe a circle of radius B with R-point (a design reference point indicating H-point—hip location) as the center. Designate the intersection of these two circles as S-point.

2. Describe a circle of radius C with S-point as the center. The intersection between this circle and a straight line forming an angle (γ) with a straight line drawn through S-point and R-point is designated to be E-point.
3. Draw a straight line through E-point forming an angle θ with the horizontal line as the major axis of the eyellipse.
4. Draw a straight line through E-point and perpendicular to the straight line drawn in (3) as the minor axis of the eyellipse.
5. Make the major and minor axes of the eyellipse shown in Figure 31 coincide with the major and minor axes described in (3) and (4) above.

Thus, side view eyellipse is established.

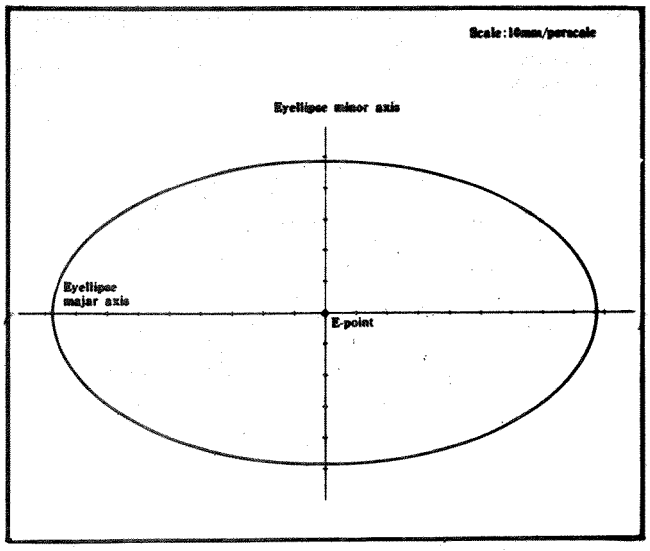

Figure 31. Eyellipse (95th percentile)

Establishment of Eyellipse in Plan View Drawing

Eyellipse is established in the plan view drawing as follows (see Figure 30):

1. Draw a straight line through the projection point of E-point on the plan view drawing and perpendicular to X-axis.
2. Draw two parallel lines at a distance of 32mm from X-axis, respectively.
3. The projection of the eyellipse in the side view drawing on the plan view drawing produces the major axis of eyellipse in the plan view drawing.
4. With two intersections (EL,ER) produced by the straight lines drawn by the procedures stated in (1) and (2) as the centers, two ellipses (eyellipses) can be described, whose minor axes are on the straight line drawn by the procedure stated in (1) and whose major axes are on the parallel lines drawn by the procedure stated in (2) (see Table 9).

Thus, eyellipses by plan view drawing can be established.

Reference Eye-point

Reference eye-point can be used as the representative location of the rider's eye. There are two cases, namely monocular reference point and binocular reference points (see Figure 30).

(1) In the case of monocular reference point: Projection of E-point on either side view drawing or plan view drawing is the reference eye-point.

(2) In the case of binocular reference points: In the plan view drawing, centers of two eyellipses (EL for left eye and ER for right eye) are the reference eye-points.

The Working Group of Motorcycle Rider's H-point of the Society of Automotive Engineers of Japan, Inc., completed its work in establishing JASO T006(6), "Procedure for Motorcycle Rider's H-point Determination," under the approval of the Japan Automobile Standard Organization in March 1985.

This standard specifies procedures for the determination of motorcycle rider's H-point as well as the construction of the manikin for motorcycles. The weight of each construction member, center of gravity, shape of seat pan, and so on in the three-dimensional manikin for motorcycles are basically corresponding to the three-dimensional manikin for automobiles in ISO 6549(7), but the manikin for motorcycles is not equipped with the back pan while having arm-hand (see Figure 32). The two-dimensional manikin for motorcycles is a template based on the side view of the three-dimensional manikin for motorcycles (see Figure 33).

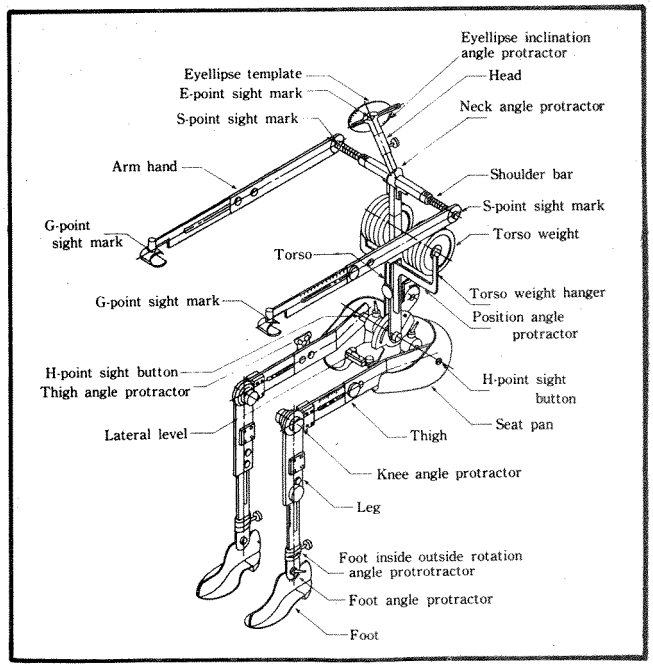

Figure 32. Three-dimensional manikin for motorcycle

Conclusion

It has been found that a motorcycle rider's eye range can be obtained from the relative position between handle grip and H-point.

Acknowledgments

The authors wish to express their appreciation to Mr. Sadahito Aramaki, Aero-Medical Laboratory, JASDF, for his helpful guidance in anthropometry; to LTC D.D. Erickson and MSGT R.G. Jacob, Mr. Noboru Horikoshi,

Cycle and Light-Powered Two-Wheeler Accidents

European Experimental Vehicles Committee

Summary

Importance of the Problem (Chapter 1)

In the various member countries of the European Experimental Vehicles Committee (EEVC), it was concluded that over the past decade much attention was paid to problems related to accidents with cars and the people using them; in recent years, attention shifted to other traffic participants and especially to pedestrians, for two reasons mainly:

- At present they are largely unprotected and therefore vulnerable in today's very complex traffic scene.
- Statistics show pedestrians actually form a large group of casualties.

Considering the scientific work already done for those groups in many countries, the public, Parliament, researchers, and authorities became aware of the growing importance of traffic safety problems for two-wheelers, relatively speaking, but to some extent also in absolute terms. The accident statistics as described in Chapter 1 indicate the following figures for bicyclists and moped riders (studied together because their position in traffic is comparable in many ways):

- In some countries, this group is the second largest after car users in terms of killed and severely injured; in other countries, it ranks third after car users and pedestrians.
- The percentage of killed (light-powered) two-wheeler users ranges from 6.7 percent (United Kingdom) to 28.4 percent (The Netherlands), with an average value of 15.8 percent for the participating countries (for pedestrians: from 13.3 percent in The Netherlands to 33.3 percent in the United Kingdon; an average of roughly 22 percent in 1979).

Chapter 1 gives a detailed description of those and other figures: number of injured, of vehicles in use, etc. It relates those figures to indicate some reasons for the variance between countries (number of casualties per

100,000 vehicles and per 100,000 inhabitants in various age groups). Work presented indicates the important influence on possible conclusions of differences in definitions and requirements (differences in accident registration systems and the related problem of under-reporting; differences in the technicalities of the vehicles). A separate paragraph describes the importance of economic assessment of these accidents, remedial measures, and some problems related to the available methods.

Description of Bicycle and Light-powered Two-wheeler Accidents (Chapter 2)

Chapter 2 gives details on typical types of accidents: accident, collision, and maneuver types are defined, and related (in-depth) studies are cited, indicating at the same time available knowledge on resulting injuries and speed at impact. All material available shows that cars most frequently are the collision partners (50 to 99 percent). There is no single category of road users ranking second; it ranges from other two-wheelers to heavy goods vehicles (HGV's), depending on various factors. Single-vehicle, light-powered, two-wheeler accidents occur so frequently they deserve special attention.

It is shown the frequency of an accident type is not the only relevant parameter; some indication of the seriousness is considered important too. A definition of lethality is suggested, indicating its influence on priorities. This approach gives more weight to collisions with HGV's. By describing collision types and to some extent maneuver types, it is shown which parts of the vehicles are mostly involved. Some similarity exists with pedestrian accidents, but additionally the sides of cars and the sides and rear ends of HGV's are involved (especially in crashes with light-powered two-wheelers), as well as some parts of the two-wheeler.

The kinematics of a rider during a collision is indicated as one of the important factors. Due to the range of accident and collision types for two-wheelers, a much wider variety of kinematics is seen for riders when compared with pedestrians; the presence of a two-wheeler and its speed can especially be a contributing factor.

As for injuries, literature gives a variety of distributions; most studies are hard to compare, for reasons indicated later, but some conclusions and tendencies are noted. The limited number of studies available indicates that the frequency of injuries to various body parts and their ranking depends on the injury severity level considered and on the type of two-wheeler involved. Most studies conclude the head has the highest frequency, especially when considering more severe injuries (and bicyclists have even higher frequencies than do riders of light-powered two-wheelers); arms and legs come in second and third, respectively.

The injury-scaling problem associated with long-term impairment, as mentioned in the report of EEVC-WG7 on pedestrian accidents, seems relevant for some two-wheeler accident types also.

The relative speed at impact is considered a very important factor. The limited number of studies indicating vehicle speeds show higher values than for pedestrian accidents: 50th percentile speed between 10 and 50km/h, 90th percentile between 37 and 72km/h (EEVC-WG7: 50th percentile between 16 and 36km/h, 90th percentile between 44 and 58km/h).

Injury-influencing Parameters (Chapter 3)

Contrary to the situation for car accidents, very little is known about the parameters for two-wheeler accidents. Therefore, only a short description is given, mainly of a theoretical and inferential nature and based on general knowledge from studies of various accident types, indicating probably the most important factors for each of the collision types that seemed important from Chapter 2.

Research Methods and Results (Chapter 4)

A global presentation of various research principles is given, indicating the advantages and disadvantages and especially indicating the usefulness of combining two or more methods. The following division is made:

- Accident studies
  - Accident statistics (police data level)
  - Intermediate (hospital/insurance data)
  - In-depth studies
- Experimental research methods
  - Full-scale tests
  - Component (or body segment) tests
  - Mathematical models

Until recently, little research was done specifically relating to bicycles and mopeds (and then mainly accident statistics). What has been done and can be used to some extent here was usually directed at pedestrians or motorcyclists. Nevertheless, a few bicycle-related studies are cited (accident studies of various levels as well as development work on mathematical models, together with the necessary related full-scale and component tests).

Current Knowledge on Human Tolerance (Chapter 5)

The accident situation for two-wheelers is different from the situation for other groups of road users, as mentioned before. This may influence typical injury-influencing parameters (kinematics, loading place, direction, and level); therefore, one would have to look for

typical cyclist and moped rider information regarding human tolerance. Very few studies have been performed, especially for cyclists and moped riders, and those were related mainly to helmets and head tolerance. For other elements, one has to rely on work for pedestrians, motorcyclists, and car users. For various body parts, parameters and tolerance values are given. Their relevance for two-wheeler users must be studied further.

Injury-prevention Measures (Chapter 6)

Starting from the basic philosophy of an integral approach to a safe vehicle (integration of requirements to benefit various groups of road users), three aspects were noted:

- Proposals for the benefit of two-wheeler users
- Consequences of these proposals for other road users
- Consequences of requirements for the benefit of other road users on two-wheeler users

Ad 1—Proposals for Two-wheeler Users

As research work in this area started only recently, availability of literature is limited, especially regarding concrete proposals. Based on information from earlier chapters, work concentrated on the car, the HGV, the two-wheeler, and its rider

Regarding cars, as for the pedestrian-to-car accidents, interest is focused on the stiffness of frontal parts. Some differences may exist: the generally somewhat higher seating position and a difference in the population (fewer younger children involved) may cause a different influence of various car components on the kinematics and loading of the human body in a crash. For two-wheeler users, the windshield and the higher parts of its frame become important, too. Considerations regarding vehicle shape follow the same lines as for pedestrians.

Regarding HGV's, two approaches exist:

- Improvement of shape and stiffness would be beneficial at the vehicle front, as for cars.
- For the HGV sides and rear, concrete proposals are indicated regarding underrun protection devices and improved rear view mirror systems and requirements (accident avoidance).

Regarding the two-wheeler itself, various protection devices are discussed, for both frontal and lateral collisions. Various types have been developed for motorcycles; whether they can be used practically on lighter two-wheelers and even whether they are advantageous on such vehicles is still unclear. This concerns side protection devices (e.g., knee bars) as well as knee padding for frontal collisions. Avoiding sharp protrusions on two-wheelers will help against minor injuries; examples introduced to some extent are sunken filler caps and handlebar expander pins.

For the passenger, especially the younger one, dress guards at the rear wheel and, up to a certain age, child seats are considered important against spoke injuries.

Regarding the rider, various well-known possibilities are described, such as safety helmets and protective clothing. Although they are widely accepted (and helmets even mandatory) in many countries for motorcyclists, this is not the same for all riders of light-powered two-wheelers and certainly not for cyclists (the use of special types of cyclist helmets has been introduced in some countries, nevertheless).

Ad 2—Consequences for Other Road Users

Little influence for others is expected from the above proposals regarding cars. Underrun guards should not create any negative effects for other road users. Rear view mirrors on HGV's might be dangerous for pedestrians and bicyclists during overtaking maneuvers, if they are not properly designed. Some doubt is expressed as to whether knee paddings may cause a rider to fly into a car's compartment; helmets may be dangerous for unprotected road users.

Ad 3—Consequences of Measures for the Benefit of Other Road Users

Bumper height is determined in SAE and ECE prescriptions, mainly for the car-to-car situation. Serious doubts are expressed on the appropriateness of these values for pedestrians and two-wheeler riders. Other requirements for car-to-car crashes are not expected to have much effect on two-wheeler riders.

Test Procedures (Chapter 7)

Test procedures, aiming at insuring conformity of a vehicle or component with relevant requirements, are discussed. The chapter was kept short because there are few concrete proposed measures to evaluate during type approval (Chapter 6), and much development work needs to be done on the methods themselves (e.g., integration of integral tests, component tests, and/or mathematical models; development of a dummy).

Accident Prevention (Chapter 8)

Injury prevention or minimization is clearly not the only and possibly not the best way to protect road users. Accident prevention would be far more preferable, but it is not expected to be effective enough for many years to come. The chapter describes various elements of the

vehicle system that may cause (or contribute to) accidents. Research work to improve these elements is described: active lighting systems, reflectors, spacers, braking systems, stability, and maneuverability. As a special aspect, the influence of the state of maintenance is discussed. Various proposals are described; some might be feasible for many countries because relevant technology has already been introduced in other countries.

Priorities and Recommendations

Introduction

Based on discussions in the group, the working group has pointed out priorities for action, general recommendations, and recommendations for future research. One conclusion is that the injury prevention research for two-wheeler riders received even less attention than injury prevention for pedestrians (Working Group 7). More attention is necessary, especially since the accident process of the two-wheeler rider is even more complex than that of the pedestrian because of the contribution of the two-wheeler itself to the injury-producing process. Also, the speed of the two-wheeler rider and his position in traffic situations leads to other collision types and speeds at impact.

Priorities for Action

1. The use of energy-absorbing materials in the front structure of the car will be beneficial for the two-wheeler rider, similar to that found for pedestrians by WG7. Whether other locations on the car should also be padded cannot be decided now. Preliminary results of experiments using dummies indicate that impact location of the two-wheeler rider's head on the car is somewhat higher than in the case with pedestrian heads in similar frontal collisions. Second priority should be given to the side of the car due to the relatively frequent side collisions with light-powered two-wheelers.
2. The use of well-dimensioned side underrun guards on HGV's will reduce the effect of the serious and relative numerous collisions of mopeds and bicycles with the sides of heavy vehicles. The risk of getting run over by the wheels will also be reduced.
3. Modern standards should be developed for lighting equipment, including reflectors, and braking performance (especially under wet conditions) of bicycles. The introduction of a high-standard retroflector at the rear end of the bicycle will probably reduce the effect of the frontal car collision with the rear end of bicycles, which is a serious type of collision. At the sides of bicycles, spoke reflectors and/or reflecting tires are recommended.

General Recommendations

- More attention should be given to accidents of bicycles and light-powered two-wheelers, especially—
  - Accident registration systems, e.g., underreporting of these accidents by police.
  - Standardization of definitions for a better comparison of the results of national accident statistics and research projects of the different countries. Especially needed is a more uniform definition of the different classes of light-powered two-wheelers.
- When introducing a new legal measure, a proper before-and-after evaluation study is necessary. Some reasons are—
  - Optimizing the measure
  - Giving arguments for possible introduction elsewhere
- In view of the differences in the proportion of head injuries between cyclists (not helmeted) and helmet-wearing motorized two-wheeler riders, it seems preferable that cyclists wear a specially designed helmet, too. Padding of certain parts of the car might have a beneficial result, depending on whether the car or the ground is the leading cause of injury. This question has to be answered yet by research.
- The use of better or additional side mirrors on HGV's will give better overview to the truck driver. Even the present EEC directive is not sufficient (an amendment is underway).
- Riders of bicycles and light-powered two-wheelers should wear conspicuous clothing. For daytime, a jacket of fluorescent material is recommended. Smaller areas of such material, e.g., on armbands or shoulderbands, are less effective. The brightest materials (highest luminance factor) should be used. Bands of reflective material applied to the jacket will help other road users recognize the presence of a rider. Spacers (i.e., devices attached to the side of a bicycle to discourage drivers passing too close when overtaking) are useful and should be promoted as a low-cost safety accessory. However, it should be noted the wearing of a conspicuous jacket has an effect on the gaps left by overtaking vehicles similar to that produced by the most effective spacer. The last recommendation is based on research and

theoretical considerations. In part, it is supported by accident studies.

Recommendations for Future Research

Real Accident Studies

Information of real accidents is needed to get better insight on injury-influencing parameters.

The first important question is: What is the leading cause of injury (taking into account speed at impact and collision type): the car, the two-wheeler, or the ground? From this, it may follow that for some collision types severe injuries occur mainly due to very high impact speeds regardless of other influences (for instance, outside built-up areas). In those cases, accident avoidance measures seem more suitable than injury-reducing ones. The next important question is: What is the influence of car shape and car stiffness on kinematics, on short- and long-term injury, and on injury severity of the two-wheeler rider (again taking into account impact speed and collision type but also human parameters such as age, length, and mass distributions)? Whether accident avoidance or injury-prevention measures should be taken may be decided with the help of cost-effective considerations.

Human Tolerance

Further research is needed on injury-producing mechanisms to develop more precise ranges of values of human tolerance criteria as a function of age, mass, height, and impact speed (visco-elastic behavior). Special attention should be given to the influence of translational and rotational accelerations of the head-on-head (brain) injury.

Mathematical Models

Computer models should be further developed and validated. This validation should be based on real accident information together with the results of cadaver or dummy experiments. Development of a simple mathematical model, capable of detecting the kinematics of the rider versus the shape and stiffness of the car, could be useful for standard test procedures in the near future.

Dummies

The dummies presently available for pedestrian research are not quite suitable. For two-wheeler rider purposes, this deficit is analog. Further development is needed to obtain dummies that give more realistic representations of two-wheeler riders.

General

- The recommendations above must be seen as complementary as they strengthen each other. A trend must be set to use as many tools as possible to solve this complex problem. This is an important argument for international cooperation and coordination of research facilities in the various countries.
- Because two-wheeler riders collide with passenger cars and HGV's in more different collision types than pedestrians do and because of the different parts of the body of the two-wheeler rider impacted in the different collision types, injury-prevention research should focus on the following collision types:

  Passenger car
  - Front of car to (left) side of bicycle/light-powered two-wheeler
  - Front of car to rear end of bicycle
  - Front of car to front of light-powered two-wheeler
  - Side of car to front of light-powered two-wheeler

  Heavy goods vehicle
  - Front of HGV to side of bicycle/light-powered two-wheeler
  - Front of HGV to front of bicycle/light-powered two-wheeler
  - Side of HGV to side of bicycle/front of light-powered two-wheeler
  - Side of HGV to front of bicycle/side of light-powered two-wheeler

  Single vehicle light-powered two-wheeler rider accidents
- Research should be undertaken into long-term consequences of injuries. Little is known about these consequences, especially their severity. This is considered a deficiency of existing injury-scaling systems.
- When using humans or human substitutes for two-wheeler rider protection research, the choice should be such that they represent the age of the real accident victims, e.g., for cyclists 5 to 25 and older than 65. For light-powered two-wheeler riders, this age group is 15 to 25.
- Research is needed for more reliable bicycle lighting equipment.
- Optimization of crash helmets should be undertaken:
  - Legal standards should be based on appropriate biochemical criteria.
  - Influence of the surface of the outer shell of the helmet on rotational acceleration of the brain and its resulting injuries should be studied.

— Research should be undertaken into the problem of losing crash helmets during accidents (although suggestions for improvements have been tabled in the relevant UN-ECE group of rapporteurs).

Introduction

In 1981 and 1982, the EEVC Working Group 7, "Pedestrian Injury Accidents," was preparing its report. At that time, the Dutch delegation suggested attention be given to bicycle-car accidents because in The Netherlands this accident type happened more frequently than pedestrian-car accidents. In 1982, EEVC accepted the task of setting up a new working group to deal with bicycle accidents and, as far as possible, light-powered two-wheeler accidents. The Dutch members of EEVC were invited to prepare a discussion paper for this group. The intention of this working group, described in the paper, was agreed to by EEVC, and the group was set up. This intention is focused on number of accidents, integrated safety approach, and international coordination. From this discussion paper, the following is cited:

- Concerning the number of accidents: "Compared to other European countries the relative proportion of bicycle casualties in The Netherlands is considerably higher, though the absolute numbers of those killed and those injured as reported from the different European countries also seem quite high. They indicate that proper measures in this field may save thousands of lives and injured, while reducing the severity of injuries."
- Concerning an integral safety approach: "Some conclusions with regard to changes of the car drawn from studies of pedestrian-car accidents may be useful for the bicycle-car situation, too; others may be indifferent, but some may be contrary to the bicycle case. For an integral approach to car safety, changes made (or to be made) for the benefit of one group of road users have to be checked carefully against knowledge about the characteristics of other groups. This can be illustrated by bumper height, for example, for which a SAE recommendation exists, as well as a UN/ECE regulation. From research on lateral car collisions, a recommendation for a lower bumper height may follow. From pedestrian accident research follows considerable doubt whether the SAE recommendation is an advantage for pedestrians. Considering two-wheeler accidents, the effects are even less predictable as yet."
- Concerning international coordination: "It seems the study of car-bicycle accidents ultimately may contribute a great deal to improvement of traffic safety. There is a need for accident data: there also seems to be a need for more experimental and human-tolerance data, as well as for better tools to gather those data. Investigations on crash protection for two-wheelers are starting in several countries. Research on crash protection for pedestrians started more than 10 years ago, which was followed some years later by international coordination. Now it seems to be the right moment for similar actions concerning bicyclists, while coordination of research is possible from an earlier stage."

As a result, EEVC gave the working group the following terms of reference:

- Review the available accident data concerning fatal accidents and injuries to bicyclists of different ages involved in road accidents in Europe and examine the accident data of light-powered two-wheelers. (The exact definition belongs to the task of the group.)
- Make recommendations including priorities for action on the vehicle to reduce the severity of such accidents and injuries. Recommendation may include direct measures to change bicycles and cars, as well as specified proposals for research.

Priority will be given to possible influences of certain proposed measures on the safety of bicyclists; changes to the car should be considered with respect to the benefit of nonoccupant road users (see also WG7).

During the first meeting of the working group, it was decided to deal also with light-powered two-wheelers because in some participating countries the number of light-powered two-wheeler casualties is higher than that of bicyclists and because it was the group's opinion there were great similarities between the two categories of road users. The group was aware of the difficulties that could arise because of differences in definitions of light-powered two-wheelers between countries. Therefore, the group decided to include a list of requirements (including definitions) for light-powered two-wheelers for the different countries. During the first meeting, the group decided to deal also with accident avoidance aspects related to vehicles.

The aim of accident avoidance is obvious, and many efforts have already been made by improving the construction of passenger cars and HGV's (brakes, tires, etc.) and by changes in infrastructure (bicycle lanes). However, there is considerable scope for improving the lighting devices and retroreflectors fitted to many bicycles and for improving the braking performance in the wet, especially of rim brakes. The decision of the group was that only specific two-wheeler, car, and HGV aspects in relation to two-wheeler accidents will be described in this report.

It is unrealistic to expect (on a short term) measures or solutions that will prevent accidents from happening at all. Some elusive elements will always remain. This is the main reason for injury-prevention work. The aim of injury prevention is either to prevent injuries or to minimize injury severity by influencing the kinematics of the victim and to minimize loads to the struck body parts, for instance, by minimizing the relative impact speeds between victim and struck object.

History of Bicycle and Light-powered Two-wheeler

Bicycle

The question of whether the first bicycle was designed by the Frenchman De Sivrac or by the German Kessler in ± 1790(2) is irrelevant since it appeared some years ago that the first drawing of a bicycle was made by Leonardo da Vinci or one of his pupils in ± 1450(3). This bicycle was already chain driven (Figure 1) contrary to the bicycles made by De Sivrac and Kessler that had to be pushed forward.

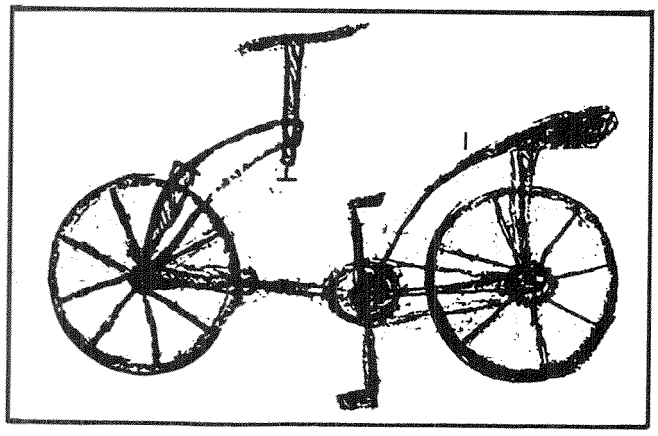

Figure 1. Bicycle designed by Leonardo Da Vinci (±1450)

The first bicycles driven by means of pedals had a front-wheel drive. To reach a higher speed, the front wheel was enlarged (Figure 2), to such an extent that it became dangerous when drivers fell off. Therefore, the first "safety bicycle" was designed by H.J. Lawson in 1874. It had front and rear wheels of equal diameter, and the rear wheel was chain driven. The first practical production machine, the Rover Safety, was made in 1885 by John Starley (Figure 3). When later (1888) it was equipped with pneumatic tires, invented by the Irish veterinary surgeon John Dunlop, the safety bicycle caused a bicycle boom in Europe and America(1). The safety bicycle had a design similar to the present vehicle,

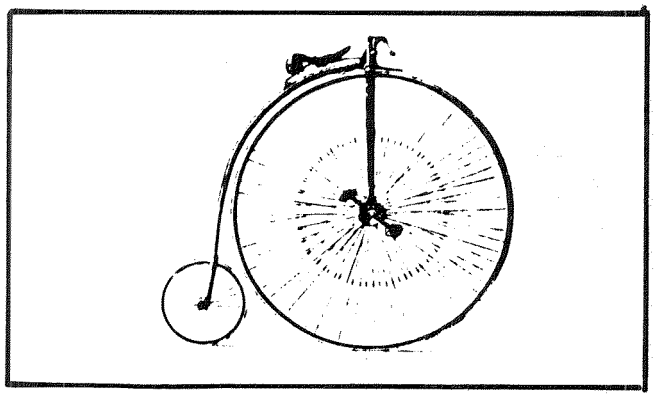

Figure 2. Bicycle with enlarged front-wheel (± 1880)

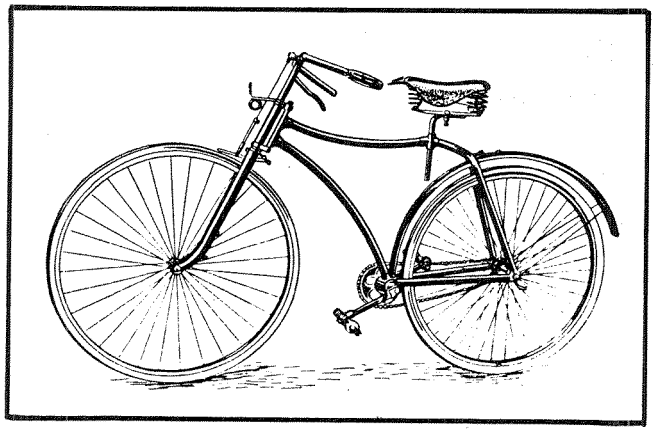

Figure 3. Rover "safety bicycle" (± 1885)

though it lacked the seat tube as a part of the frame structure.

Bicycle use in some countries became enormous and will probably grow even more due to rising energy prices, more spare time, and health care. At this moment, many alternative bicycle designs and prototypes are produced. They have in common the bicyclist lying backwards, and in some designs he or she is protected against weather conditions(5).

Light-powered Two-wheeler

According to Raucke(6) and Schneider(7), the first powered two-wheeler was constructed by Wolfmüller and Hildebrandt in 1894 (Figure 4). According to Elsevier(4) the first attempt to construct a light-powered two-wheeler dates from 1920; it is named the "Briggs and Stratton" (1894-1920: a matter of definition?). The engine was connected directly to a wheel next to the rear wheel. In later years, the engine could be found almost anywhere on the two-wheeler, but today the engine is normally placed under the frame, between front and rear wheel, driving the rear wheel. Use of the moped in The Netherlands increased strongly after 1960 but decreased after 1975 and is still decreasing.

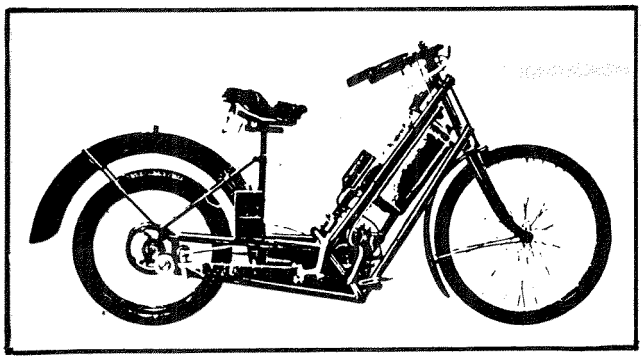

Figure 4. First patented, serially produced motorcycle by Hildebrandt and Wolfmüller (München, 1894)

1.Description of Two-wheeler Accident Statistics

This section deals with a comparative survey of the situation of vehicle numbers and number of persons involved in accidents in general. Special emphasis is placed on describing the situation of pedal cyclists and riders of light-powered two-wheelers in the member countries participating in the working group: France, Federal Republic of Germany, Great Britain, Italy, The Netherlands, and Sweden. The interpretation of the data will have to be undertaken with great caution since the definitions of a light-powered two-wheeler differ in the participating countries. The definition of a fatally (or severely or slightly) injured accident victim can also differ considerably, as well as the associated parameter definitions in the national accident statistics. Beyond that, other influencing parameters should be included in a comparative assessment as well, such as mileage (vehicle-kilometers per annum), road network, land use, topography, and climatic conditions of the countries under study.

This is to show that a statistical analysis based only on a one-dimensional way of looking at things (e.g., the number of accidents in a population of a defined age group) can easily lead to wrong conclusions. For this reason, only the tendencies of developments will be pointed out in this chapter.

Definitions of Bicycle, Light-powered Two-wheeler, Road Accident, Killed, Severely Injured, and Slightly Injured

The definitions of bicycle, light-powered two-wheeler, road accident, killed, severely injured, and slightly injured, enabling a better classification of the numbers of accident victims within the overall context, are summarized in Tables 1 to 5. The definitions of a bicycle found in Table 1 are based largely on the characteristics laid down in the

Table 1. Definition of a bicycle

France:	A vehicle which has at least 2 wheels and is propelled only by muscular force
Federal Republic of Germany	Bicycle means any vehicle which has at least two wheels and is propelled solely by the muscular energy of the persons on that vehicle, in particular by means of pedals or handcranks
Italy	Bicycle is a vehicle with two or more wheels, propelled by muscular power through pedals or similar mechanism
The Netherlands	No exact legal definition—a carriage or vehicle that is not a motor vehicle (WVR art. 1.1)
Sweden	1. A vehicle designed to be propelled by pedals which is not a toy vehicle 2. Electrical wheelchair designed for a maximum speed of 15km/h
Great Britain	Has no power assistance and includes toy cycles ridden on the carriageway, tandems and tricycles. (from Sept. 1983 the definition of pedal cycles for the purpose of regulations has been changed to include "Electrically assisted pedal cycles"; 0.2kW, 24km/h

Table 2. Some of the relevant legal requirements for bicycles(10)

Requirement for Bicycles	Federal Republic of Germany	France	Italy	The Netherlands	Great Britain	Sweden
Brakes						
— One front and one rear	X	X	X	—	X	—
— One brake	—	—	—	X	—	X
Lighting						
— Headlamp white	X	X	X	X	X	X
— Rearlamp red						
— By day and night	X	—	X	—	—	X
— By night or poor visibility	—	X	—	X	X	—
Reflectors	X(1)					
— On pedals						
— Obligatory	X	X	X	X	—	—
— Admitted	—	—	—	—	X	X
— Red rear	X	X	X	X(3)	X	X
— White front	—	—	—	—	—	—
White rear mudguard	—	—	—	X(2)	—	—
Reflecting tires Admitted	X(1)	—	X	X	X	X
Bell	X	X	X	X	—	X
Other construction Requirements	X	—	—	X(4)	—	—

1) In 1983 all new bicycles must have reflectors in the spokes or reflecting tires
2) Yellow reflecting is admitted
3) Additional high-performance reflector (min1000mcd/lx) required, seperate from the rearlamp (reflector)
4) Some requirements onthe seating position of child-passengers under age 10

Vehicle Codes(8). In some countries, bicycles are additionally subject to certain legal regulations, as listed by Horn(9) and in Table 2.

Defining a light-powered two-wheeler, and thus its description, is more difficult. In Table 3, the spectrum of the principal characteristics of a two-wheeler is represented on which a definition can be based. Taking the Federal Republic of Germany as an example, it can readily be seen the moped is only one of three classes of light-powered two-wheelers. According to the definitions given for mopeds and mokicks, the only difference between these vehicles appears to be the presence or absence of pedals or footrests. In contrast to that, the

Table 3 Definitions and requirements for a light-powered two-wheeler

	Federal Republic of Germany			France	Great Britain	Italy	The Netherlands		Sweden
Name of Class	Mofa	Moped	Mokick	Cyclomoteur	Moped	Ciclomotori	Snorfiets[4]	Bromfiets (1)[4A]	Moped[17]
Class Introduced in	1965	1954	1967	1970	1977	1959	21.4.1976	Since 21.11.1966 with pedals	July 1, 1952
Speed limit (km/h)	25	40	40	45	48[10]	40	20[5]	30/40[5A]	30
Piston displacement (cc)	≤50	≤50	≤50	≤50	≤50	≤50	≤50[6]	≤50[6]	≤50
Minimal Age (years)	15	16	16	16[1)]	16	14	16	16	15
Helmet obligatory since	No	24.7.78	24.7.78	1979	1973	Not yet obligatory	No	Yrs. since 1.2.1975	Sept. 1,1978
Driving licence	Only theor. test certificate	Yes	Yes	No	Yes	Not necessary	No	No	No
Driving on bicycle tracks allowed/mandatory	Mandation	Not allowed	Not allowed	Mandation	Permitted[11]	Not allowed	Mandation[7]	Mandation[7]	Allowed
Pedal or footrest	Pedal	Pedal	Footrest	Pedal	Pedal[12]	Not specified	Pedal	Pedal	No requirements
Min. and max. diameter of the wheels	B.T.[3] Min. 580	Not specified	Not specified	Not specified	No[13]	Not specified	254mm≤305mm	≥405mm	No requirements
Maximum mass (kg)	Not specified	Not specified	Not specified	Not specified	250[14]	16 (Engine)	No limdit[8]	No limit	2 Wheels: No limit 3 Wheels: 400
Admitted number of passengers	0	1	1	1[2]	1[15]	0	1	1	0
Brakes	2	2	2	2	2[16]	2	2[9]	2	2

1 14 years old with a special school training
2 Plus passenger if less than 14 years old
3 Minimum outer diameter of the back tyre
4 "Buzzle Bike"
4A Moped
5 IM "Woonerven" not faster than "walking speed"
5A 30km/h in built-up areas: 40km/h outside built up areas (and 5)
6 ≤50cc or approved electromotor
7 Some tracks mandated, other tracks allowed with engine off
8 50kg for "empty" vehicle, fully ready for use
9 $\geq 5 m/s^2$ (both brakes together)
10 Must have a design speed not greater than 48km/h if registered later than August 1977
11 Permitted in some cases but never mandatory
12 If registered before August 1977 must be equipped with pedals by means of which the moped is capable of being propelled
13 No requirements for pneumatic tyres, 670mm min. diameter for nonpneumatic tyres
14 250kg if registered later than August 1977
15 One passenger if proper seat fitted
16 Either must have a single system with two means of operation or two systems operating independently
17 Since January 1984 mopeds are divided into class 1 and class 2: class 1: moped old definition class 2: vehicle kerb mass ≤60kg and a transmission including maximum two gears or an automatic transmission without steps

definition of a mofa as for the legal speed limit, minimum age of rider, and driving license regulations are basically different. Legal speed limits for light-powered two-wheelers vary from 20km/h (NL, snorfiets) to 48km/h (GB, moped). The lowest possible first-time user age varies from 14 (Italy) to 16 (in most other countries).

Compulsory helmet use also does not apply in all countries to all categories of light-powered two-wheelers. Furthermore, regulations relating to the use of cycle lanes in the various countries have led to different forms of integrating the light-powered two-wheeler into road traffic as a whole. In some countries, for light-powered two-wheelers it is mandatory to use cycle tracks; in others, they may use them.

There are countries where light-powered two-wheelers are banned from cycle tracks and others where they are tolerated with the engine off. Applicable definitions of a road accident in the various countries, which are summarized in Table 4, differ only slightly. It can be assumed these are definitions of characteristic features. However, for the inclusion of accidents in the national accident statistics, the following additional information will generally be required:

- Event site and time
- Road users and vehicles involved
- Direct causation factors and accident circumstances as recorded by the police
- Accident injury consequences

The definitions of accident consequences applying to casualties in the various countries are summarized in Table 5. The definition of a person killed in an accident varies in terms of the time period applied in each country within which a victim dies, i.e., between 6 and 30 days. A period of 30 days is used in the majority of the countries. The definitions of severely or slightly injured accident victims also differ considerably, the extreme case being the Italian statistics where such difference is not made at all. In most cases, severely and slightly injured accident victims are distinguished by the kind of medical treatment required—hospitalization or outpatient treatment.

Table 4. Definition of a road accident for national statistics for casualties

Federal Republic of Germany	Accidents in road traffic with killed or injured persons on public roads and places (registered in official statistics; STVUNFG, BGBL. 1982, 2069
France	Accident in road traffic which generates at least one victim occurring on a public open road and involving at least one vehicle or ridden animals
Great Britain	One involving personal injury occurring on the public highway (incl. footways) in which a vehicle is concerned, and which becomes known to the police
Italy	Road accident is a collision involving vehicles or animals on public roads, which generates personal injuries
The Netherlands	Accidents included are those • that occurred or originated on a highway or street open to public traffic • that resulted in one or more persons being killed or injured • in which at least one moving vehicle was involved
Sweden	Accidents included are those • that occurred or originated on a way or street open to public traffic • that resulted in one or more persons being killed or injured • in which at least one moving vehicle was involved

Table 5. Definition of casualties; distinction between persons killed, severely, or slightly injured in road accidents.

Federal Republic of Germany	Killed	See ECE*
	Severely injured	An injury for which a person is detained in hospital as an in-patient
	Slightly injured	An injury for which a person is not hospitalized
France	Killed	Victim died immediately or during 6 days after the accident
	Severely injured	Accident victim who has sustained a traumatism needing medical treatment with at least a 6 days stay in the hospital
	Slightly injured	Accident victim who has sustained a trauma needing medical treatment with less than a 6 days stay in the hospital
Great Britain	Killed	See ECE*
	Severely injured	An injury for which a person is detained in hospital as an in-patient, or any of the following injuries whether or not he is detained in hospital; fractures, concussions, internal injuries, crushings, severe cuts and lacerations, severe general shock requiring medical treatment, injuries causing death 30 or more days after the accident
	Slightly injured	An injury of a minor character such as a sprain, bruise or cut not judged to be severe, or slight shock requiring roadside attention
Italy	Killed	All persons who die within the next 7 days after the accident
	Severely/ slightly injured	Are not distinguished in Italian statistics
The Netherlands	Killed	See ECE*
	Severely injured	Victims who are hospitalized for more than one day
	Slightly injured	Other injured victims
Sweden	Killed	See ECE*
	Severely injured	Fracture, concussion, internal lesions, crushing, severe cuts and laceration, severe general shock requiring medical treatment and any other serious lesions entailing detention in hospital
	Slightly injured	All injured not belonging to killed or severely injured

* ECE definition of killed: Any person who was killed outright or who died within 30 days as a result of the accident (for further definitions see ECE (26)).

Total Vehicle Numbers (Vehicle Population)

The vehicle numbers grouped in vehicle categories are found in Table 6 for all the countries participating in the working group. It should be pointed out that these populations, being subject to dynamic development processes, cannot be regarded as stable quantities. The development of mofas in the Federal Republic of Germany is a good example.

Table 6. Vehicle population in 1981 (in 1,000's)

	Cars	Goods Vehicles	Motor-cycles	Mopeds	Mofas/ Snorfiets	Pedal cycles*
France	19,725	2,568	645	4,900	—	19,000
Federal Republic of Germany	23,730	1,307	690	652	1,224	38,500
Italy	17,686 (1980)	1,338 (1980)	828 (1980)	3,461 (1980)	—	17,500
The Netherlands	4,594	339	114	700	10	10,800
Sweden	2,893	186	16	205	—	6,000
Great Britain	14,796	2,286	973	398	—	13,000

* Rough estimated data

Mofas were introduced in 1966; in 1974, the mofa population exceeded 1 million and reached a peak in 1980 with 1.4 million vehicles. In 1981, there was a slump in the number of mofas down to 1.2 million. Development of the mofa population from 1981 must be assessed in light of another development, namely, the introduction of the newly developed Leichtkraftrad in 1980 (80cc, 80km/h, minimum age 16 years).

Table 7 shows the number of vehicles in each vehicle category per 100,000 inhabitants. The peak value in the passenger car category, with a figure of 38,000, is displayed for the Federal Republic of Germany. Great Britain, with 27,000, shows the lowest figure in this category. The bicycle peak value is displayed for The Netherlands (76,000); here again, the lowest number is found in Great Britain (24,000). France has the highest number of light-powered two-wheelers (9,100) and Great Britain once more the lowest (700).

Table 7. Vehicle numbers (in 1,000s) per 100,000 inhabitants in 1981

	(1,000s)			
	Cars	Pedal cycles	Light-powered two-wheelers	Inhabitants 1981
France	36	35	9.1	53,960
Federal Republic of Germany	38	64	3.0	61,680
Great Britain	27	24	0.7	55,830
Italy	31	31	6.1	57,200
The Netherlands	32	76	5.0	14,250
Sweden	35	72	2.5	8,320

Statistical Records on Persons Killed and Injured in Road Accidents

The total number of casualties with a breakdown in light-powered two-wheeler victims and users of bicycles are represented in diagrammatic form below for the years 1977-81. The development of the number of accidents in the various countries in the same time period is found in Figures 5 to 10. Compared with the overall development of number of accident victims, a striking decline in fatalities in the Federal Republic of Germany, The Netherlands, and Sweden is noticed.

The group of severely injured also displays a slight downward trend with the exception of The Netherlands where a pronounced decline can be noticed in this group. In all the countries under study, the number of slightly injured also continued to decline. Great Britain, Italy, and France, however, display a quite different development of the overall number of road accident victims. In Great Britain, all three categories display a slight downward trend. In Italy, the number of persons killed in accidents remained nearly constant, whereas the number of injured accident victims displayed an upward trend. Casualty numbers in France, apart from the absence of

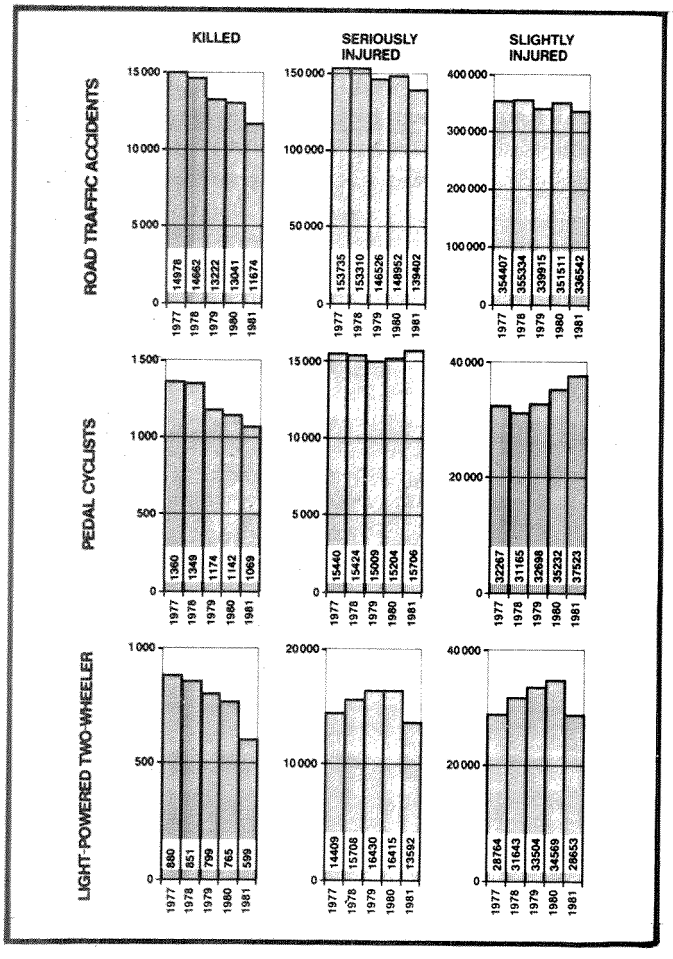

Figure 5. Number of accidents—Federal Republic of Germany (1977-1981)

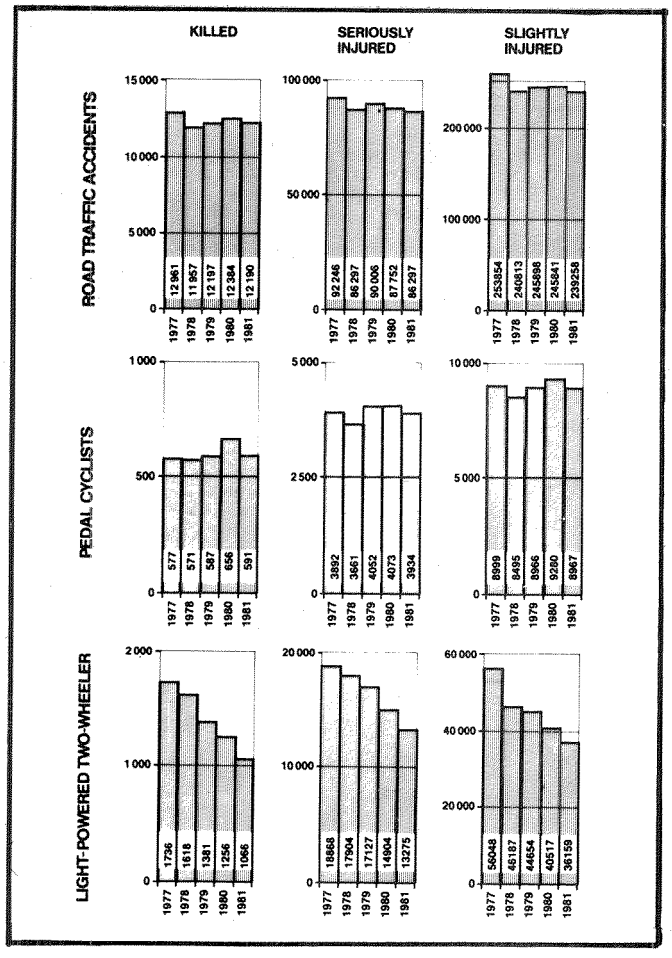

Figure 6. Number of accidents—France (1977-1981)

extremely low values and clear peaks, remained more or less constant.

The development of casualty numbers in the group of bicycle riders in participating countries also displays considerable variations in the three casualty groups. In the Federal Republic of Germany, the number of killed bicycle riders displayed a clear decline; the number of severely injured remained at a nearly constant level, whereas the number of slightly injured increased considerably. The development of the number of casualties in France appears to be balanced in all three categories in the years 1977-81.

In Great Britain, although the number of bicycle riders killed in accidents remained nearly constant during this period, the number of severely and slightly injured accident victims displayed upward trends. The Italian statistics show a slight decline in the number of accident victims in both injury categories. In The Netherlands, the number of killed bicycle riders dropped continuously (an exception being 1980) but is still on a high level.

The number of severely injured victims remained at a nearly constant level whereas the number of slightly injured displayed increasing rates. In Sweden, too, with the exception of 1980, the statistics show a clear decline in the number of killed riders of bicycles, whereas an overall rising trend is displayed by the overall number of severely and slightly injured accident victims.

In the group of light-powered two-wheeler riders involved in accidents, the statistics display a clear downward trend in the number of casualties in France, Great Britain, The Netherlands, and Sweden. The reductions in this category in France and Sweden even appear disproportionally high. In the German statistics, the absolute number of riders and passengers of light-powered two-wheelers involved in fatal accidents displayed clearly downward sloping curves. The number of severely and slightly injured increased until 1980. In 1981, a reverse trend took place, and the number again reached the values recorded in 1977. In Italy, the number of persons killed remained nearly constant during the time period considered, whereas slight increases were found in the number of injured accident victims.

The magnitude of the number of pedal cycle and light-powered two-wheeler accidents in the various countries is

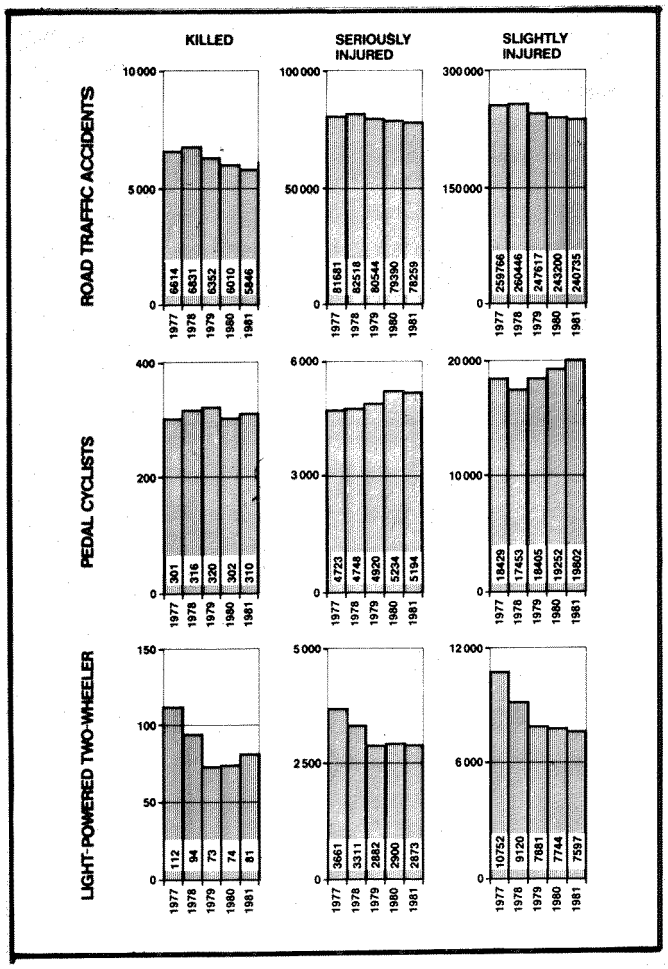

Figure 7. Number of accidents—Great Britain (1977-1981)

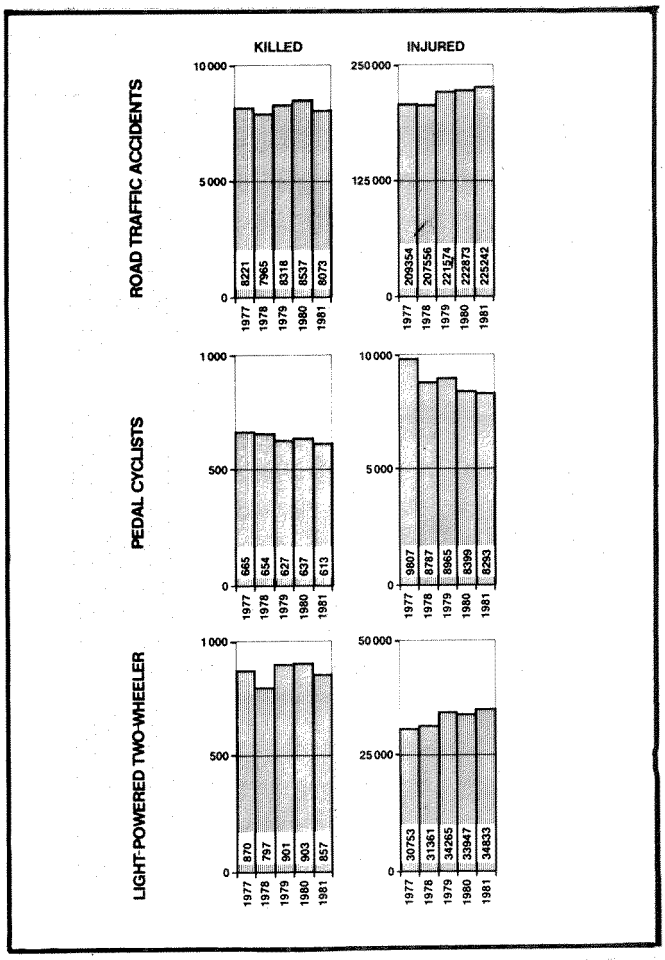

Figure 8. Number of accidents—Italy (1977-1981)

seen clearly when relating them to the total number of road casualties. The percentage of killed pedal cyclists and users of light-powered two-wheelers in 1981 is given in Table 8. The table shows in particular the importance of the accident involvement of this category of two-wheeler users in The Netherlands. As an example, the percentage of killed pedal cyclists is from two to four times as high as in other countries.

Great Britain, with an overall rate of about 7 percent, is the only country clearly remaining below the 10 percent level.

Table 8. Percentage of pedal cyclists and users of light-powered two-wheelers killed in road traffic

1981	Percentage of Killed Pedal Cyclists in Traffic	Percentage of Killed users of Light-Powered Two-Wheeler in Traffic	Total
Federal Republic of Germany	9.2	5.1	14.3
France	4.8	8.7	13.5
Great Britain	5.3	1.4	6.7
Italy	7.6	10.6	18.2
The Netherlands	19.7	8.7	28.4
Sweden	9.7	4.1	13.8

When the vehicle population is changing, the casualty rate in terms of the number of casualties per 100,000 vehicles shows the trend more clearly. The rates for killed pedal cyclists and users of light-powered two-wheelers for 1981 are found in Table 9. The table shows that, if calculations are performed on this basis, The Netherlands no longer is outside of the accident patterns displayed by the other countries participating in the study. In this case,

Table 9. Number of killed pedal cyclists and users of light-powered vehicles per 100,000 vehicles

	Number of Killed/100,000 Vehicles	
1981	Bicyclists	Light-Powered Two-Wheelers
Federal Republic of Germany	2.8	31.5
France	3.1	21.8
Italy	3.5	25.2
The Netherlands	3.4	22.6
Sweden	1.3	16.0
Great Britain	2.4	20.3

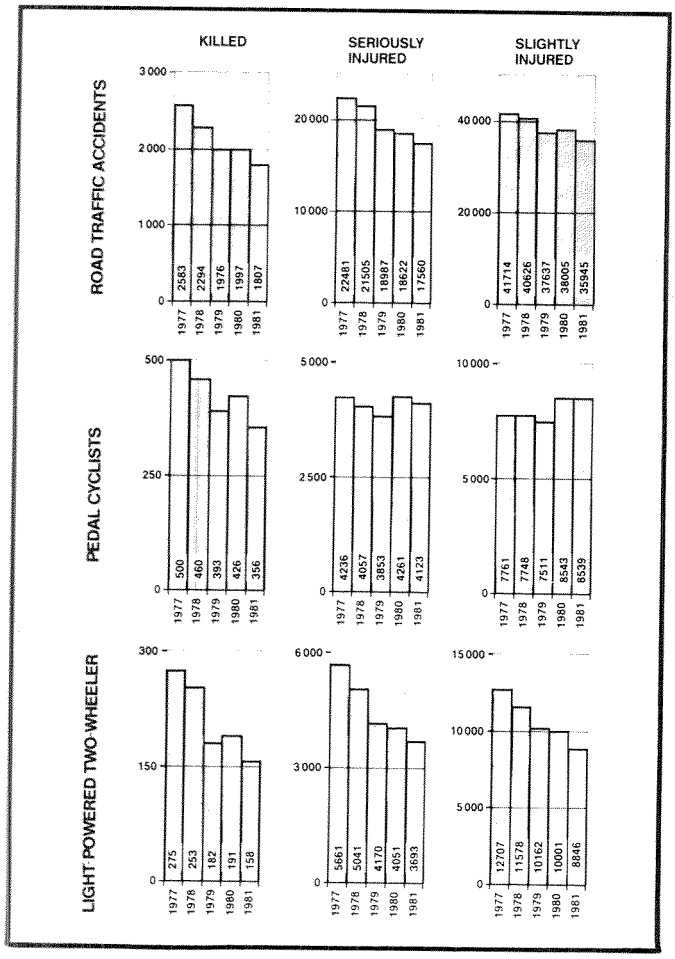

Figure 9. Number of accidents—The Netherlands (1977-1981)

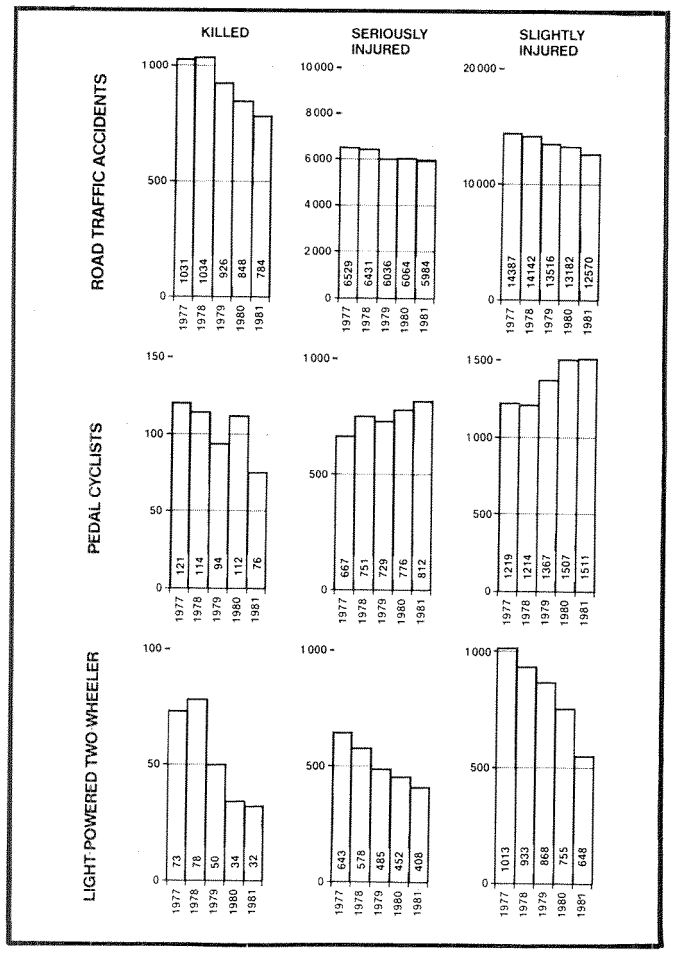

Figure 10. Number of accidents—Sweden (1977-1981)

it is Sweden that shows up as a positive example with its low rates, both for fatal pedal cycle and fatal light-powered two-wheeler accidents. The Federal Republic of Germany shows up as the leading country in the group of fatal light-powered two-wheeler accidents.

The absolute number of killed and injured users of bicycles and riders or passengers of light-powered two-wheelers, classified into age groups, is shown in Tables 10 to 15.

In all countries, fatal, severe, and slight injury peak values are reached in the age group of 10- to 14-year-old users of bicycles. The age group of 65 and over also displays a high frequency of fatalities. In the Federal Republic of Germany, fatalities in the age group of 65

and over are three times more frequent than in the age group of 10- to 14-year-old riders of bicycles, the ratio for severely injured accident victims being 1:2. Similar ratios were found in The Netherlands. In Sweden and Italy, the comparison revealed still more unfavorable figures for the elderly.

The number of accident victims among riders and passengers of light-powered two-wheelers reach peak values at a later age—the group of 15- to 17-year-olds. Compared with the bicycle riders age 10 to 14, the fatalities displayed numbers that, on average, were two or three times as high.

With the exception of Italy, the number of fatalities in the age group of 65 and over is generally much lower than in the case of cyclists.

Tables 16 to 21 show the number of accident victims per 100,000 inhabitants of each age group. High frequencies and peak values are similar to those found in the absolute number (with the exception of Sweden where fatality and injury peak values are reached in the higher age groups of bicycle users). A striking fact, revealed by Italian and Swedish statistics, is the fairly low fatality rate in the group of 10- to 14-year-old juveniles, generally considered to be a particularly high-risk group.

Compared with these numbers, the increased fatality rate for the elderly, especially in the age group of 65 and over, should be noted in particular.

Figures 11 and 12 show population-based numbers of casualties enabling a comparison between the participating countries. The number of killed and injured pedal cyclists is given in Figure 11 and the number of killed and injured users of light-powered two-wheelers in Figure 12.

Extremely high casualty figures for pedal cyclists are displayed by The Netherlands and the Federal Republic of Germany. This applies to all degrees of injury severity but particularly to the group of severe injuries. Once more, the diagrams are evidence that the proportion of persons age 65 and over increases disproportionally with increasing injury severity, Great Britain being the exception.

The variation in the number of casualties per 100,000 inhabitants for users of light-powered two-wheelers is not as large as for pedal cyclists. They are narrowly concentrated around the age group of the 16-year-olds.

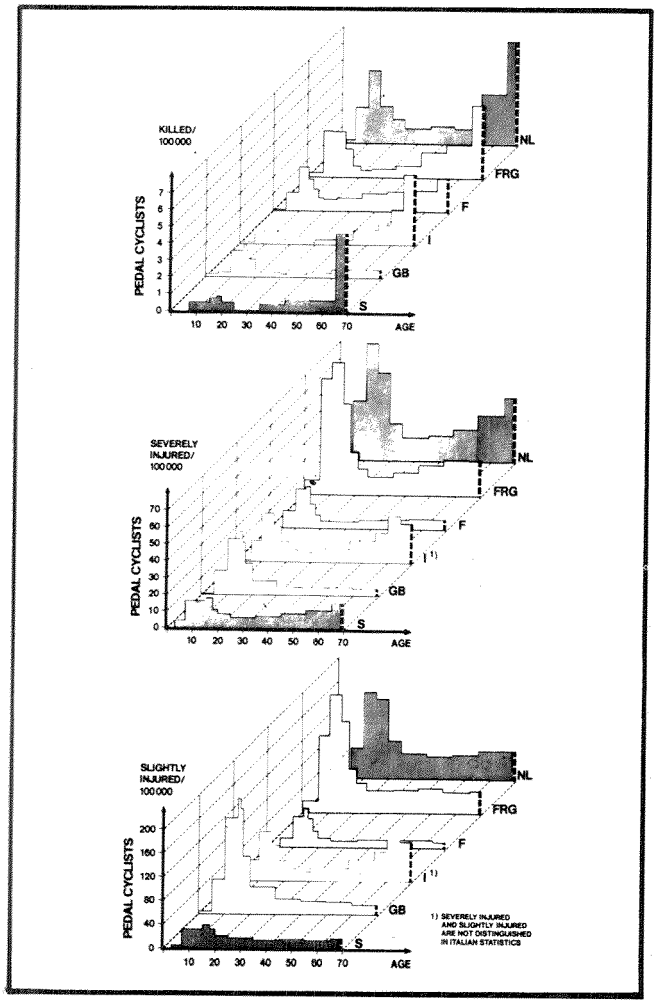

Figure 11. Killed and injured pedal cyclists per 100,000 inhabitants/age group (dotted line for age 70 stands for age group 65 and over)

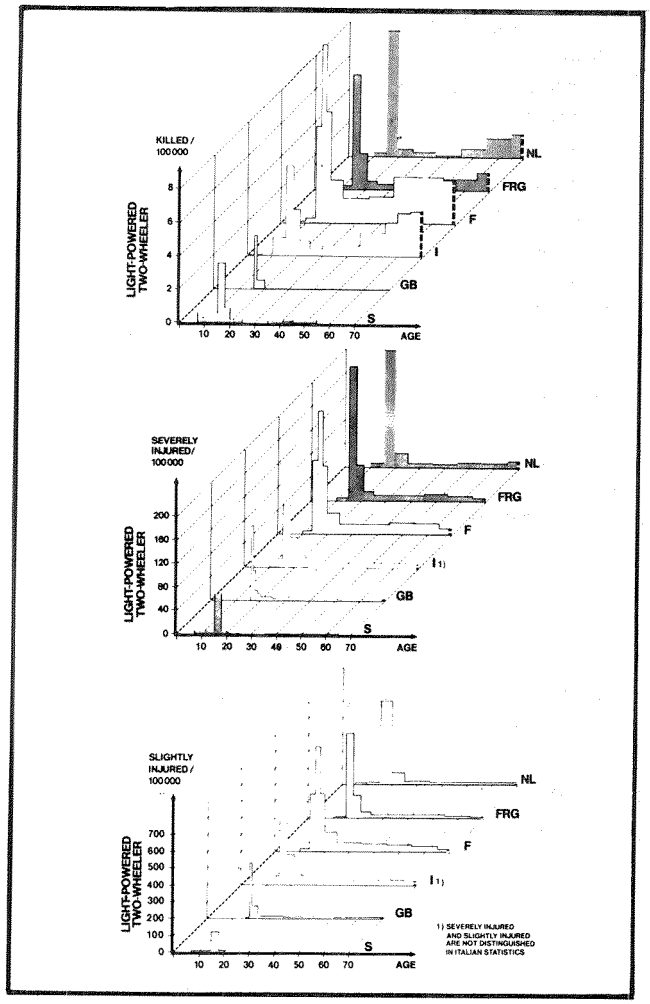

Figure 12. Killed and injured users of light-powered two-wheelers per 100,000 inhabitants/age group (dotted line for age 70 stands for age group 65 and over)

France, The Netherlands, and the Federal Republic of Germany display the highest figures in all these accidents. France, in particular, displays a remarkable death rate for the age group of over 40.

Unreported Accidents

The most important systematic error in all national accident statistics results from the material damage and injury accidents not reported. These so-called unreported accidents can reach considerable values, particularly with decreasing accident severity. Various studies have been consulted.

Sweden

Roosmark/Fraki(11) and Thorson/Sande(12) concluded that on the whole not more than half of the traffic casualties are reported in the national accident statistics.

In the case of material damage, unreported numbers are estimated at 85 percent even.

Based on a regional study in Göteburg, Bunketorp(18) determined a correction factor to describe the relationship between the overall number of accidents and those recorded by the police. For fatal accidents, a factor of 1.0 was found; for severe injury accidents, 1.4; and for light injury cases, 1.8. This corresponds to unreported rates of 0 percent for fatal accidents, 29 percent for severe injury cases, and 45 percent for light injury accidents.

Denmark

Nordentoft(13) revealed in 1972 in the Odense area an estimation of unreported injured accident victims of more than 60 percent. Unreported numbers are reportedly particularly high in single-vehicle injury accidents.

Switzerland

Hehlen(14) reports a high percentage inside urban areas at 70 percent and outside urban areas at 63 percent. The unreported accidents of cyclists were estimated at 81 percent, and for mofa riders at 74 percent.

The Netherlands

A study on unreported numbers, published in 1982, was conducted in The Netherlands(16). This study was based on the period 1977-79 and revealed the proportion of unreported numbers appeared to have remained unchanged over the entire period. A comparison with police accident records for 1979 showed that, in the case of accident victims hospitalized as a consequence of their accidents, only 17 percent appear to remain unreported. The underreporting seems to be a function of the mode of transport. The CBS/SMR ratio of reported accidents (police information/hospital information) is in vehicle categories and pedestrians:

Car occupants	Mopeds	Bicycles	Pedestrians
98 percent	97 percent	82 percent	78 percent

Germany

A study conducted by Lenhardt(17) in 1982 (still unpublished) was based on approximately 4,000 accidents and arrived at an estimated percentage of unreported numbers of about 54 percent. The number of unreported cases drops with increasing severity. The proportion of unreported fatalities is estimated at 4.8 percent; in the case of severely injured accident victims, 22.3 percent; and in that of slightly injured victims, 37.5 percent. The global estimate of 54 percent comprises material damage accidents. A breakdown in vehicle categories and pedestrians has not been undertaken.

Great Britain

Pedder(19) revealed the number of unreported accidents shown in Table 22. The figures are based on data collected by Pedder (1977-78) and Bull (1973) at Birmingham Accident Hospital and by Hobbs at a hospital in Berkshire.

Table 22. Casualties in nonreported accidents

Pedder(12)	58	29	540	91	83	459
Bull(13)	37	28	145	81	65	145
Hobbs(8)	45	27	754	71	59	488

[1] Fatalities have been excluded

The comparison shows how difficult it is for a regional study of this nature to arrive at a conclusive result of general validity. The year of data collection (Pedder: 1977-78; Bull: 1973) and the legal framework and social conditions applying therewith certainly would also affect an interpretation of the large differences found in the estimates, but also differences in sample sizes of the studies may contribute.

Injury Severity and Hospitalization of Users of Two-wheelers (Including an Approach to an Overall Economic Assessment)

It has generally been found that data are not collected on a national scale in any of the participating countries on the various degrees of injury severity and length of in-patient treatment. The research findings available are results of regional studies and thus involve the problem of translation to be of value at a national level.

A thorough analysis would have to consider also the economic significance of human accident costs, which, apart from hospital costs (during the period of a victim's hospitalization), also include the production loss during the period of a victim's inability to work (involving a much larger time and cost factor than the period of treatment as an in-patient). However, these are aspects that would be outside the scope of a regional study on a medical treatment facility concentrating on the classification of injuries into appropriate categories (e.g., AIS, OAIS, MAIS).

For the Federal Republic of Germany, first hints for an analysis of the time and cost factors involved in treating accident victims are found in studies conducted by Otte(21) and in the comparison of Otte's findings with the results obtained by Willeke(22). In Table 23, the periods of hospitalization relating to various degrees of injury severity (OAIS) are shown (on average in terms of days).

Note that Willeke's study is based on an all-road-user sample, whereas Otte concentrated on the users of two-wheelers only. The term "sum total of days of in-patient treatment" may include readmittance to the hospital, where necessary. The number of cases studied here was 123. Based on 282 case studies, Otte arrived at average periods of in-patient treatment (including complications or not) as stated on the last line in Table 23.

For calculating costs of treatment, the average length of hospitalization in each AIS group was linked with the hospital cost per day charged currently by the Medical University of Hanover (DM 310). The cost of medical treatment for users of motorized two-wheelers involved in injury accidents with resulting injuries of the OAIS 2 category (without complications) are thus estimated at DM 3,950. If complications have to be considered in addition, the costs rise to DM 10,000 (base: 123 cases).

A survey concerning the length of hospitalization in relation to the severity of injuries (MAIS) can be found in a study by Danner(23). One remarkable result of the study is that the high number of leg injuries with long treatment periods are dominating at the injury scale MAIS 3, whereas, at MAIS 4 and 5, head injuries determine the injury pattern (Table 24).

A study conducted by Krupp(24) describes the periods of hospitalization and resulting costs for severely injured riders of bicycles and motorized two-wheelers. The medical treatment costs and the costs with a breakdown into categories accounting for the absence and presence of effects on earning capacity, as estimated by health insurance companies or insurance companies for occupational accidents, are found in Table 25.

Table 23. Length of hospitalization in days related to OAIS

	OAIS	1	2	3	4	5	6

Length of In-patient Treatment*	11	34	11	43
Costs (DM)	1,800	5,900	1,900	7,800

* Days

A survey among nearly all hospitals in The Netherlands(25) shows as a result the following average number of days in hospital for bicyclists and users of powered two-wheelers: bicyclists, 18 days; moped riders, 20 days; motorcyclists, 20 days. The average total costs per patient do not differ as much: bicyclists, 6,200 HFL; moped riders, 6,900 HFL; motorcyclists, 6,800 HFL.

In the TRRL study by Hobbs(15), the period of hospitalization and degrees of accident severity are considered separately for cyclists and users of motorized two-wheelers. In the case of cyclists, the degrees of injury severity fall primarily into the AIS 2 and 3 categories. On account of the limited number of case studies, the periods of hospitalization were classified into those of less or greater than 2 days. The group of accident victims with injuries in the AIS 2 category mainly involved periods of in-patient treatment of ≤ 2 days (57 out of 83 cases). In the case of injuries of the AIS 3 category, the period of hospitalization is clearly greater than 2 days (in 22 out of 29 cases). In 57 out of 85 cases, accident victims in the user group of motorized two-wheelers, whose injuries had been classified as corresponding to AIS 2, had to undergo hospital treatments of ≤ 2 days. The peak value reached by the injury cases of the AIS 3 category also exceeds 2 days of hospitalization by far: between 11 and 20 days in 27 out of 100 cases. Injury cases corresponding to AIS categories other than 2 or 3 were so few that statistically significant information was not obtained.

Summary

This chapter presents a survey of the national accident statistics of the countries represented in the working group. The frequencies of injuries of cyclists and users of light-powered two-wheelers are considered at greater depth. At the beginning, the numbers of registered vehicles are presented and the definitions of a bicycle and a light-powered two-wheeler, as applicable in the various countries, are summarized. In the case of the numbers of injured accident victims, given as overall figures and with a breakdown by vehicle categories, the distributions are fairly heterogeneous and often also display falling trends, in particular in the case of fatalities.

A consideration of the development of vehicle numbers in each vehicle category needs to be included in the study. In addition, the number of vehicles per 100,000 inhabitants needs to be considered both in the evaluation of the number of accidents and in the assessment of relative accident numbers. Due to the complex nature of the relationships and the basically different definitions given, e.g., of light-powered two-wheelers, a ranking of the countries by their rates of injured accident victims was refrained from in this conjunction.

With respect to the number of unreported accidents, there is still the problem of translating the results of regional studies to the conditions at a national level. On the whole, it was found that the percentages of unreported accidents tend to increase with decreasing injury severity.

No statistically supported findings on a national level can be given on the correlation between injury severity and periods of hospitalization. Only initial data material is available from regional studies.

2. Detailed Description of Bicycle and Light-powered Two-wheeler Accidents

This section deals with more detailed data of bicycle and light-powered two-wheeler accidents, such as collision partners, collision types, resulting injuries, and speed at impact. These data are in general not available from national statistics. Therefore, most of the information is obtained through special accident studies.

Nevertheless, as is the case in The Netherlands, useful and more detailed information is gathered on a national base by the police and computerized at the Road Accident Record Office (VOR). To give direction to the injury-prevention research of bicyclists and moped riders, some priorities in the distribution of accident and collision types are made in The Netherlands(34). Many criteria may be used for this, but for some practical reasons magnitude and severity were used.

For magnitude, the number of killed and severely injured road users is used. Severity of road accidents is a

very complex term. Many dimensions are involved, such as damage, injury, cost of delays, etc. In injury-prevention research, the injury dimension of accident severity is used. But injury can also be distinguished in place, nature, and severity.

Injury severity is also complex and can be defined by threat to life, disability, etc. Scaling with the Abbreviated Injury Scale (AIS) seems to be the most appropriate, although there is some concern about the influence of long-term effects on the scaling(30). For the Dutch accident situation, only the number of killed or severely injured road users for the accident and collision types were available. Therefore, as a criterion for injury severity, lethality was used. (Lethality = 100 × number of killed / (number of killed + number of severely injured.)

There is a general problem concerning the accident data of different countries with regard to motorized two-wheelers. In most cases, this group cannot be divided into motorcycles and mopeds; the latter may even contain several types. This is needed for a proper comparison of the data since the distribution of these two groups differs considerably for the different countries.

Another more general problem in comparing the results of the different accident studies is caused by sample differences, e.g., the large differences in under-reporting figures for the different countries as shown earlier. In The Netherlands, the reporting of killed and severely injured road users is complete enough information to indicate priorities in injury-prevention research.

This section starts with a description of collision opponents of the two-wheeler riders, with respect to kind of opponent (accident type) and with respect to collision direction (collision type), with some information about the maneuver of the collision opponents just before the accident.

The resulting injuries (injury pattern) will be described, followed by a review of the impact speed, as mentioned in a number of accident studies. Information about braking (of the collision partners) before, during, or after the collision, as described in the report of EEVC Working Group 7 about pedestrian injury accidents, was not found in literature.

Accident Type

The particular combination of a two-wheeler and its collision opponent is called accident type (for instance, bicycle-car, moped-car, moped-HGV vehicle). The distribution of collision opponents will depend on the severity class of injuries considered; therefore, a large variety of distributions in the various studies may be noticed.

Great Britain

The distribution of collision opponents (motor vehicles only) for bicyclists according to (33) is:

Car and taxi	75%
Light goods vehicle	9%
Heavy goods vehicle	3%
Medium goods vehicle	1.5%
Others	11.5%

The group consists of accidents in 1974, reported by the police. There is no information about the collision partners of mopeds.

More recent information (1980) from national statistics(42) about accident types of two-wheeler casualties reported to the police, excluding accidents with three or more vehicles, is given in Table 26. The car is the most frequent collision partner in bicycle and two-wheeled motor vehicle accidents (73.1 percent; 60.3 percent) followed by the light goods vehicle and two-wheeled motor vehicle for the bicyclist (6.1 percent; 6.1 percent) and the light goods vehicle for the two-wheeled motor vehicle rider (4.8 percent).

The share of single-vehicle accidents (no pedestrian involved) for two-wheeled motor vehicle users is much

Table 26. Number of two-wheeler casualties (all severities) reported to police for different accident types in Great Britain (1980), Department of Transport (42)

	Single Vehicle				Two Vehicle				
	No Pedestrian	With Pedestrian	Pedal Cycle	Two-Wheeled Motor Vehicle	Car	Bus or Coach	Light Goods Vehicle	Heavy Goods Vehicle	Total
Pedal Cycle User	1794 (7.7%)	140 (0.6)	229 (1.0)	1,411 (6.1)	17013 (73.1)	457 (2.0)	1,433 (6.1)	807 (3.5)	23,284
Two-Wheeled Motor Vehicle User	15,522 (23.7%)	1950 (3.0)	765 (1.2)	2,434 (3.7)	39,428 (60.3)	615 (0.0)	3,146 (4.8)	1,504 (2.3)	65,364

* Excludes three or more vehicle accidents and accidents where details are not known.

higher (23.7 percent) than for the pedal cycle users (7.7 percent). In fact, these shares will probably be much larger due to the already mentioned underreporting.

Germany

A distribution of collision partners in Germany for 1982 is given in Table 27.

The group consists of killed road users in a single-vehicle accident or in collision with a car or an HGV. The table shows that, in collisions with another road user, the car in most cases is the collision partner (55 percent for bicyclists and 57 percent for motorized two-wheeler riders). Single-vehicle accidents occur more often with motorized two-wheeler riders (13 percent) than with bicyclists (11 percent).

(A)	Killed	Severely Injured
Bicyclist	89%	79%
Moped rider	72%	78%

(B1) The shares for bicyclists and moped riders are identical:

	Killed	Severely Injured
	4%	8%

(B2)	Killed	Severely Injured
Bicyclists	1%	3%
Moped Rider	17%	7%

(C) 5 to 10% The group defined in A will be considered for the distribution of collision partners.
The results for 1979 are shown in Table 28 and visualized in Figures 1 and 2.

Table 27. Number of killed bicyclists and light powered two-wheeler riders for different accident types in Germany (1982)

	Accidents with Two Participants		Single Vehicle Accidents	Total Number of Killed
1982	Car	Vans and HGV's		
Bicycle	598	127	116	1,085
Mofa/Moped	305	57	71	543

Source: BASt

The Netherlands

The Dutch data of the distribution of accident and collision types based on police information for 1978 and 1979 are available separately for fatal two-wheeler accidents and for accidents in which the two-wheeler riders were taken into hospitals for at least 1 day.

The data were coded by the Dienst Verkeersongevallen Registratie (VOR), manipulated by SWOV, and reported by Huijbers(34). These accidents are very well reported as already stated; almost 100 percent of the two-wheeler fatalities and 80 percent of the hospitalized casualties are reported by the police(35).

The bicycle and moped accidents can be divided into the following groups:

(A) Accidents with a pedestrian or a parked or moving vehicle
(B) Accidents with no other vehicle or pedestrian involved, divided into (1) collision without obstacle (tree, pole, animal, etc.), and (2) collision with an obstacle
(C) Multi- (> 2) vehicle accidents

For 1979, the total number of killed and severely injured bicyclists and moped riders is divided over these groups:

Fatalities—The car is the most frequent collision partner for bicyclists (62 percent) and moped riders (48 percent). The second most frequent collision partner is the HGV: 23 percent for bicyclists and 21 percent for moped riders.
Severely Injured—For the severely injured, the car is also the most frequent collision partner for bicyclists (69 percent) and for moped riders (74 percent). The second most frequent collision partner is the moped for bicyclists (10 percent) and for moped riders themselves (7 percent), together with the HGV (7 percent) for moped riders.

When lethality is used as a severity criterion, the collision with a tram or train has a high severity because there are few registered severely injured patients. But the number of these accidents is small. For bicyclists, the collision with an HGV has the next priority, followed by the collision with a delivery van. The collision with a car does not seem to be as severe. For moped riders, the collision with a motorcycle (or a scooter) has the next priority, followed by HGV's and delivery vans. The collision with the car does not seem to be relatively as severe (Figures 13 and 14).

United States of America

In Cross(28), a distribution from the United States is given. This group consists of bicycle casualties. In 87

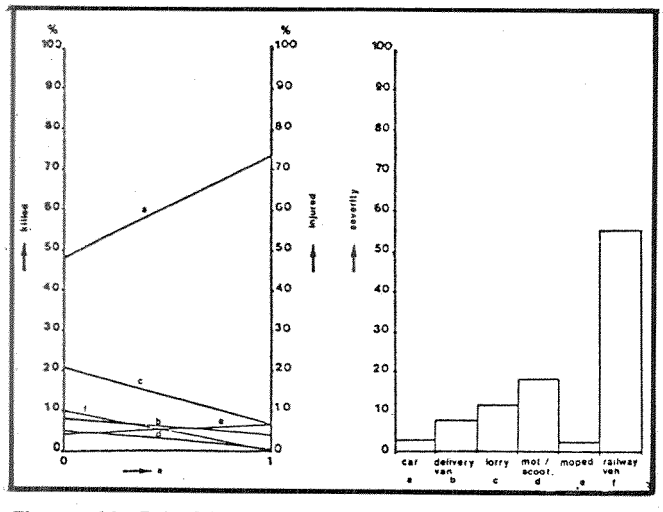

Figure 14. Priorities within the various accident types resulting in killed and severely injured moped riders(34)

percent of the cases, the car was the collision opponent; in 9 percent, it was a pick-up or van.

Collision Type

A collision type is a particular combination of impact sites of the two-wheeler and its collision opponent (for instance, front of a two-wheeler against the side of a car). The different collision types will probably result in different impact places on the body; for some types caused by the car and for others by the two-wheeler. This may cause different injury patterns.

This paragraph deals mainly with the car-to-bicycle, car-to-moped, HGV-to-bicycle, and HGV-to-moped accident types. As far as possible, collision type or impacted sites of two-wheelers and opponents are given, as specified in the different accident studies. Comparison of the results of these different studies is clearly limited due to sampling differences, as mentioned earlier.

Great Britain

Whitaker(40) gives a summary of impact sites on motorized two-wheelers. Frontal impacts occur in 59 percent, followed by lateral impacts in 38 percent of the cases. More left-side than right-side impacts were found. No information is given on the impacted sites of the collision opponent.

Riley(42) studies fatal accidents involving HGV's: 37 percent of the bicyclists hit the front of an HGV, 57 percent the side, and only 2 percent the rear end. There is no information about the impacted site of the bicycle.

Germany

Otte(37) states that in bicycle-to-car accidents 46 percent of all casualties occur with collision type front of

car-side of bicyclist, followed by the collision type front of car-rear end of bicyclist (20 percent) (Figures 15 and 16).

In a frontal collision (front of car-front of bicyclist), 17 percent of the persons were killed or injured; in side collisions (side of car-front of bicyclist), 15 percent of the casualties occurred. The distribution of some collision types causing casualties for motorized two-wheelers is 28 percent in collision type front of car-side of motorized two-wheeler, 24 percent in collision type front of car-front of motorized two-wheeler, and 21 percent in collision type side of car-front of motorized two-wheeler.

Figure 16. Distribution of two-wheeler collision types in bicycle crashes(37)

From this information, it seems the distribution of the collision types for the motorized two-wheeler-to-car accidents is much more homogeneous than the distribution of the bicycle-to-car accidents. The collision type front of car-rear of two-wheeler occurs relatively often for the bicyclist but not for the motorized two-wheeler. The distribution of collision types for HGV's can be seen in a study of the HUK-Verband, Büro für Kfz-Technik, which treats the problem of truck accidents(44).

In almost 80 percent of all bicycle accidents, the contact area on the truck was the front or the right side in

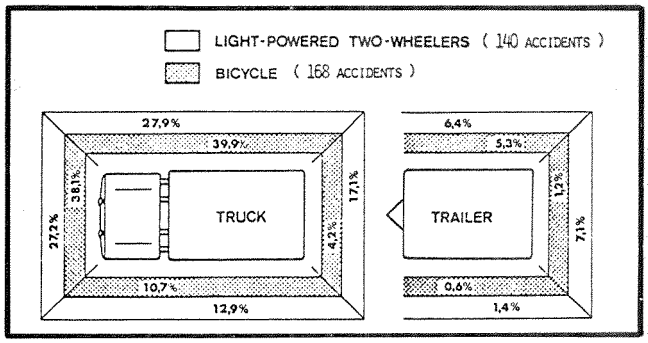

Figure 17. Heavy goods vehicle region contracted by bicycle or light-powered two-wheelers(44)

nearly equal proportions. For the light-powered two-wheelers, the contribution is a little more homogeneous (Figure 17).

The Netherlands

For the Dutch accident situation, priorities for injury-prevention research within the distribution of collision types (1978/1979) were based on the criteria of magnitude and severity (lethality). The collisions were categorized in some collision types (Figure 18)

Bicycle-to-car Accidents (Figure 19)—Most of the cyclists were hit in the side by the front of the car (type F1): 65 percent of those killed and 60 percent of the severely injured. The left side of the bicycle was hit twice as much as the right side. The other collision types did not occur as much; of these, the types F2 and F3 were most important. The collision with the side of the car happened most of the time with the front of the bicycle (type S1): in 10 percent of the cases with severely injured cyclists. With lethality as a criterion, collision type F3 (front of car-rear end of bicycle) was the most severe.

Moped-to-car Accidents (Figure 20)—In moped-to-car accidents, the collision type F1 (front of car-side of moped) dominated, too: 62 percent of the killed moped riders. The severely injured moped riders were hit nearly

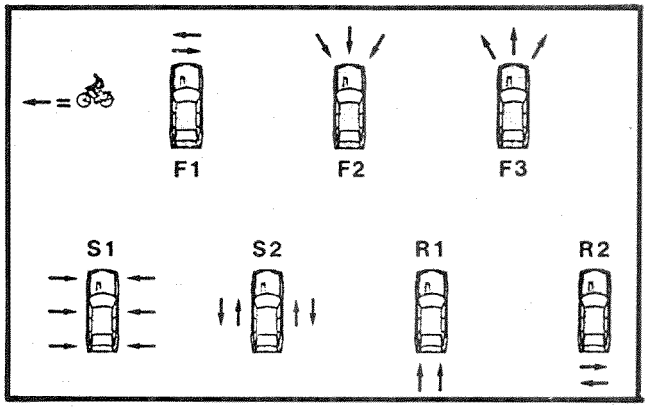

Figure 18. Definition of specific collision types(34)

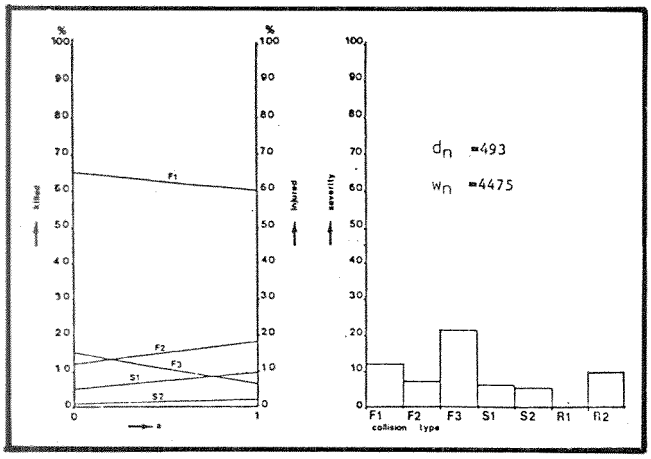

Figure 19. Priorities within the various collision types for bicycle-to-car collisions(34)

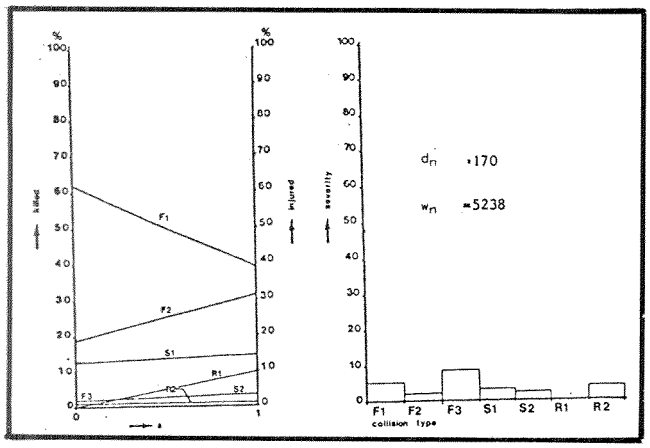

d_n = number of people killed w_n = number of people injured

Figure 20. Priorities within the various collision types for moped-to-car collisions(34)

as often sideways (F1) as frontal (F2) by the front of the car (39 percent; 31 percent). Frontal collisions with the side of the car happened nearly as frequently for the killed moped rider (13 percent) as for the severely injured. The collision type F3, where the front of the car hit the rear end of the moped, did not occur as much as for cyclists (3 percent killed; 1 percent severely injured), although this collision type had the highest lethality in analogy with the bicycle-to-car accident. The opposite rear-end collision (R1) happened for 10 percent of the severely injured moped riders. The lethality from this type was minimal because there were no killed moped riders registered in this collision type.

Bicycle-to-HGV Accidents (Figure 21)—The collision front of HGV-to-side of bicycle (F1) happened most frequently (42 percent for killed and severely injured cyclists). The second most frequent collision type was F2 (front of HGV-to-front of bicycle) for killed (19 percent) and S1 (side of HGV-to-front of bicycle) for severely injured cyclists (18 percent). The frontal collision with the rear end of the HGV (R1) happened relatively often with

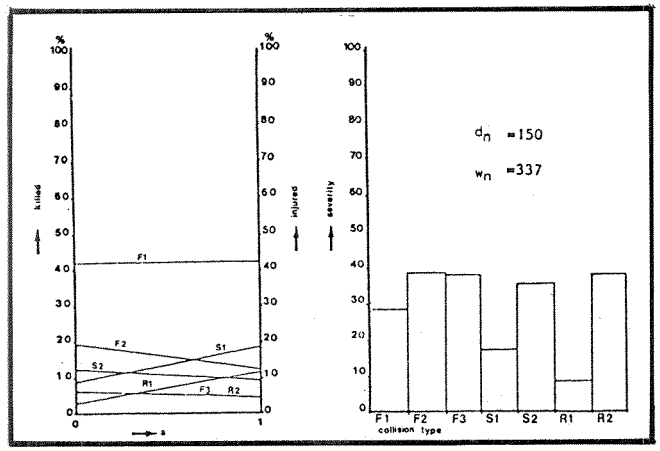

Figure 21. Priorities within the various collision types for cycle-to-HGV collisions(34)

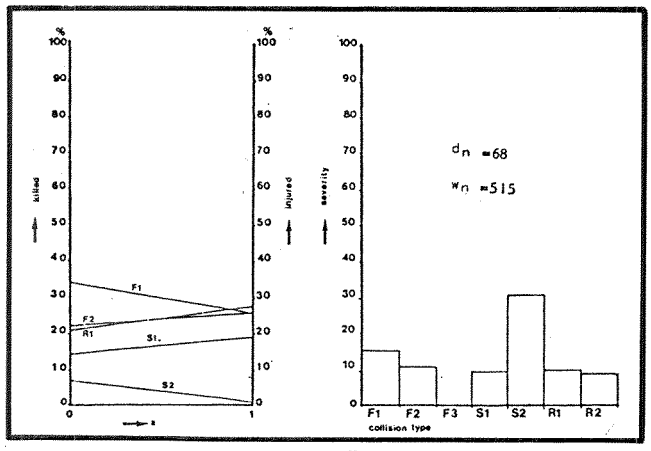
severely injured cyclists (11 percent). The collision types F2, F3, S2, and R2 have nearly the same and highest lethality.

Moped-to-HGV Accidents (Figure 22)—The collision type distribution for this accident type is more or less homogeneous. Collision type F1 dominated for killed moped riders, but the collisions with the front of HGV's (F1 and F2) happen nearly as frequently as the collision with the rear end (R1) for the severely injured moped riders (28 percent), followed by the collision with the side of the HGV (S1).

The collision type side of moped-side of HGV (S2) seems to be the most severe, followed by F1.



d_n = number of people killed w_n = number of people injured

Figure 22. Proirities within the various collision types for moped-to-HGV collisions(34)

United States of America

Data from the United States about impact points from car-to-bicycle crashes in Roland(39) show nearly the same pattern as in The Netherlands:

	Car	Bicycle
Front	63.2%	25.6%
Left side	10.7%	49.6%
Right side	23.4%	21.2%
Rear	1.9%	3.6%

The sides of the car are struck more frequently than in The Netherlands. This may be due to differences in injury severity in the samples. There is no information about collision types.

Maneuvers

The majority of accidents involving cyclists and light-powered two-wheeler riders in urban areas take place at road junctions(45). In Great Britain, accident statistics show that nearly two-thirds of injury accidents involving a pedal cycle occur at junctions(46).

In a study of accidents occurring at intersections, the Danish Council of Road Safety Research(47) found that, for urban accidents involving a bicycle and another vehicle, the most frequent maneuver type was where each was traveling on a different road before the collision. This was also the finding in a British study of national accident statistics. According to Gauss(44), nearly 45 percent of the HGV-to-two-wheeler accidents happened when one of the vehicles was changing direction.

Injuries

For injury-prevention research, injury is the most important output variable in the accident system. Injury can be described in terms of place, nature, and severity. These three dimensions are described in literature, mostly separately.

The place of the injury is reported in most of the studies, sometimes in relation to severity. Severity is mostly scored with the Abbreviated Injury Scale (AIS) system. Injury severity is a complex term. Probability of death but also temporal or permanent impairment will influence severity. The role of these long-term consequences in the AIS is under discussion, in particular for pedestrian injuries(30).

Whether this is also important for bicyclist or light-powered two-wheeler rider injuries cannot be answered now, but, for outcome variable injury severity, the scaling with the AIS seems to be the most suitable for injury-prevention research at this moment.

There is a wide variety of injury distributions in literature. As stated in (30), it is hardly possible to compare the results of accident studies because of some major differences, for instance—

- Differences in levels of injury severity in the sample (e.g., fatalities only, fatalities + hospitalized)

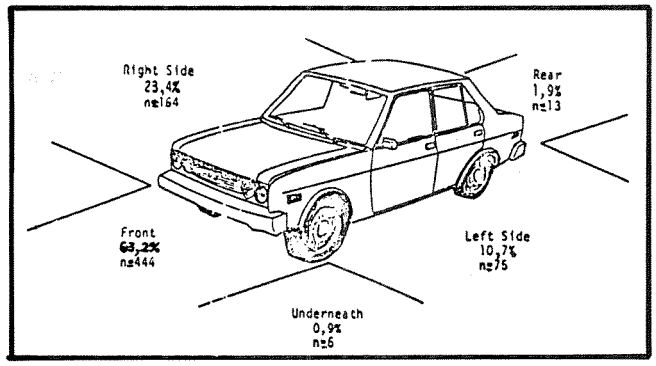


Figure 23. Motor vehicle region contacted by bicycle/-bicyclist (702 cases)(39)

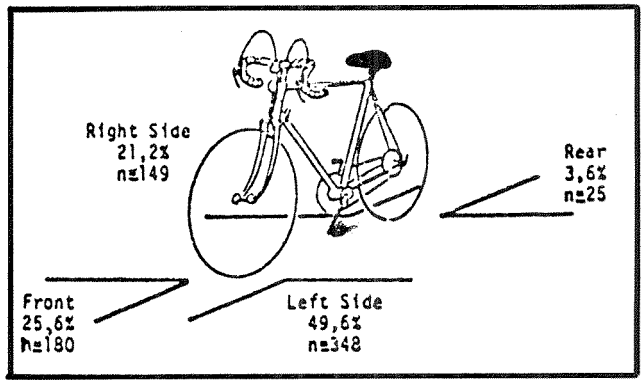

Figure 24. Bicycle region contacted by motor vehicle (702 cases)(39)

- Differences with respect to accident type (some studies contain all accident types, some only collisions with cars, some only specific collision types)

What matters are the main tendencies, common for all studies, and the differences and similarities within separate studies between injuries of bicyclists and moped riders (motorized two-wheeler riders). It seems obvious that injury distributions are dependent on accident and collision types because of differences in relative impact speed and impacted body areas. Therefore, as already stated, comparisons have to be made carefully.

When all injuries are considered, Pedder(38), Whitaker(40), Otte(37), and Grattan(31) state that arms and legs are the most frequently injured body areas, followed by the head.

Pedder(38) finds more arm injuries for bicyclists than leg injuries, and the opposite for the motorized two-wheeler riders. The other studies mentioned do not support this finding.

From Huijbers(34) and Nicholl(36), it follows that the head is the most frequently injured body area. Data from the first study are available from the Stichting Medische Registratie (SMR), containing information on 95 percent of all Dutch hospitalized casualties. Data of the second study are from a British hospital.

When the more severe injuries (AIS > 2) are taken into consideration in the studies of Pedder, Whitaker, Otte, and Grattan, the head is the body area most frequently injured.

Speed at Impact

As with the pedestrian-to-car accident, speed at impact seems one of the more important parameters. It is better to speak of relative impact speed since not only the impact speed of the car but also the impact speed of the two-wheeler and the direction of impact (collision type) have a big influence on the relative impact speed.

In this section, data on impact speed from the different studies are presented as in the report of Working Group 7 of EEVC(30). In some studies, it is not quite clear what is meant by impact speed. There were no impact speed data related to specific collision types. Therefore, the results must be looked at with great care.

Some results follow (Figure 25):

- Otte(37) indicates that, at impact, speeds of cars in collisions with motorized two-wheelers are, in general, lower than those in collisions with bicyclists.
- There is a wide variety in impact speeds of cars for the various studies:
  - 50th percentile speed varies from 10 to 50km/h.
  - 90th percentile speed varies from 37 to 72km/h.
  - This variety is larger than for pedestrian accidents(30).
- Gauss(44) found that speeds at impact depend on the collision types, but, in general, the speed at impact of the two-wheeler was remarkably higher than the speed of the HGV. Nearly two out of three two-wheelers collided with a speed between 31 and 60km/h.

Summary

In all the studies mentioned, cars are the most frequent collision opponents, rating from 50 to 90 percent of all opponents in bicycle and light-powered two-wheeler accidents. This is more or less similar to the situation for pedestrians as mentioned in EEVC(30). Second are vans and HGV's. In The Netherlands, mopeds are the second most frequent collision partner for injured bicyclists and moped riders. With motorized two-wheelers, single-vehicle accidents (in collision with an obstacle) happen relatively often. If a criterion such as lethality is used for accident severity, collisions with HGV's seem to be the most severe accident type for bicyclists and the second most severe for moped riders. An accident between a moped and a motorcycle or scooter seems to be the most severe for moped riders. The collision with a car does not seem to be very severe in relation to the other accident types.

From this, it seems obvious injury-prevention research for bicyclists and light-powered two-wheeler riders should focus on a confrontation with cars (magnitude) and

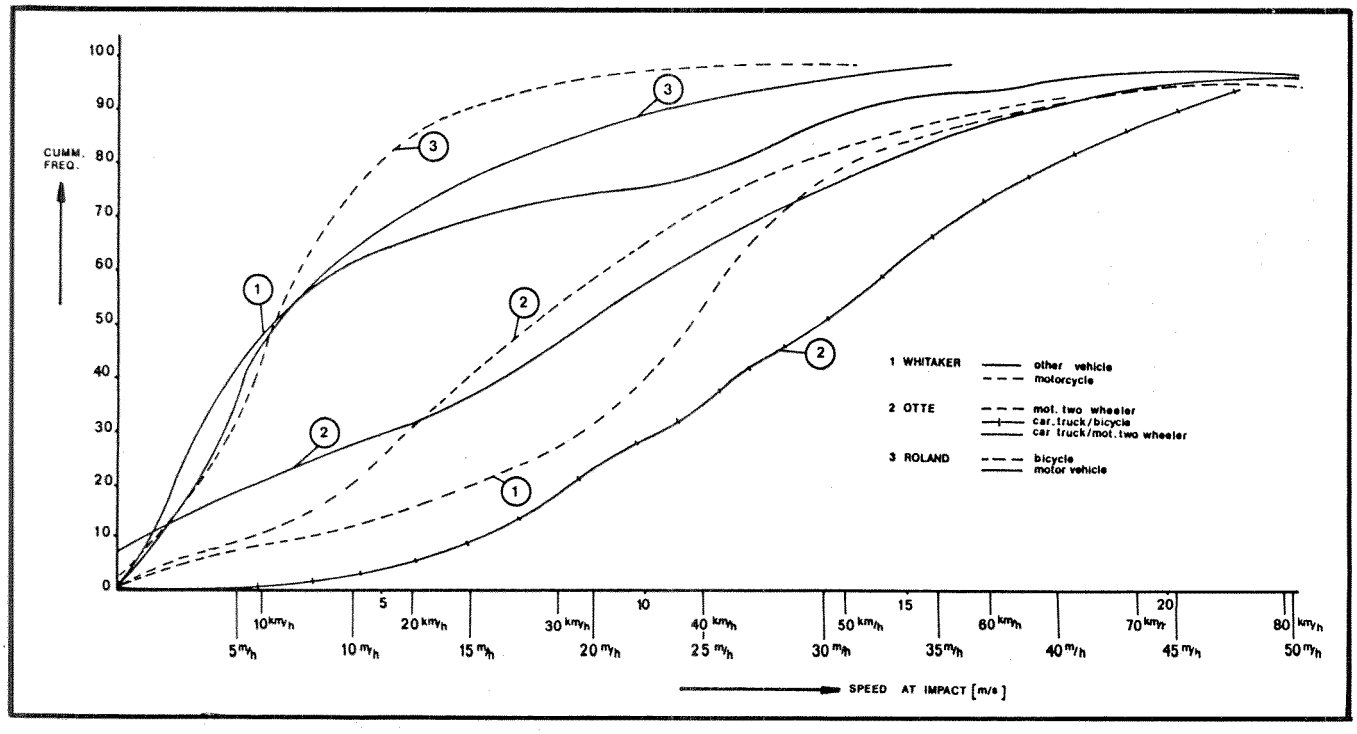

Figure 25. Cumulative distribution of vehicle speeds at impact in two-wheeler-to-car accidents by several studies

HVG's (severity). The single-vehicle motorized two-wheeler accidents happen so often that this accident type must be considered also.

For determining the collision types to be studied in the next section, a distribution of the collision types for the various countries was made. This information indicates also which parts of the motor vehicle need to be considered in injury-prevention work for bicyclists and moped riders. There are some differences in the results of the presented studies. These differences may be caused partly by sample differences, especially levels of injury severity. Other differences, such as infrastructure, modal split, etc., may also be present and influence the outcome. Also some similarities between the results of the various studies were noticed.

In most bicycle-to-car accidents, the bicycle is impacted at the left side by the front of the car. The collision type front of car-rear of bicycle occurs more often in accidents where the bicyclist was killed than when he was hospitalized. Collision types involving the side of the car did not occur often in the more severe bicycle accidents.

In light-powered two-wheeler-to-car collisions, the two major collision types are front of car-left side of light-powered two-wheeler and front of car-front of light-powered two-wheeler, followed by side of car-front of light-powered two-wheeler. The front of the light-powered two-wheeler therefore plays a more important role than the front of the bicycle. When lethality was taken into consideration, the collision type of front car-rear of bicycle (light-powered two-wheeler) seems to be the most severe, followed by the most frequent occurring type front of car-side of bicycle (or light-powered two-wheeler).

It seems obvious, therefore, the attention of injury prevention should be directed both toward the front of the car (as for pedestrian accidents) and to the side, particularly with respect to light-powered two-wheeler accidents.

Data of HGV accidents with bicyclists and light-powered two-wheeler riders from The Netherlands and Germany suggest that bicycle collisions with the front of HGV's happen most often. But collisions with the side of HGV's are also relatively frequent. Accidents with light-powered two-wheelers happen nearly as often with the front and the side as with the rear end of HGV's. Therefore, it seems obvious the attention of injury prevention should be given to all sides of HGV's.

Literature gives a wide distribution of injuries as a result of bicycle and light-powered two-wheeler accidents. These results can hardly be compared due to differences in injury severity or collision types under study. The various results indicate that the head has the highest frequency, especially when considering the more severe injuries. Arms and legs are the second and third most injured body areas.

Relative speed at impact depends not only on the speed of the collision partners at impact but also on collision type. The speeds at impact found in literature have a wider variety than for pedestrian-to-car accidents. The 50th percentile values range from 10 to 50km/h, the 90th percentile values from 37 to 72km/h. In HGV-to-two-wheeler accidents, it was found the speed of the two-wheeler was remarkably higher than the speed of the HGV.

3.Injury-influencing Parameters

Knowledge of injury-influencing parameters in different types of road traffic accidents is gained through in-depth investigation at the scene of the accidents, combined with detailed reconstruction and experimental studies. A large number of reports from this kind of investigation are found in the literature regarding cars colliding with fixed obstacles, other cars, motorcycles, or pedestrians. Very little is known about light (motorized) two-wheeler accidents. The following account of injury-influencing parameters in such accidents is, therefore, mainly inferential and rests on deductions from what is generally known in this field of research. This section deals mainly with comparisons of other accident types, and the conclusions drawn from these can, of course, be disputed.

Nevertheless, it was considered desirable to have this kind of a résumé of factors thought to be of importance for the production of injuries to two-wheeler riders colliding with cars and HGV's.

The rider here, if not otherwise stated, is generally supposed to be a teenager or an adult person, and the two-wheeler a bicycle or a moped with an internal combustion engine but otherwise essentially of the same basic construction as a bicycle. The car is considered to be an average size European-type sedan. For children on smaller bicycles, the kinematics may be similar to those of adults although the front structures of the car may hit the child's trunk rather than the lower extremities. In some cases, the child may have a more upright posture than an adult rider and the kinematics may then be more like that of a child pedestrian.

The kinematics of the two-wheeler rider in this kind of accident depend on the type of collision, velocities of the two vehicles, rider's posture at the moment of impact, and construction of the two-wheeler.

While a pedestrian hit by a car is usually upright at the moment of first contact, the rider of a two-wheeler is thought to be in a more or less seated position. This implies that his feet are usually some distance off the ground; the head may be at about the same level as that of an upright pedestrian, but this depends very much on the posture of the rider. The center of gravity of the rider's body may well be at approximately the same level above the ground as that of a standing adult pedestrian. While the velocity of a pedestrian is often negligible in relation to that of the car, the two-wheeler travels much faster.

This velocity may sometimes be as high as 50 to 70km/h and has, therefore, to be taken into account in many accident situations. However, the parameter of importance for injury production is, of course, not the speed of travel but the relative velocity between the rider's body, and that of the car at the time of impact and for each body part.

Another important difference between pedestrians and riders of two-wheelers is the presence of the two-wheeled vehicle; this presence may influence the kinematics of the rider. The inertia of its mass may in some collision types place an extra load on the rider's body, and his extremities may get entangled in the main structure of the vehicle during the accident sequence. A two-wheeler with an engine may also have parts that are hot enough to cause burns if the rider contacts them during the accident sequence.

Collision Types

The collision types referred to below are those depicted previously in Figure 18. Due to existing knowledge and the priorities indicated earlier, this paragraph will deal mainly with collisions with passenger cars.

Passenger Car

Type F1—In this type of accident, the front of the car impacts the left or right side of the two-wheeler traveling in a direction perpendicular to that of the car.

This collision type is similar to the most frequent type of car-pedestrian impacts. In both cases, the adult victim is hit below the center of gravity and comes into contact first with the bonnet or windscreen and then with the ground. One obvious difference is the usually higher speed of the two-wheeler at impact. This implies the rider's upper body will often hit the bonnet at a point further in the direction of his travel than a pedestrian would. The ratio between the speeds of the two vehicles will be decisive for where the rider's head and trunk will impact the car structures. In some cases, this ratio may, of course, be such that the upper body of the rider does not impact the car structure at all, but instead he falls directly to the ground.

The seated position of the rider at impact may sometimes induce a rotation of his body about its longitudinal axis. This is particularly the case when the car structure is low relative to the rider's torso and the thigh on the struck side is at about a right angle with the rider's torso. The lower leg and, to some extent, the arms are then accelerated by the car at an earlier moment than the rest of the body. The direction of rotation, therefore, is such that the back of the rider's trunk and head are turned against the car.

The rider's legs will thus be accelerated by the front structure of the car and may then be loaded also by the inertia of the two-wheeled vehicle's main structure. His torso will usually impact the bonnet or the upper parts of the wings. Where the head impact will take place will depend on the speed of the car and the car configuration parameters (e.g., bumper height, bumper lead angle, and length of its bonnet). It may be either on the bonnet, the upper parts of the wings, the windscreen, or the windscreen frame. The compliance of these car structures varies considerably and, as has been pointed out in connection with pedestrian-to-car accidents, is an important injury-influencing parameter. The speed of the car and the weight and construction of the two-wheeler are also important parameters.

Type F2—The two-wheeler is traveling in the opposite direction to that of the car and the impact occurs front to front; the closing speed is the sum of the speeds of the two vehicles. The mass of the two-wheeler is small compared to that of the car. This may, therefore, be the most violent accident situation. It is also a situation where the rider's body may be traveling with the head as the leading part of the body. Even if the trunk is not stooped forward before impact, the legs may get caught by the handlebar of the two-wheeler during the accident sequence, and this may induce a forward rotation of the trunk. Should the impact then be headfirst into the windscreen area, the axial load of the body would often lead to severe fractures at the base of the skull and in the cervical spine. These kinds of injury are usually lethal even at low velocities. In this situation, the total velocity change is the most important parameter, and the compliance of the impacted structures—or the use of a helmet by the rider—can probably influence the outcome only to a minor degree.

Type F3—The direction of travel is the same for both the car and the two-wheeler; the difference between the speeds of the two vehicles is a decisive factor. The position of the rider's upper body then governs his kinematics. He may more or less remain in his original position, slide over the bonnet, and impact the windscreen area with the lower part at his back. Severe back injuries can result from this type of accident. The main injury-influencing parameter is again the velocity, and the compliance of the structures is of secondary importance.

Type S1—In this type of accident, the two vehicles move perpendicularly to each other or the car may be stationary but the two-wheeler impacts either side of the car. Due to the higher speed of the two-wheeler, this type of accident has more similarities with the corresponding type of motorcycle accident than when a pedestrian walks into the side of a car.

If both vehicles are moving in this configuration, the front of the two-wheeler will be influenced by the moving car in such a way that the two-wheeler will rotate during the sequence and the rider will impact the car side in an oblique way. Usually the rider's head will be at or above the roof area of the car.

If the impact occurs at the passenger compartment in the middle of the car, the rider's body generally will be stopped by the car's side structure. The velocity of the two-wheeler and the compliance of the car's side structure will be the injury-influencing parameters and to some extent the structure of the two-wheeler.

If the impact occurs at the front or the rear of the car, where the car structures are lower, there is a possibility that the rider of the two-wheeler will pass over the car and fall to the ground on the other side. While airborne, the rider may tumble and it is therefore difficult to predict his attitude when impacting the ground.

Types S2 and R2—In the case of a near miss or side sweep, only one leg and possibly one arm and shoulder of the rider may impact a front corner of the car. Axial or near-axial loading of the femur is then possible. Severe leg injuries and even traumatic amputations at high-speed impacts are seen in this type of accident. Compliant car structures may be of some help, but the relative impact speed is probably more important. The arm and shoulder may be injured in a similar way, but the direction of force is probably more favorable.

Type R1—The two-wheeler impacts the rear of a car, and the relative velocity is likely to be less than in most of the other accident types. The car structures, other than vertical ones, are therefore probably less important, but attention should be drawn to the possible existence of spoilers, which should for this reason be as compliant as possible.

Oblique Impacts

Oblique impact directions may produce a combination of the injury mechanisms mentioned above. When a rider's upper body impacts the top of the bonnet, a higher relative velocity may result in a more oblique head impact than is the case for pedestrians. It is not possible to state on the basis of present knowledge whether this may lead to more severe head injuries due to angular acceleration of the head.

Accidents Involving Buses and Lorries

In the case of the frontal collision types (F_1, F_2, F_3), the configuration parameters do not seem to have as much influence on the kinematics and injuries of the two-wheeler rider. Compliance seems to be important. The configuration of the sides of HGV's seems to be important for the injuries of the colliding two-wheeler rider, due to the large gaps between the truck wheels. The two-wheeler rider will be hit at the head or neck level by the relatively stiff parts of the HGV. The risk of being run over seems to be important, too, just as the speed of impact of the two-wheeler rider.

The Structure of the Two-Wheeler

When the two-wheeler is hit from the side, there is a possibility for the rider's leg to be squeezed between the two vehicles. The construction and inertia of the two-wheeler is then of importance for injury production. If the two-wheeler collides in a frontal or oblique direction with another vehicle or an obstacle, it is possible the rider may be caught by the handlebar in the groin area. This may lead to vascular and/or nerve injuries and may change the kinematics of the rider. Any other protruding detail on the two-wheeler may cause injuries if the rider hits it during the accident sequence.

A special type of injury occurs when children are carried as passengers on two-wheelers without adequate protection for the child's legs. If the child's foot gets caught in the wheel, it will be squeezed between a spoke and the frame, and the resulting injury usually requires hospitalization.

The Ground

For pedestrians, it is now believed the ground is of little importance in relation to the car for injury production. The same is probably true for two-wheelers. At higher speeds, there may be a more substantial influence by the ground. The oblique impact of the head to the ground and possible kerbstone impacts may then become important for the severity of brain injuries. Another important factor is the dirt on the road surface. Open wounds caused by the primary impact to the car or resulting from the sliding of the rider on the ground after impact may be smeared with dirt. This prolongs the healing process and may lead to complicating infections. Normal clothes are of little use for protection since they are easily torn under these circumstances.

Obstacles

In the streets, there are several obstacles that a two-wheeler can contact violently after loss of control. Street appurtenances are sometimes designed to break away or yield when hit by cars to minimize the risk of injuries to car occupants. Because of their low mass, two-wheelers will normally not be capable of deforming these structures to any appreciable degree. Hence, the risk of having an injury is much greater for these categories. On country roads, trees and fences can also cause injuries if violently contacted by the rider of a two-wheeler.

Children particularly, and sometimes teenagers, also use their vehicles in playing grounds, parks, and other places outside the roads where there are several possibilities for contacting fixed obstacles. The types and severities of the resulting injuries from such contacts depend on many variables, such as type of accident,

which determines the kinematics and attitude of the body at impact, the velocity, the object struck, etc.

Children seem more prone than adults in overturning to fall on the end of the handlebar in such a way that abdominal injuries occur. Due to the very low tolerance of the child's abdomen to the high level of loading resulting from this kind of impact, very little can be done with the bicycle to prevent these injuries.

4.Research Methods and Results

Injury-prevention research for two-wheeler riders got less attention than injury-prevention research for pedestrians. The accident process of the two-wheeler rider is even more complex than that of the pedestrian because of the contribution of the two-wheeler itself to the injury-producing process. Also the speed of the two-wheeler and its position in traffic situations lead to other collision types and speeds at impact. There are several ways to study two-wheeler injury protection. One is analysis of accident data and another is experimental research.

Accident Studies

Accident studies give samples of reality to estimate the size of the problem, defining priorities within the problem and developing hypotheses in which relations between injury-influencing parameters and injury severity are postulated. Accident studies also give results with regard to the quantification of these relations. The study of the effect of a specific (legal) measure is a special application of this type of accident investigation.

One might distinguish at least three levels of depth of accident studies:

1. Accident statistics (police data level)
2. Intermediate level studies
3. In-depth studies

To describe the size of the problem, the relative proportions of collision types, etc., levels 1 and 2 are needed. These data may also form the basis for experimental studies under laboratory conditions.

The difference between level 2 and level 3 data is normally that, in level 3, far more detailed data are gathered including data on scene for each accident. Emphasis with level 2 data is on the statistical side, which means the sample size, sampling method, and detail of information are balanced with respect to representativeness and statistical analysis. For both levels, investigators of more than one discipline are often used (i.e., technical, medical, etc.).

Since accidents involving two-wheelers are complicated with respect to the exact cause of injury (for instance, contribution of vehicle and road factors), the in-depth level of data gathering is often used.

Level 3 in-depth data may provide the following for each case:

- Data from observation on scene, soon after the accident, helping to understand the sequences of the collision phases
- Data on the vehicles or obstacles involved, with emphasis on vehicle types, damage, marks for reconstructing the collision type, collision severity, and, if possible, injury mechanisms
- General data on two-wheeler riders, especially their position on the two-wheeler, their means of protection, etc.
- Detailed injury description for every casualty, if possible by direct observation or through hospital records

Level 2 data may also contain valuable information on injuries and the accident in general, and, since emphasis is on representativeness, a far more reliable picture of all occurring crashes is acquired than by means of police data (level 1).

Level 2 studies may be based on insurance data, hospital data (though these will be restricted to only part of the injury population), towaway accidents, or any other starting point. As in level 3 studies, damage, accident, and injury information will be gathered, often on a statistical basis (e.g., by a written inquiry to car owners, occupants, hospitals, or police). Visiting the scene of the accident is not part of this method since this would take too much time and effort.

For two-wheeler accidents, a visit to the scene and a full investigation of the surroundings and vehicles involved seems necessary if all injury-causing factors are to be known. However, the in-depth approach limits the quantity of cases to be studied in a given period. Therefore, level 2 data are needed to get a view of the problem and its relevant distributions as part of reality, especially if level 1 data are not available or are incomplete, as is the case in many countries.

Some Results

Cross(51) studied 753 nonfatal and 166 fatal bicycle casualties in collisions with motor vehicles (level 3). From the nonfatal group, only 17.5 percent remained in the hospital longer than 1 day. Contact with the road surface seemed to be the cause of injury in 60 percent of the cases, contact with the motor vehicle in 23 percent, and contact with the bicycle in 6.2 percent.

The conclusion from Roland(52), after examining 700 motor vehicle-to-bicycle accidents (level 3), is an agreement with this last statement as far as the injury causation of the bicycle is concerned. Roland concluded the bicycle did not seem to be a major source of severe injuries.

There were only four injuries resulting from a contact with the bicycle that produced an AIS rating greater than 1. There is a significant overrepresentation of the motor vehicle as the source of injury rather than the environment. For all the defined speed categories, more severe injuries

tend to result when the contact source was the motor vehicle as opposed to the bicycle or the environment. This does indicate the injuries are being produced in the initial contact rather than from secondary contacts with the environment. No significant influence on injury severity was found for estimated speed of bicycle prior to impact, bicyclist's age, handlebar type, and bicycle region contacted. Significant influence of motor vehicle variables was found for estimated speed at impact and vehicle maneuver prior to impact.

Some studies described specific injuries:

- The influence of the bicycle on intra-abdominal injuries(68,66). These injuries are usually caused by falling on the free end of the handlebar.
- Bicycle spoke injuries(67). These lesions occur if a child passenger's foot is caught in the wheel of the bicycle.

Some advantages and disadvantages of accident studies in relation to experimental research are the following:

- Advantages
  - — The only way to establish the size of the problem
  - — The only method that gives insight into the injury-influencing parameters in the real accident situation
- Disadvantages
  - — Approximation of some of the accident data (e.g., speed at impact, contact places)
  - — Only the influence of the values of the parameters, as they exist in real traffic, can be studied

Experimental Research Methods

In a collision between a two-wheeler and a car, type and severity of injuries sustained by the two-wheeler user may depend on its kinematics but also on the relative speeds of the two vehicles. The two-wheeled vehicle may have an important speed. Moreover, the crash configuration can differ from one case to another in a large range.

The main collision types are F1, F2, and S1. Experimental research on bicycle and moped collisions is mostly focused on type F1. Type S1 is dealt with in motorcycle collision experiments. The posture seems to have a small influence on the kinematics, and one can imagine that differences in height would also have a minor influence, as most of the two-wheeler users are adults.

Three main methods are available for research in two-wheeler safety:

1. Full-scale tests between a two-wheeler and a car (or a mobile barrier), the two-wheeler rider being a dummy or a cadaver. Even if they have the advantage of being realistic, for car-to-two-wheeler collisions they will have to be performed in a large number of configurations as the potential collision types are numerous and the impact speed can vary in a large range. The problem of impact with escape may be difficult to reconstruct.
2. Body segment tests (or component tests) in which the safety problems involving a specific body area are investigated. They would not be fundamentally different from research made on pedestrian safety since the same body segments are concerned. Moreover, specific research dealing with two-wheeler safety concerns head injury protection with crash helmets, as well as some other parts of cars, trucks, etc.
3. Mathemetical model. This can be used as a general tool to evaluate and predict two-wheeler rider kinematics and dynamics. Mathematical models are especially useful in parameter variation studies. As a result, mathematical modeling has the advantage (and may be the only practical tool capable) of determining generalized output for complete populations. The use of mathematical models in two-wheeler safety research is relatively recent. The method is promising for the near future. Mathematical models have to be validated with test results and/or accident investigation output.

Full-scale Approach of Two-wheeler Safety Research

This approach generally consists in reconstructing a collision between a car and a two-wheeler vehicle on which a model of a human being is seated. The impacts sustained by the two-wheeler rider ejected from his vehicle can be analyzed in relation to car-to-two-wheeler collisions or to impacts against objects in the surroundings(57). Two main research projects used this car-to-two-wheeler full-scale approach to study two-wheeler protection.

In the first tests(49), 22 collisions between a passenger car and a moped were reconstructed. These tests were made in six different configurations, most of the tests representing a road crossing collision, the moped either striking or being struck. All the tests except two were performed with a 50th percentile dummy; the other two used cadavers. In 13 tests, the two-wheeler user was helmeted; in the other 9, his head was not protected.

This research found, in the case of the struck moped, the two-wheeler user kinematics can be compared with pedestrian kinematics. The car modifications made to protect a pedestrian can be favorable for two-wheeler users also. The head-ground impact gave higher HIC values than the head-car impact. The helmet insures a certain measure of head protection; it is less effective in the temporo-parietal area. Finally, an interaction between the moped and the dummy pelvis has been found in several cases.

The second study(56) was made in Japan. For this research, 10 collisions were performed, in which a standing motorcycle was struck laterally by a car or a rigid mobile barrier. The aim of this research is to study lower limb protection of motorcyclists, so the tests were made with a 50th percentile dummy equipped with frangible legs.

The research found the modification of cars to optimize energy absorption would insure a better protection of the rider against leg injuries. It seems possible to protect from leg injuries at a speed up to 40km/h, and the authors think the other injuries are acceptable in this range of speed. The protecting device tested in lateral collisions would have a beneficial effect in other crash configurations, especially avoiding leg crush under the motorcycle in case of rollover and underride of the motorcycle under a car. The effect of the rider ejected from his motorcycle and impacting a guardrail has been studied experimentally(57) with tests in which a dummy is laid down on the back, the head forward, on a mobile platform that is suddenly stopped; the dummy is projected forward and hits a guardrail, the head first and under a chosen angle. This research has shown it is possible to design deformable shields avoiding the direct impact between the two-wheeler rider and the rigid and sharp parts of the guardrail (posts and rails).

The third study was done at TNO(64). Dummy tests were executed (type F1) as a first step to validate the MADYMO mathematical model. The first results indicate the kinematics of the bicyclists resemble that of a pedestrian but that the impact places of the bicyclist head on the car are somewhat higher.

There are advantages and disadvantages of the full-scale approach for two-wheeler protection research. This approach would give generally a realistic view of the two-wheeler vehicle-to-car collision, but the realism of the reconstruction is limited by the behavior of the dummies and by the selection of crash configurations. Making tests with a standing vehicle decreases the interest of this approach. These tests do not have a good repeatability, and each test can only allow a safety evaluation in one specific configuration, whereas the accidentology shows an important diversity of real crash configurations. The two-wheeler vehicle type has a big influence on the results of the tests; thus these results cannot be applied to all two-wheeler vehicles (e.g., mopeds versus motorcycles).

Component Tests Used in Research for Two-wheeler Safety

Many studies using the component test approach and dealing with two-wheeler protection have been performed; most of them concerned head protection, i.e., study of crash helmet protection. Some of these studies are limited to the verification of helmet performance in tests similar to standard tests(56,57).

Other more fundamental studies allow us to know better the mechanisms that govern the head protected with a helmet and then to increase the performance of these devices. One biomechanical research project (60) investigated injury mechanisms and head protection possibilities on the basis of drop tests. Eleven tests have been performed with cadavers. Nine of them were helmeted: the drop height was 1.83m or 2.50m. The subject was inclined at 30° downward, the head first hitting a rigid flat surface. These tests were completed by some tests using only the helmeted head of a Hybrid II dummy or a helmeted metallic head model. In this study, the HIC values are very high even in tests performed at 1.83m, but the measurements were not obtained at the center of gravity of the head. Tests performed with a head only (dummy head or metal form) gave HIC values lower than those obtained in tests using whole bodies.

Another research(61) studied the influence of horizontal velocity of the head when it hit the ground, the kinematics, and the linear and angular accelerations sustained by the head. Helmeted head and neck of a dummy, attached by a lever arm to a rail-guided carriage, sustained free falls on a ring simulating the road surface. The horizontal ring rotated to simulate the horizontal component of the head speed related to the ground. These tests showed that in these conditions the head sustained important angular accelerations and speeds while the HIC value, which takes into account only the linear acceleration components, remained generally below 1,000. This study concludes that some helmets have a shell made of material that is too soft to provide a desirable low friction between helmet and road surface.

Another study(62) compared the energy-absorption characteristics of a protective helmet and a coconut shell and showed on the basis of experimental tests that the coconut has greater energy-absorption capacity than the foam used for helmets. The author proposed to design helmets without a rigid external shell.

There are advantages and disadvantages of component tests as a basis of two-wheeler rider protection research. Component test methods allow research based on a large number of tests, having a good repeatability at a relatively low cost. But these tests give only a global view of the two-wheeler accidents as they reproduce just one phase of the accident. Moreover, the conditions in which they are performed are simplified (2D motions) and their realism is limited. From this point of view, the conclusions found in research using the component tests approach should be validated through full-scale tests.

Mathematical Models for Research in Two-wheeler Protection

It seems there is no mathematical model that is especially designed for bicycle and light-powered two-wheeler safety research. Existing models of car occupants

or pedestrians could be used for two-wheelers, but their adaptation and validation would need a sufficient number of test results.

The three-dimensional CVS 3 Calspan model has been adapted by the Denver Research Institute to study the behavior of crash victims in motorcycle accidents(63). In The Netherlands, SWOV and IW-TNO are working on a program to produce a validated mathematical model for two-wheeler accidents with cars. At this moment, dummy tests have taken place as a first step to validation(64). In Germany, a mathematical model exists that simulates the impact of a motorcycle in the side of a standing car(65). In fact, it seems that up to now there are practically no results of light-powered two-wheeler safety research using mathematical modeling.

There are also advantages and disadvantages of mathematical models. Potentially they have many advantages as they allow investigation of a large number of situations in a short period at low cost, without repeating experimental tests. For that reason, they can generalize output (complete) populations involved in certain (or all) crash configurations. The accuracy of the results of mathematical model studies are largely dependent on the quality of the validation of the model. For validation, not only full-scale test results must be used, but results from in-depth accident investigations and specially developed validation test results can be used. Compared with full-scale tests, the results of mathematical models can be stated to be at least as realistic. The condition of the representation of the real situation with dummies or cadavers is somewhat questionable.

5.Current Knowledge on Human Tolerance

Accidents involving bicyclists and moped users can occur in various situations, and, contrary to pedestrians, mechanisms producing two-wheeler user injuries are numerous and can be very different from one case to the other.

For this reason, it is not possible to describe a typical kinematic of a two-wheeler user involved in a traffic accident. The human tolerance can also vary according to the loading process (age, diseases, conditions, anthropometry, impact speed) and may, therefore, be different for cyclists and riders of light-powered two-wheelers.

Tolerance can be considered in terms of severity. Injuries sustained in real-world accidents can have several degrees of severity, as simple bone fractures or severe internal organ contusions corresponding to AIS 2 or 3 are considered tolerable.

There are few studies conducted to determine human tolerance of two-wheeler users involved in traffic accidents. Nevertheless, some of the studies dealing with pedestrians or car occupants can be taken into account.

Head Tolerance

Concerning head tolerance, it is necessary to investigate cranial and/or facial head injuries and brain injuries separately.

Bone Injuries

The tolerance of a skull to fracture depends mainly on the dimensions of the impacting structure. The main values published by the literature are shown as:

Impacted Area	Small		Large	
Frontal	5	(69)	7	(70)
Temporal	1,8	(71)	8,3	(72)
Partietal	3,4	(69)	8,5	(70)
Occipital	?		9,6	(72)

The tolerance of the facial bones is lower than the tolerance of the skull.

The main results found in the literature are summarized:

	Tolerance Force	
Zygoma	800 to 1800	(73)
Maxilla	650 to 1000	(72,73)
Mandible	800 to 3000*	(73)
Nose	1300	(74)

* Depending on impact direction

These two tables show the potential effect of helmets in avoiding small impacts that correspond to the lowest skull tolerance and in protecting facial bones from direct impact.

Tolerance of the Brain (Brain Concussion)

Brain tolerance is not well established, and brain injuries have no evident correlation with skull fractures. Tolerance of the head as a function of pulse duration has been established by Lissner(75) and is called Wayne State Curve. The corresponding parameter to this curve is the GSI (Gadd Severity Index), which is defined by:

$$GSI = \int_{o}^{t} a^{2,5} .dt$$

in which a is head acceleration in g's and the value of 1,000 is considered the tolerable limit.

A more recent index called HIC has been developed and is used for car occupant frontal impacts. The HIC is defined by:

$$HIC = \left[\frac{1}{t2 - t1} \int_{t1}^{t2} a(t).dt \right]^{2.5} \cdot (t2 - t1) \Bigg|_{max}$$

The proposed limit of tolerance for HIC is 1,000 or 1,500, but recent studies have shown this criterion is not very pertinent to predict head injuries. Some other criteria have been proposed, but none were widely accepted. However, in the absence of a pertinent criterion, the HIC can be accepted in dummy tests.

Two-wheeler accidents can correspond to large body motion, and the wearing of a safety helmet could increase the amplitude of head motion. For these reasons, the rotational acceleration that has been proposed to be correlated with brain injury would be considered a tolerance parameter.

Theoretical analysis using the mechanics of similitude seems to indicate children have a higher brain tolerance than adults(76), either if we consider translational or rotational acceleration; this is confirmed by the higher breaking strength of arterial tissues of children found by Yamada(77).

Thoracic Tolerance

Recent studies on thoracic tolerance indicate the tolerance to rib fractures is more correlated to thoracic deflection than to thoracic acceleration either in frontal or in lateral impact(78,79). However, the tolerance is not the same for frontal and lateral loadings. The proposed value of tolerance is 30 to 35 percent of the half thorax width in lateral impact.

Comparison of rib characteristics between children and adults seems to indicate children can sustain higher thoracic deflection without rib fracture, but in this case internal thoracic injuries can occur. In a general way, increasing the number of rib fractures enlarges the risk of thoracic internal organ injuries.

Abdominal Tolerance

The tolerance of the abdomen has been studied with cadaver free falls hitting an armrest model laterally(80). This study proposes a limit of 28 percent of abdomen width corresponding to 4.5N impact force as a human tolerance. These tolerance data mainly concern liver injuries.

Pelvis Tolerance

The tolerance of the pelvic bones has been studied for car occupants either in frontal or in lateral impacts. In frontal impacts the pelvis is loaded through the femur, when knees are impacted. This mechanism can be found as well in car occupants as in some two-wheeler accidents. The proposed tolerance in this case is close to 10kN(81).

In side impacts the pelvis can be loaded either through the hip or directly on the iliac wing. These mechanisms can occur in some two-wheeler accidents, as for example when a two-wheeler is hit laterally by the front of another vehicle. The proposed tolerance in this case is 10 to 12kN impact force(82).

Lower Limb Tolerance to Fracture

Several studies dealing with leg tolerance have been made either for car occupants or for pedestrians. The tolerance of the femur in a bending fracture depends on the point of impact, the lower tolerance corresponding to the mid-shaft impact. In this case, the tolerance seems to be close to 10kN.

Tibia tolerance to horizontal loading seems to be between 3,000N and 9,800N depending on the impacted area, with an average value of 5,000N(83).

However, a recent study conducted in Sweden dealing with pedestrian safety(84) has found a much lower value of lower limb tolerance. The value of the momentum corresponding to the fracture is about 200Nm(85). However, these values are related to a small surface impact, and the tolerance in a bumper-like impact is probably higher. In general, the child seems to have a tolerable bone strength higher than an adult(76).

6.Injury Prevention Measures for Bicyclists and Riders of Light-powered Two-wheelers

This section will deal with—

- Proposals for injury prevention of two-wheeler riders
- Consequences of these proposals for other groups of road users
- Consequences of (proposed) legal requirements for injury reduction of other groups of road users to the injuries of bicyclists and light-powered two-wheeler riders. The philosophy of the integral approach of the safety vehicle will take a central place; at the same time, it will be quite obvious that the amount of concrete proposals is limited due to just starting research activities in this area.

This section will deal also with the proposals as a function of the different relevant collision types. The proposals made are based mainly on information from literature.

Proposals for Injury Prevention of Two-wheeler Riders

Contact with a car is the leading cause of injury. Therefore, efforts concerning injury prevention should be directed to these contacts.

The proposals can be distinguished concerning—

- The car
- The HGV
- The two-wheeler
- The two-wheeler rider

In general, the aim of these proposals is to influence kinematics and minimize the loads to the struck body parts.

Car-to-Two-wheeler Collision

Car—The collision types F1, F2, and F3 (Figure 18) for bicyclist collisions and F1 and F2 for moped rider collisions seem to be the most important; in these collisions, the front of the car is hit.

Changing the stiffness of some parts of the car will probably have the same positive effect on the injury minimization for two-wheeler riders and pedestrians. The optimum values for the stiffness from a viewpoint of biomechanical tolerance cannot be measured at this moment. The parts of the car to be considered depend on the collision types but vary from bumper to the upper side of the windshield frame.

For shape, the same variables as for pedestrian impacts seem to be important, but no concrete proposals can be made at this moment; it seems obvious sharp protrusions and popping-up headlamps would probably have a negative effect.

Two-wheeler—For F1, side protection devices for motorcycles are proposed by Bourret(88), Rau(91), and Taneda(94) (Figures 26 and 27). According to Bourret, the leg injury severity in an F1 type of collision is strongly related to the mass of the two-wheeler. Whether these side protection devices are realistic for mopeds (or even bicycles) cannot be answered at this moment.

For F2, the question of whether the two-wheeler has to be ejected over the colliding object (if possible) or has to

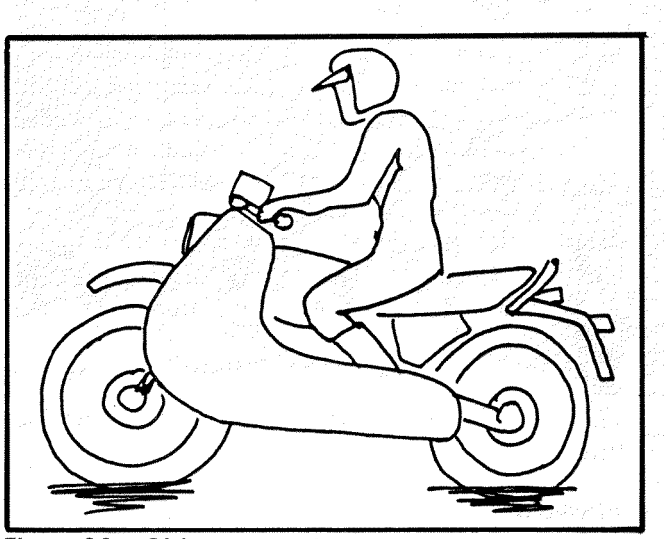

Figure 26. Side protection device proposed by Bourret(88)

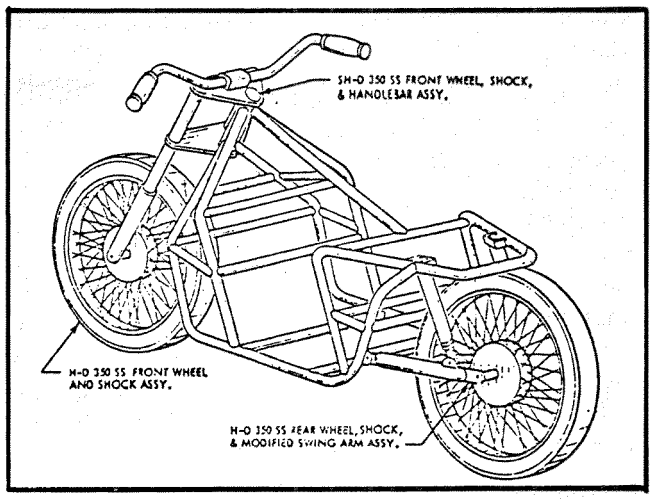

Figure 27. Side protection device proposed by Rau(91)

to be tightened to his two-wheeler also cannot be answered at this moment. Knee paddings were first proposed by Langwieder(97) (Figure 28). The aim is to avoid contact with the colliding object. Whether this can

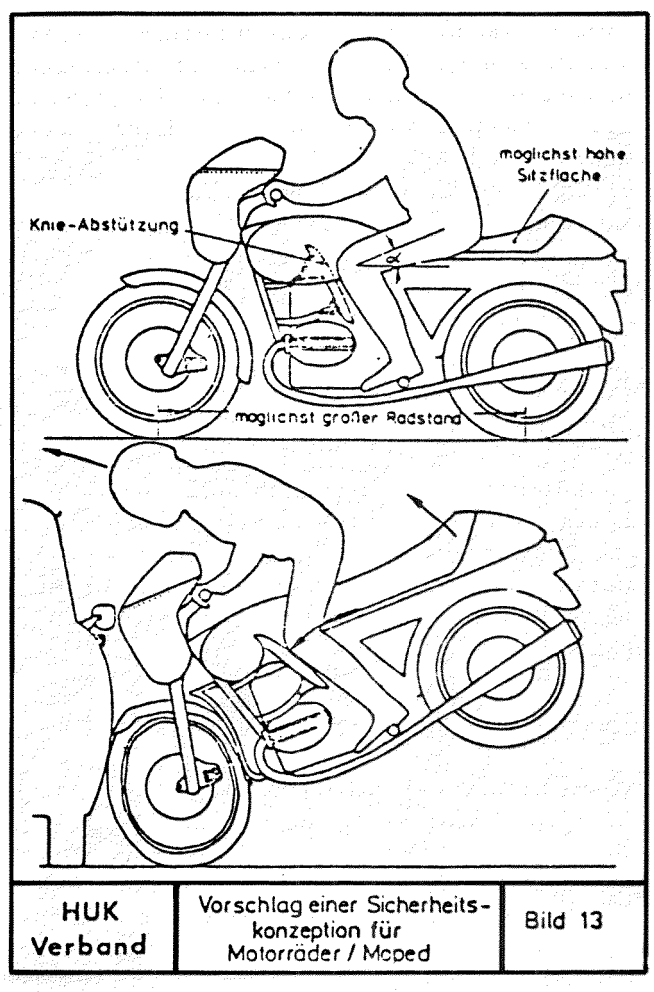

Figure 28. "Knee-padding" ejection device proposed by Langwieder(97)

be effective in a frontal impact (F2) is doubtful. If a rider is launched headfirst and contacts the motor vehicle, this will probably lead to brain stem injuries. The helmet cannot protect against this kind of injury. Filler caps or expander pins on handlebars cause minor injuries. Therefore, sunken caps are applied on motorcycles and sunken pins on bicycles.

HGV-to-Two-wheeler

It is later indicated that collision types F1, F2, S1, S2, and R1 are most important.

HGV—For F1 and F2, the same remarks as for the passenger car about stiffness and shape apply. For S1, S2, and R1, side and rear-end underrun guards seem to be the most concrete proposals at this moment (Volvo(96); Riley(92); Gauss(98); Figures 29,30, and 31). The use of better or additional side mirrors will be beneficial to give the truck driver a better overview.

Two-wheeler—For F1, S1, and R1, the knee padding proposal made by Langwieder(97) does not seem to be as effective due to the dimensions of the HGV.

For F2, whether the suggested side protection will be effective is an open question because the first impact point will probably take place at a higher level than for collisions with passenger cars.

For S2, no protection proposals are known.

Two-wheeler Injuries

Adequately designed child seats and/or a simple dress-guard can prevent bicycle spoke injuries.

Two-wheeler Riders

Helmets and protective clothing can prevent injuries. The positive effect of crash helmets in motorcycle accidents is well documented. The effect of moped helmets is not as well known. In a Dutch study made by SWOV, it is described as "a decrease in the chance of getting fatally injured of 40 percent and a saving of 500-600 lives for the years 1975 until 1977" (SWOV(93)). The proportional share of head injuries differs considerably for the bicyclists (not helmeted) and the helmet-wearing moped riders for the different studies:

		Bicyclists	Moped Riders
Grattan	(99)	48%	26%*
Huijbers	(100)	51%	36%
Nicholl	(101)	75%	52%*
Otte	(102)	85%	60%*

* Including motorcycle riders

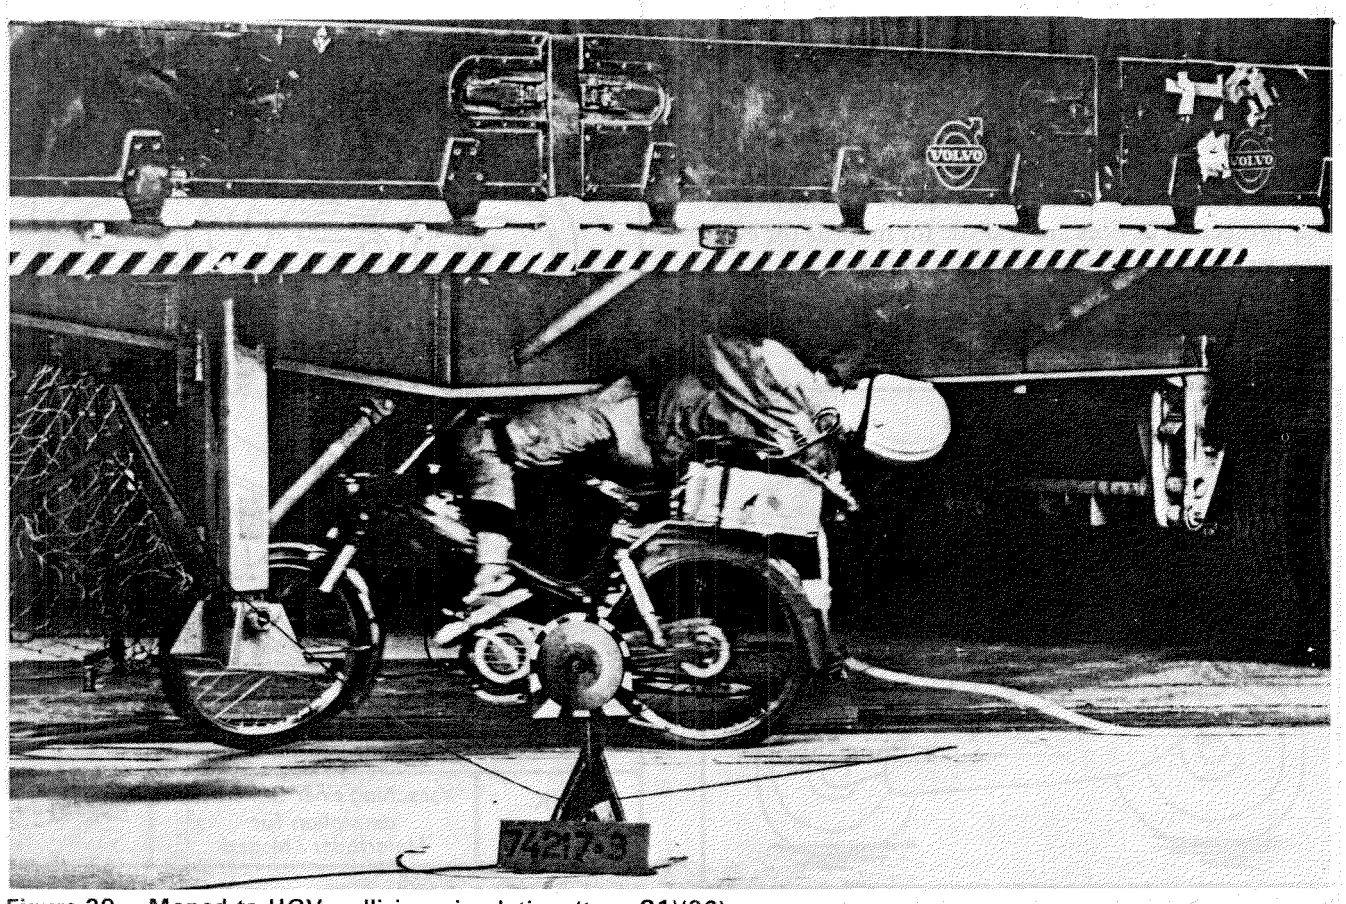

Figure 29. Moped-to-HGV collision simulation (type S1)(96)

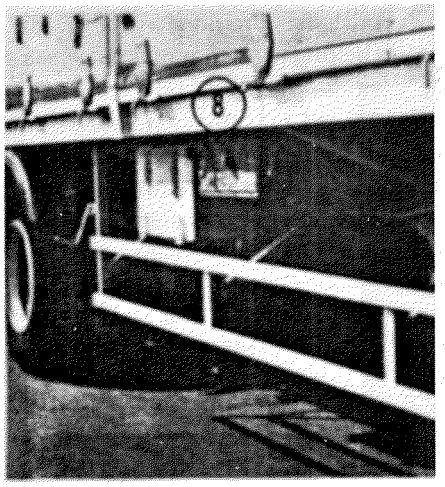

Figure 30. Side protection device for HGV(96)

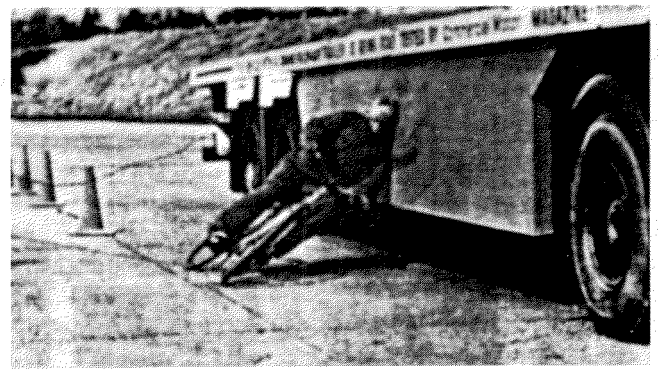

Figure 31. Side protection device for HGV(87)

Wearing helmets seems to be an obvious explanation for these differences, but differences in accident and collision types for bicycles and mopeds may also contribute. Adequate protection against head injuries may be achieved by the use of helmets. For bicyclists, this kind of protection is still not very widely accepted because, to some extent, existing bicycle helmets tend to become uncomfortable due to inadequate ventilation. For moped or motorcycle helmets, there is, among others, a European set of requirements (ECE Regulation 22); some countries already have requirements for bicycle rider helmets(98,99).

According to the studies of Otte(102), Appel(104), Pedder(105), and Ramet(106), some of the crash helmets came off during accidents. The wearing of protective clothing by motorcyclists has some positive effect on the minimization of injury severity, according to Hurt(90) and Aldman(86). The question is whether this is a practical solution for riders of light two-wheelers.

Speed at Impact

Speed at impact will probably be strongly related to injury severity, especially for the impacts with the fronts of motor vehicles. Lowering the speeds at impact in any way will therefore be favorable.

Consequences of These Proposals for Other Groups of Road Users

Car

As far as stiffness is concerned, the consequences may be a small reduction of the decelerations for car-to-car collisions. Because there are no concrete proposals for shape at the moment, there are no consequences either, but contradictions may occur.

HGV

If dimensions of the side and rear-end underrun guard are properly chosen, a positive effect for other accident types may be expected. Rear view mirrors mounted on the sides of vans and small trucks may extend beyond the sides of the vehicles and pose a hazard to other road users, e.g., two-wheeler riders(103).

Two-wheeler

The proposed knee paddings may have a negative effect. If the attempt is not successful, the two-wheeler rider might fly into the interior of the car and hit the driver or a passenger, just as in other cases without knee padding.

Two-wheeler Rider

Contact between a helmeted two-wheeler rider and a nonhelmeted victim may be a hazard for the one unprotected.

Consequences of Proposed Legal Requirements for Injury Reduction of Other Groups of Road Users to the Injuries of Bicyclists and Riders of Light-powered Two-wheelers

As far as bumper height is concerned, there is some doubt whether the required value is beneficial for pedestrians (e.g., ECE Regulation 42). Considering two-wheeler accidents, the effects are even less predictable as yet. The other requirements, e.g., for front-front or front-side impacts, do not seem to have as much effect on the

injuries of two-wheeler riders due to the differences in the amount of energy to be dissipated.

7. Test Procedures

The test procedures examined here are aimed at insuring conformity of the vehicle (bicycle, moped, car, and truck) and/or safety device (helmet, underride protection, etc.) to bicycle and moped rider protection requirements. As stated previously, accident case history for bicycle and moped riders is ample and cannot be reduced to a single standard situation. Doubts also exist about the possibility of considering the bicycle and moped together for studying any countermeasures. It seems, in fact, the two vehicles give rise to two different types of accidents.

Because of this complexity, proposals on test procedures for bicycle and moped rider safety are practically nonexistent or incomplete. To conclude, it is evident that, as far as test procedures for the protection of bicycle and moped riders are concerned, there are no exhaustive proposals. It is therefore necessary to draw from the experience acquired in other areas of safety and to extrapolate the methods that must obviously be verified experimentally to make sure they are feasible and meet the objectives.

Discussion on Possible Test Methods

The test methods that can be adopted are—

- Component tests
- Full-scale tests
- Subsystem tests
- Validation tests by mathematical models

Each of these methods has advantages and disadvantages, and, depending on the situation, it may be more convenient to adopt one method rather than another, or even to use them together. However, it is important to point out that the degree of knowledge of the phenomenon and the devices available determine the test method to be developed. For example, it is impossible to develop a test method based on a full-scale test if the accident mode is unknown (impossibility of obtaining the test conditions scientifically) or if a reliable dummy is not available (impossibility of having a reliable conformity response).

Component Tests

Component tests are tests performed on a single component or on a single safety device. Requirements are either design (geometrical and/or stiffness) or, in the more sophisticated cases, biomechanical. Included in this category are some of the first regulations developed for vehicle safety; it is, in general, a primitive approach whereby the result on a single component is often taken to represent overall safety provided by the vehicle. When component tests belong to a series of tests whose scope is to cover the various aspects of safety, there is a shift toward methods based on subsystem tests. Component tests are still valid today in those cases where it is demonstrated the objective is attained with a specific solution (e.g., if the objective is protection of the cyclist's head wherever it will strike, the helmet solution can be accepted and this component can be submitted to various tests).

By applying the above to the specific case of the bicycle and moped rider, it is possible that a method based on component tests has the following advantages and drawbacks:

- It is relatively easy to define, in the sense that a single aspect of the phenomenon can be examined (e.g., impact of the head) and requirements can be provided even with very little knowledge of the overall phenomenon.
- Method efficiency is low, and the method itself can prove to be inadequate because influence of the vehicle shape on the bicycle and moped rider is not taken into account. In this case, design requirements would prove particularly detrimental because they would be applied to all vehicles (even where not needed) and limit design. The result would be a poor quality product and a high cost for the user, but upgrading of safety would not be insured (e.g., when a bonnet is specified).
- This method can be applied correctly only to tests on particular safety devices developed for a specific purpose, such as helmets.

Full-scale Tests

A full-scale test reproduces the conditions of a typical road accident. This method poses many problems, the most important point being, however, the definition of test conditions. In fact, it is necessary that the full-scale test be equivalent to the actual accident. In the case of the bicycle and moped rider, more than one test condition must be defined, and this poses a few serious economic problems when a new model is developed and approved.

The situation with regard to the test equipment to be set up is more complicated. In particular, no reliable dummies, representative of cyclists, are available today, and it may be that the physical parameters traditionally recorded on dummies are inadequate for this type of accident. Moreover, for full-scale tests aimed at evaluating the effectiveness of a modification to the bicycle or moped, there would also be the problem of designing one or more standard impactors. As for this method, it is possible to conclude that its adoption for rider protection is more difficult than for other types of accidents. Because of the need to conduct more than one full-scale

test and the lack of reliable dummies, other methods should be adopted.

Subsystem Tests

Subsystem tests are those series of tests on different components whose results permit an assessment of the overall degree of protection provided to the rider in a specific accident. The difficulty of developing subsystem tests as defined is due to the need to know the phenomenon perfectly and the required capability to shear it into many single tests, taking into account the interaction between the impacts of the various components and body segments. (For example, for a given impact speed, the shape of a vehicle can determine particular data on speed, area, and direction of impact of the cyclist's pelvis against the bonnet; the type of impact of the pelvis and vehicle shape affect the head speed, area, and direction of impact; etc.)

Validation Tests by Mathematical Models

Development of a test method based on mathematical models will not be feasible for many years because the use of mathematical models in two-wheeler safety research is relatively recent.

It should also be noted the use of mathematical models for type approval on different computers and at different test centers poses the problem of issuing such procedure standards as to insure response identity. This is a field of activity for which the existing technical services are probably not yet prepared, but it enables a simulated vehicle to be assessed before it is actually produced.

Summary

None of the methods examined is capable today of verifying the degree of protection that can be provided to a struck cycle or moped rider. There are no proper, validated mathematical models of cyclists colliding with cars or HVG's at this moment and, above all, problems for transforming a model in a type approval instrument would arise. The full-scale test approach is likewise not feasible. There is no single equivalent test. Several full-scale tests would have to be carried out, and the test device (dummy) is not reliable. Component tests neglect the effect of vehicle shape on the kinematics of the cycle and moped rider.

Knowledge of rider collision is insufficient to permit the development of a method based on subsystem tests. The only feasible approach, in which it is desirable to carry out research, studies, and design of adequate devices, is the development of a mathematical model based on the use of a bicycle and moped rider elementary mathematical model to determine the impact conditions of each body segment and on tests of the corresponding elements. The elementary model is not used to evaluate impact severity but only to determine the initial conditions for testing the parts struck by the pelvis, chest, and head. Moreover, this model defines the angle, direction, and impact velocity for each body segment. It is, in practice, a subsystem test method integrated with an elementary mathematical model. An approach of this type can only be feasible when the approach for protection of the pedestrian is also of the same type. In fact, both pedestrians and cyclists are unprotected road users for which similar countermeasures should be developed.

8. Accident Prevention

Accident prevention or primary safety measures can make important contributions to the safety of the cyclist or moped rider. Accident studies suggest that conspicuity is a factor in accidents involving the two-wheeler and another vehicle. The parameters influencing conspicuity are related to the two-wheeler and its rider (active lighting, retroreflective materials, and the rider's clothing), to the other vehicle (optimal headlamps, good view), and to the surroundings (other light sources). In the overtaking situation, the gap left by the driver when overtaking the two-wheeler is critical, and experiments show the percentage of vehicles passing very close can be substantially reduced by spacers and conspicuity aids. Better brakes will reduce injuries by avoiding accidents or reducing speed at impact, especially in rainy conditions. Test results show that, with the correct combination of rim and brake blocks, significant improvements are possible. The state of maintenance of the two-wheeler was found to be an important factor in many accidents, and results of a survey are given. Studies on bicycle stability and maneuverability are also reported that show significant differences between styles of bicycles and mopeds.

Conspicuity

The conspicuity of bicycles and mopeds is an important factor for the prevention of accidents. The conspicuity presupposes an observer for which the different objects must be conspicuous: this observer obviously in many cases is the driver of a car. A number of factors may influence, hamper, or even obstruct the visual observations to be made by those drivers. Conspicuity will be described for daytime and nighttime.

Daytime Conspicuity

Accident Studies—From accident studies described previously, it follows that two-thirds of the injury accidents involving a pedal cyclist occur at junctions,

when in most cases the collision partners were traveling on a different road before collision. In another study, interviews with involved drivers who had not given way when emerging from junctions into the major road indicated a lack of awareness of the presence or movement of the cyclist(114). Cyclists often wear dark clothing; in one survey, only about 10 percent of the cyclists were wearing high-visibility aids. In addition, a two-wheeler rider presents a relatively small area to other road users, the frontal area being only one-third that of an average size car. The rider is also readily obscured by roadside objects, other vehicles, windscreen pillars, etc. The rider is often near the edge of the road and may be overlooked if a driver carelessly directs his attention only at heavier faster vehicles closer to the center of the road.

In cases where the driver fails to give way, the conspicuity of the frontal aspect of the rider is likely to be most important; since most accidents occur during daytime, initial studies at TRRL concentrated on comparisons of frontal conspicuity in daylight. From previous accident analysis, it is not possible to determine the number of cases where the driver failed to give way to the cyclist or moped rider. Where the rider is at fault, the importance of conspicuity may be less, although in instances where he is highly visible, the driver may see the rider sooner and appreciate his speed and direction more accurately, thus allowing more effective avoidance action to be taken.

Tests and Surveys—In a TRRL study, it was decided to use a peripheral detection technique similar to that used by Horberg and Rumar(115) to evaluate high-visibility aids for cyclists because the experimental conditions resembled a cycle accident situation common at junctions.

The test conditions are shown in Figure 32. Under constraint of an operational task (subjects were required to fixate a visual display and repeat random numbers that appeared), the driver had to signal when he first became aware of the cyclist. The detection distances were used as a measure of conspicuity. Initial tests(116) indicated that bicycle attachments were not as effective as clothing items in making the cyclists detectable and that the brightest materials (highest luminance factor) performed best against commonly encountered backgrounds. Color was found to be a less significant factor than brightness.

Further tests(117) were therefore aimed at establishing the most effective clothing styles (see Table 29), all made from one type of bright material. This was a fluorescent greenish-yellow woven nylon material with a luminance factor of 74 percent. The average detection distances for each each option are given in Table 29. Testing between

Table 29. Average detection distance of clothing options

Option	Detection Distance (m)
Jacket	63.2
Waistcoat	55.8
Hat	53.9
Armbands	49.8
Black Jacket (control)	49.6
Shoulder and Waist Belt	47.1

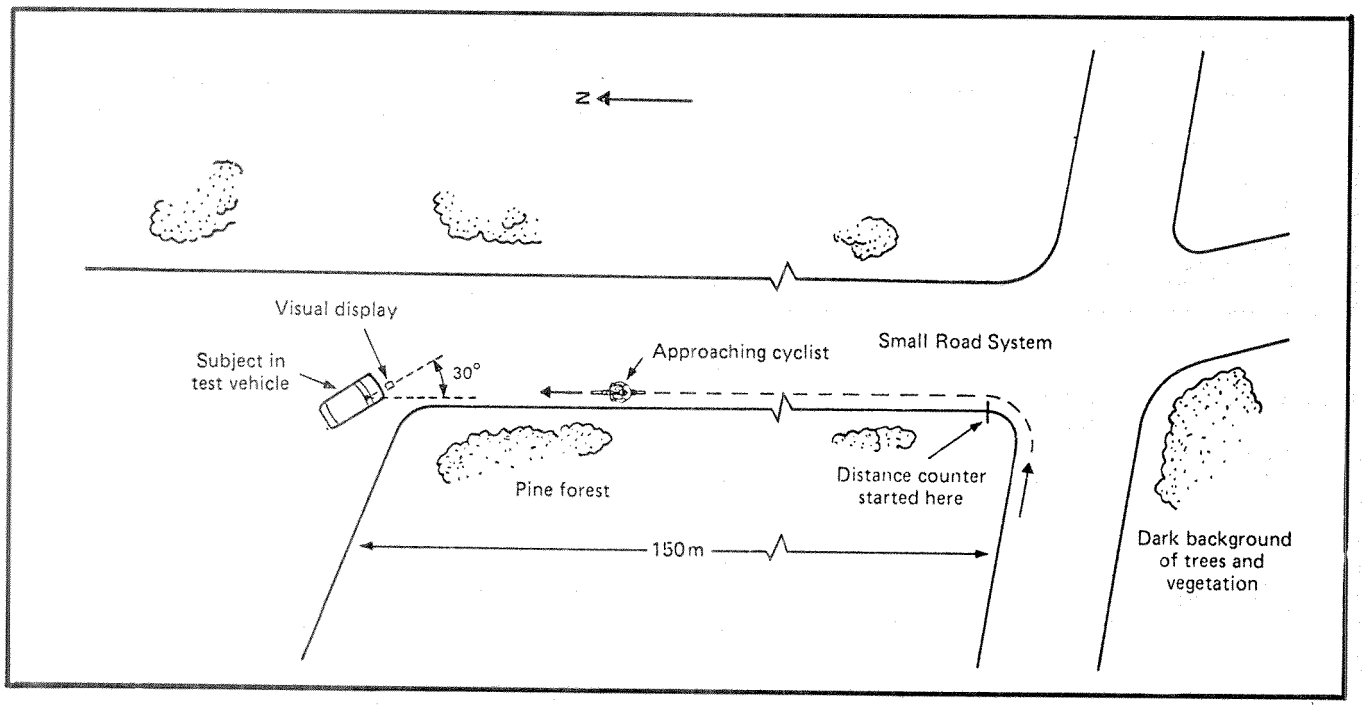

Figure 32. Test conditions for conspicuity aids

means it was shown that the jacket was most effective having a significantly longer average detection distance than the other items.

The effectiveness of conspicuity aids in the overtaking situation where the visibility of the back is likely to be important was assessed by measuring the gaps left by overtaking vehicles. It was considered that an effective aid would be one that significantly reduced the number of close passing vehicles, i.e., those passing within 0.8m of the cyclist's elbow on the off side. An ultrasonic device attached to a front carrier of a bicycle was used that, when actuated by the test cyclist, automatically recorded the closest passing distance between the bicycle and near side of the overtaking vehicle. It measured the gap to within a few centimeters and automatically recorded the distance in one of eight passing distance bands. The clothing items described above were tested in turn in daylight on four straight sections of road. The average results are given in Table 30. It can be seen the jacket had the greatest effect. The number of close passing vehicles was more than halved, compared with the control. The effect of brightness of fabric was established by making a number of jackets of similar color (greenish-yellow) but of widely different luminance factors. Results are given in Table 31. Tests were also carried out on white, yellow, and orange color jackets of similar brightnesses, and, as expected, their effects on passing vehicles were not significantly different.

In addition to providing effective conspicuity aids for the rider, there are other measures that may prove effective.

Table 30. Passing distances for clothing options of different styles

Option	Median (m)	Percentage Less Than 0.8m	Number of Readings
Jacket	1.20	8.4	547
Waistcoat	1.16	10.1	544
Hat	1.14	11.0	520
Armbands	1.13	14.1	475
Shoulder and Waist Belt	1.09	16.4	482
Black Jacket (control)	1.03	21.1	526

Table 31. Passing distances for jackets of different luminance factors

Option	Color Specification*			Median	Percentage Less Than 0.8m	Number of Readings
	x	y	Y			
Thin nylon	0.39	0.44	0.49	1.10	15.2	841
Thick nylon	0.36	0.51	0.74	1.13	12.4	833
Reinforced PVC	0.38	0.52	0.95	1.15	12.1	840
PVC	0.38	0.53	1.37	1.17	9.4	879
Black jacket	*(not measured but expected reflectance close to zero)			1.05	23.5	927

A number of factors may influence the visual observation made by drivers. The visual scene could be structured so there is less demand on a driver's limited attention span; thus, irrelevant objects that could distract or hamper the observation of the cyclist could be removed or repositioned. Glare from the sun can be annoying and dangerous, and signaling lights should have adequate luminous intensities to insure a conspicuous signal under most of these conditions.

Discussion and Conclusions—There was good agreement between the results from daytime detection and public road experiments indicating that a jacket was more effective than all other aids tested. A waistcoat-styled aid was the second most effective in both studies. When viewing from the rear, it is likely the arms of the jacket contribute only a small amount to the overall conspicuity because the backs of the arms were poorly illuminated. From the front, however, the tops of the arms were visible and relatively well illuminated, receiving direct light from the sky; therefore, they contributed significantly to the visibility of the cyclist. In this study and in a previous pilot experiment(116), a jacket was shown to be more effective than a waistcoat when viewed from the front. Drivers' increased awareness of the presence of the rider and earlier detection when approaching are possible for the larger gaps left by overtaking vehicles.

The relatively small and statistically nonsignificant effects of the armbands and belt are probably due to their small total area. For its size, the hat performed well, and this is probably due to its relatively high illumination—receiving direct light from the sky. Its domed shape resulted in high luminance or brightness levels when viewed from most directions. The jacket is preferable to other aids for the additional reasons that arm signals are more conspicuous and the sides of the rider are likely to be more visible. Road tests with jackets of various reflectances and colors indicate the importance of brightness rather than color in determining the conspicuity of clothing. However, there are likely to be a number of situations where color contrast may aid detection because luminance contrast is low; for example, where the rider is viewed against a bright desaturated background such as a concrete facade or cloudy sky. To offer maximum visibility, a conspicuous garment should be made from material having both a high luminance factor and highly saturated color. Finally, a conspicuous garment must attractively styled and comfortable to wear, as well as retailing at a reasonable price, if its use is to be encouraged.

Nighttime Conspicuity

Accident Studies—A comparison of accidents in Belgium, Denmark, Spain, Germany, and Ireland(111) showed that the percentage of casualties occurring in darkness

ranged from 18 to 33 percent for bicycles, and from 26 to 38 percent for mopeds. In The Netherlands, recent data(118) shows that 21 percent of severe injuries to cyclists involved in collisions with other vehicles and 24 percent of severe injuries to moped riders occur at dusk or at night.

It was found that accidents after dark were more serious, and the cyclists concerned were usually older and more frequently struck from behind. In Great Britain, a total of 4,549 (18 percent) pedal cyclists were reported as killed or injured on the roads during the hours of darkness in 1980(119). A study in The Netherlands(120) has shown that the risk of a fatal collision between a cyclist and a traveling motor vehicle is nearly four times greater under dark conditions. It is not known to what extent the poor conspicuity of the pedal cycle or cyclist is a factor in nighttime accidents, but, obviously, cyclists riding without adequate lights are likely to incur considerable additional accident risk.

Tests and Surveys—Cyclists in Great Britain, as in most other countries, are legally required to show a white light to the front and a red light to the rear when riding after dark. Observations were made in four towns in England to determine the extent to which cyclists comply with these lighting regulations(121). Details relating to over 2,500 bicycles were collected in a 2-week period during December 1980. Observations were made after dark, and it was shown overall that approximately 25 percent did not have complete lighting and 9 percent had no visible lights at all. Where lamps were fitted, 9 percent were off and nearly one-quarter were either dim or gave an unsteady output. Three-quarters of the lamps observed were battery-powered. It therefore appears that many cyclists at night will be inconspicuous and therefore at increased risk. Interviews with over 600 cyclists revealed some reasons for this. Many only replaced batteries when they were exhausted, and important reasons given for the poor performance of lamps were damage and poor connections.

The observations showed that dim lamps were common, and, in order to establish the importance of bicycle reflectors for safety, tests were carried out on the TRRL test track after dark to compare the detectability of two reflectors (25 and 75mm diameter) and a common type of battery lamp modified to give two levels of light output(121). These levels were low and corresponded to dim lamps where the batteries were close to being exhausted. The test track layout is given in Figure 33.

The average detection distance for the reflectors and two levels of light output against the glare source are given in Table 32, for observers closing in on the bicycle

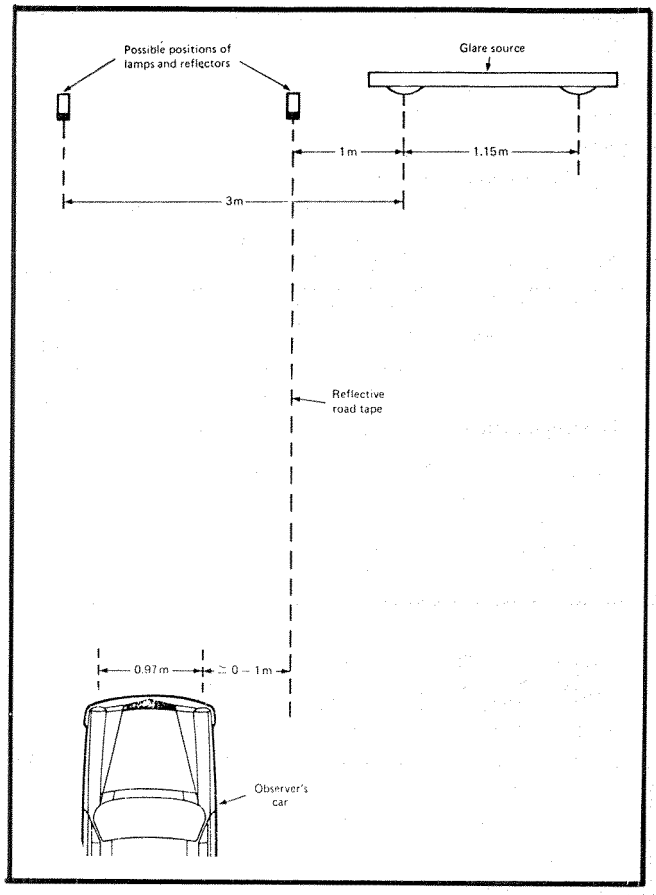

Figure 33. Layout for visibility studies

Table 32. Mean detection distances of rear lamps and reflectors

Distance of Glare Source from Bicycle	Rear Lamp Luminous Intensity (cd)		Reflectors Coefficient of Luminous Intensity (med/lx)*		No Reflectors or Lamps (Control)
(m)	0.65	0.15	1450	101	
1	358	241	247	153	41
3	635	507	399	214	64

* Coefficients of luminous intensity were measured at 0° 12' observation angle and 0° entrance angle. The observation angle is the angle between the straight lines connecting the reflector to the source of illumination and to the observer's eye. The entrance angle is the angle between the line perpendicular to the plane of the reflector face and the straight line connecting the reflector to the source of illumination.

at 35km/h. Not only is early detection of the rider by the approaching driver important but also recognition at an early stage. Early recognition of the rider can be important since for safety the driver needs to know the likely behavior of the road user he is about to overtake. In further tests, the distances at which observers were certain that a cyclist was present were used as a measure of effectiveness. Since the motion of the cyclist on the cycle was thought to provide important cues to recognition, a test cyclist rode the bicycle on rollers. The options were a commercially available flashing amber lamp designed to be attached to the cyclist's clothing, a reflective jacket, a reflective shoulder and waistbelt, a reflective spacer, and a set of pedal reflectors. Each of the options was tested in turn in conjunction with the control, i.e., rear light and mudguard reflector. The average detection and recognition distances based on results from six subjects are given in Table 33.

Table 33. Mean detection and recognition distances for conspicuity aids (glare source 3m from bicycle)

	Rear Lamp (11.1cd) and Reflector (100mcd/lx*)	Flashing Amber Beacon	Reflective Jacket (10,000mcd/lx)	Shoulder and Waist Belt (1000mcd/lx)	Spacer (500mcd/lx)	Pedal Reflectors (100mcd/lx Each)
Detection Distance	651+	588	284	185	292	182
Recognition Distance	54	59	102	68	60	124

* Coefficients of luminous intensity were measured at 0° 12′ observation angle and 0° entrance angle

\+ Maximum detection distance was limited to just over 650m corresponding to the length of the range

A survey in The Netherlands(122) has shown that 4 percent of front lamps and 4 percent of rear lamps were missing. It was also shown that 7 percent of the front lamps were defective in some way. The legally required large rear reflector was present in 93 percent of the cases.

Some indication of the effectiveness of this large rear reflector and pedal reflectors in reducing accidents can be judged from another Dutch report(123), which details the change in accident rate to cyclists following their legal requirement in November 1979. This preliminary report using only one year's after data records a drop in casualties. As accident data accumulates, it may be possible to precisely quantify their contribution to the reduction in accident risk.

The Institute of Road Safety Research SWOV(118) has carried out an analysis of accidents and concluded that a small reduction in casualties will result from the mandatory use in The Netherlands of spoke reflectors or reflective tires.

In the United States, Burg and Hulbert conducted a series of tests on bicycle spoke reflectors and reflective tires(124). Using dipped headlamps, it was found that spoke reflectors were detected at a greater distance than reflective tires when viewing the side of the bicycle. The average detection distance for the most effective spoke reflector was 354m, while for the most effective reflective tire it was 297m. However, in static viewing tests, the reflecting tires were easier to recognize. In dynamic trials where observers had to determine the direction correctly, the reflective tires were more effective at indicating direction of travel.

In West Germany, viewing trials were held to assess the contribution to conspicuity of various types of reflector(125). Spoke reflectors were judged to be superior to reflective tires.

The International Federation of Senior Police Officers (FIFSP), after a study of safety equipment for bicycles(126), concluded that a large rear reflector would be beneficial and that dynamo lighting systems should be provided that would automatically switch to battery power when the bicycle is stationary. They also attached special importance to flank protection of the bicycle rider and recommended the use of retroreflective tires(126,127).

In addition to insuring that two-wheeler lighting and reflectionization is adequate, there are other vehicle factors important for adequate visibility. The transmission of light through motor vehicle windscreens is of obvious importance since modern cars have windscreens that usually make an angle of 35° to 40° to the horizontal plane. These small angles seem to be unfavorable for the transmission of incident light coming from the traffic scene, especially where dim lamps near the threshold of perception are being viewed. A dirty, scratched, tinted, or highly raked windscreen will limit transmission of light or reduce contrast and could cause a poorly lit cyclist to be missed. Poorly aligned vehicle headlamps are a problem in that they can cause high levels of glare that can interfere with the detection of lights and can cause distraction.

Discussion and conclusions—It has been demonstrated that a reflector having a coefficient of luminous intensity of 1,450mcd/lx (75m dia reflector measured at zero entrance angle and 0° 12′ observation angle) can perform reasonably well when compared with a dim rear lamp.

In fact, under the worst conditions of glare (bicycle positioned 1m from glare source), the detection distance

of the large reflector was similar to that of the dimmest lamp. Without a reflector or rear light of any description, visibility distances are dangerously low (41 to 64m) when it is considered that, at a speed of 110km/h, a driver may need a distance of up to 200m to stop after an unexpected object becomes visible. The light output from a dim front or rear lamp when viewed from the side can be very low indeed, and side reflectors in this case can substantially improve conspicuity. The obvious disadvantage of a reflector is that its visibility depends on the illumination it receives from the driver's headlamps. If the headlamps are dim or misaligned or the two-wheeler is not directly ahead of the vehicle, then the reflectors may prove ineffective. In addition, the performance of most reflectors decreases with increasing entrance angle, although wide angle reflectors are available, and these significantly decrease the reduction in reflected light at large entrance angles.

In Great Britain and to a lesser extent in The Netherlands, it has been shown many bicycles are not equipped with adequate lights at night even though they are legally required. The widespread use of a good quality bicycle reflector might make a worthwhile contribution to safety in these and other countries where such problems exist. Should the lights flicker, dim, or go out completely, a bicycle equipped with good reflectors should be visible in a number (but by no means all) of accident situations. It is, of course, desirable that bicycle lighting performance should improve to a point where reflectors are needed only very rarely for the purpose of insuring the bicycle is visible. Bicycle reflectors are useful for aiding in detection and also for improving recognition.

After the rear light of a bicycle has been detected by an approaching driver, early recognition that a cyclist is ahead is probably important on many occasions. Pedal reflectors proved most effective at increasing recognition distance as they more than doubled the distance at which a cycle equipped with a rear lamp and mudguard reflector could be recognized. The reflective jacket was also effective; observers quickly recognized the cyclist by the side-to-side motion and outline of the cyclist. In addition, both these aids should give the driver a useful indication of the distance to the cycle. For example, the amplitude of the pedal motion can be clearly seen soon after the pedal reflectors are detected, and this is likely to be a useful cue in judging distance. Tests show that large errors in judging distance can result when only a single red light is visible, and this could be a possible cause of accidents. Reflective tires have been shown to indicate the presence and direction of travel of a two-wheeler when viewed from the side. Spoke reflectors are more effective at improving detection distance in this situation but are less efficient at improving recognition.

The need for adequate bicycle reflectors has been recognized. In The Netherlands, a high-performance rear reflector and pedal reflectors have been required on bicycles since 1979. The FIFSP has recommended the use of large rear reflectors and retroreflective tires on bicycles.

The British Standards Institution(129) has published a standard that specifies minimum requirements for bicycle reflectorization. This standard is based on the work of the International Organisation for Standardisation and specifies high-grade reflectors at the front, rear, and side of a bicycle as well as for the pedals. The British Government has been considering the possibility of insuring that all bicycles offered for sale meet these and other safety requirements.

Bicycle Spacers

Because of the inherent instability of two-wheeled vehicles, cycle and moped riders need to be given sufficient clearance by the overtaking driver to take account of possible course deviations. Experimental studies of course holding by cycle and moped riders under a range of conditions(130) show that riders need a road width in excess of lm; an additional safety margin is necessary.

A spacer is a device attached to the bicycle to discourage drivers from passing too close to the cyclist when overtaking. Commercially available spacers usually consist of a plastic rod with either a flag or disc attached at the end, the overall length being about 400mm. It is to be mounted horizontally on the rear off side of the bicycle so it projects into the road. They have been widely used in Scandinavia but have only recently gained acceptance in Great Britain.

Accident Statistics

In Great Britain, national accident data for 1980 indicate that about 30 percent of fatal pedal cycle casualties occur in situations where other road users collide with the cyclist while overtaking or strike the rear of the bicycle, both vehicles initially traveling in the same direction and going ahead. French and Danish accident studies show the dominant maneuver type involving cycles and mopeds in rural areas is that of the overtaking situation(111). It has been shown that, when lethality was calculated for bicycle-to-car accidents, the collision front of car-rear end of bicycle or moped appeared to be most severe. Attention should be given to reducing the risks in this particular accident situation.

Evaluation of Spacers

Previous studies in Great Britain, Finland, Sweden, and France(131,132,133,134) of the effects of spacers on the gaps left by overtaking drivers (used as a measure of the accident risk) have shown a range of effects from none

to an increase in average passing distance of 220mm. Differences in road conditions, driver behavior, and measurement technique could account for these differences. At TRRL, the ultrasonic range-finding technique described above was used to measure the effect of spacers of various lengths during daytime and nighttime(135). Because of the ease of measurement and subsequent analysis, it was possible to quantify for the first time the effects of spacers of various types in reducing the percentage of drivers passing very close.

For determining the effects of spacer length, a red reflective disc shape[1] 9,000mm^2 in area was employed. The shaft of the spacer was 8mm in diameter and white in color. The overall lengths of the spacers tested were 0.35, 0.40, 0.45, and 0.50m. These lengths covered the range of those commercially available and produced estimated projections beyond the rider's elbow of 25, 75, 125, and 175mm. The rider's elbow was the part closest to overtaking vehicles. For comparison purposes, the cyclist wore a black jacket of a near zero luminance factor, and this acted as the control when testing without a spacer present. Four sites were chosen for test purposes. Road width varied from 5.1 to 6.3m and speed limits from 48 to 96km/h. Broken centerline markings were present along all sections. Each spacer was tested several times at each site in a balanced order to reduce the effects of time-dependent factors.

Data collected at the four test sites were combined as there were no substantial differences between the results. Table 34 gives the averaged results for daylight and nighttime tests. Statistically significant differences at the 0.1 percent level were found under both lighting conditions.

Table 34. Passing distances for spacers of various lengths

Lighting Condition	Length of Spacer (m)	Projecting Length (from elbow) (m)	Median Gap (m)	Percent Passing Less Than 0.8m	Number of Measurements
Day	Control (no spacer)	—	1.097	14.97	855
Night	Control (no spacer)	—	1.076	16.14	477
Day	0.35	0.025	1.156	11.50	844
Night	0.35	0.025	1.198	8.85	407
Day	0.40	0.075	1.132	9.74	780
Night	0.40	0.075	1.134	11.08	415
Day	0.45	0.125	1.192	9.16	819
Night	0.45	0.125	1.194	7.28	481
Day	0.50	0.175	1.215	7.83	855
Night	0.50	0.175	1.221	6.92	492

Further tests were carried out to compare the effects of the longest spacer (0.5m) and the yellow jacket used in the detection distance studies previously described. Table 35 gives the results.

Table 35. Comparison of longest spacer with a conspicuous jacket (daylight)

Option	Median Gap (m)	Percent Passing Less Than 0.8m	Number of Measurements
Control	1.060	21.77	698
Spacer	1.157	11.37	686
Yellow Jacket	1.162	11.09	712

Discussion and Conclusion

The effects produced by spacers in increasing median overtaking distances and decreasing the percentages of vehicles passing very close are probably due to the increase in the effective width of the bicycle and rider, although some of the effect may be due to increased conspicuity. In most cases, the increase in effective width is not quite matched by a corresponding increase in median passing distance. This could be a result of the knowledge that the consequences of striking the end of the spacer when overtaking are not as severe as hitting the cyclist. The results show, that by using a spacer 0.5m in length, the percentage of overtaking vehicles passing less than 0.8m from the cyclist was approximately half that recorded when no spacer was present. This spacer had a similar effect on overtaking behavior across a wide range of road and traffic conditions. Results obtained during the day were similar to those recorded at night. As the length of the spacer decreased, effectiveness was reduced so that a spacer length of 0.35m was only about half as effective as a spacer 0.50m long. The effects on overtaking drivers of the long spacer were very similar to those of a fluorescent yellow jacket across a range of daytime road conditions. The fluorescent jacket would obviously confer extra benefits on the cyclist by increasing overall

[1] The material has a luminous factor of 0.51 and its color specification in CIE coordinates was x = 0.58, y = 0.36. Its coefficient of luminous intensity under typical viewing conditions (0° 12′ observation angle and zero entrance angle) was approximately 1,200mcd/lx.

conspicuity. However, the cost of a spacer is low and, if of sufficient length, it offers good value.

Field of View of Truck Drivers

From a Dutch study(112), it followed that most of the accidents in which a two-wheeler rider collided with the side of an HGV happened when the HGV turned to the right. From an analysis of the EEC directives on rear view mirrors, it appeared certain areas could not be seen when the vehicle was equipped only with mirrors according to these requirements (Figure 34). Therefore, additional requirements need to be recommended.

Braking

The rim brake has been fitted to bicycles for many years in some countries and is widely used on all types of bicycles. On applying the brake lever, the rubber block is forced against the metal wheel rim. The latter is normally chrome-plated steel and often gives a very low coefficient of friction when wet, which results in poor braking performance(136,137). In dry conditions, the braking force can be high, and the possibility exists of the rider going over the handlebars during emergency braking. Hub (both internal-expanding and back-pedaling) and disc brakes have a generally superior performance in wet weather because the braking surfaces are not as exposed to water. However, they are more expensive, heavier, and can make wheel removal difficult. This is perhaps the reason for many new lightweight bicycles being equipped with rim brakes.

It is difficult to obtain reliable estimates of the number of injury accidents due to inefficient brakes, but bicycle accident reports received by the Consumer Product Safety Commission of the United States (138) show many injuries to children result from the inability of the bicycle to stop quickly in emergency situations. In West Germany, Wobben(137) refers to the complaints of many cyclists concerning the inadequate braking efficiency of rim brakes in the wet. Currently, the British Government is considering setting minimum permitted wet and dry braking efficiencies for new bicycles based on the recent British standard for cycles(129). TRRL has been involved in preparing this standard and has conducted a series of tests on rim brakes.

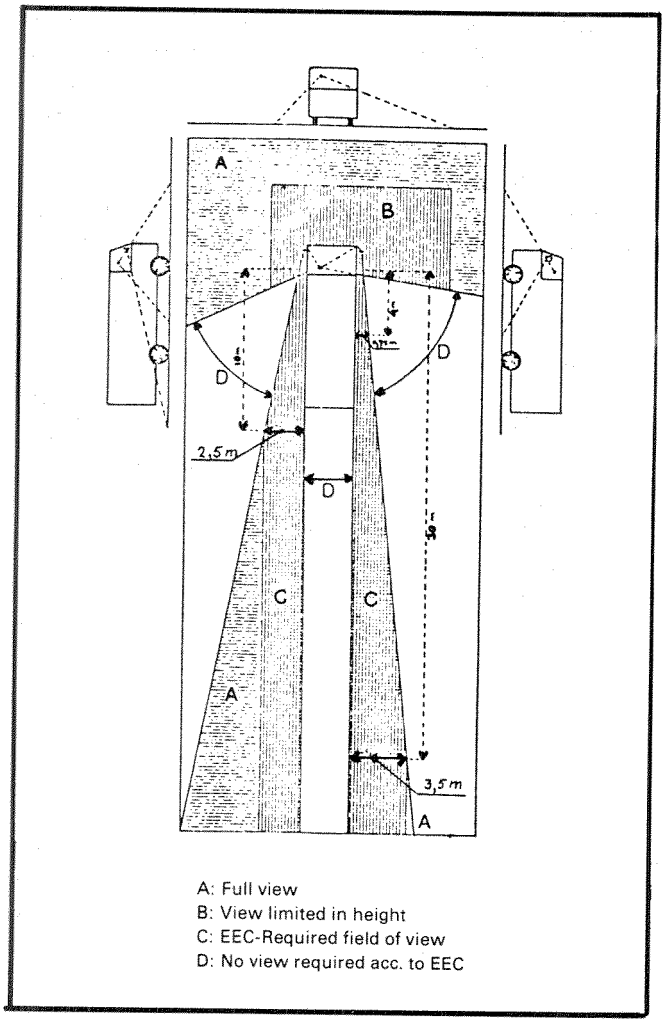

Figure 34. Field of view for HGV's right-hand traffic; right and left external mirrors according to EEC requirements(112)

Braking Studies

In one study at TRRL, the size of the problem was established by allowing children to carry out emergency braking tests under wet conditions(139). In addition, road tests were carried out to determine the performance of a common type of caliper brake, using a number of different brake blocks and wheel rims to determine whether one or more combinations would prove satisfactory in both dry and wet conditions. Recently, manufacturers have produced new types of brake blocks that are claimed to be effective in wet conditions. Nine commercially available brake block sets were tested: three synthetic blocks, five rubber blocks of various hardnesses and patterning, and one leather block. All nine sets of blocks were tested on plain chrome-plated and light alloy rings, and three sets, representing the three types of material, were further tested on dimpled and grooved chrome-plated rims. The test bicycle was a standard touring model with 686mm diameter wheels and fitted with a side pull caliper brake. To reduce variation between tests, one adult rider was used. The bicycle was equipped with a water reservoir and jets to each wheel that applied 4ml/s at each rim, and brake force was controlled by attaching brake lever stops to the ends of the handlebars. These were adjusted so that loads of 180N were effectively applied 25mm from the lever ends when the brake levers were pulled up to the stops.

(Tests have shown that loads of this magnitude are possible to achieve by male adults under emergency braking conditions. However, many children and adult females would not be expected to exert these forces.) The braking distances were measured from a speed of approximately 16km/h for each combination of block and rim. The rims were tested both dry and when continuously wetted. Table 36 gives the average deceleration achieved for each set of brake blocks under dry and wet conditions, together with the expected braking distance from a speed of exactly 16km/h. Figure 35 illustrates the relative effectiveness of the various types of block.

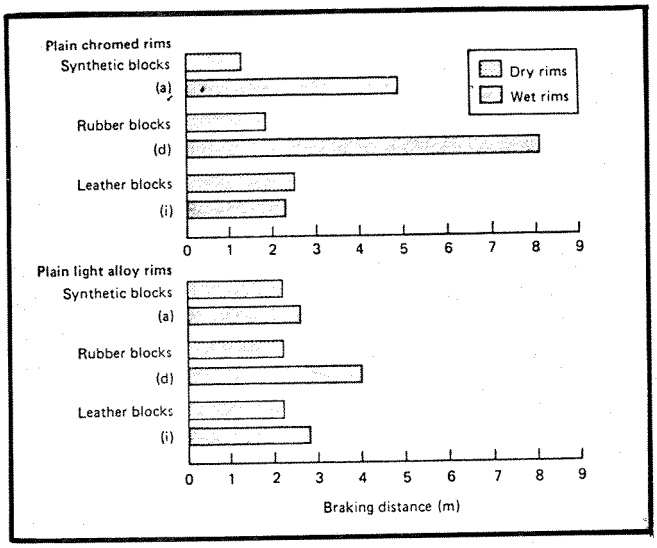

Figure 35. Expected braking distances from a speed of 16km/h

Nineteen children whose ages ranged from 6 to 11 also took part in further tests. In this case, a small bicycle was used (457mm diameter wheels) equipped with chromed rims and rubber blocks. They each made four runs under wet conditions similar to those described above. The average braking performance was 0.08g corresponding to an expected braking distance of 12.6m from a speed of exactly 16km/h. The lowest rate of 0.047g (equivalent to a braking distance of 21.4m from 16km/h) was achieved by the youngest child and the highest rate of 0.113 by the oldest.

Discussion and Conclusion

The result of the tests involving children illustrate well the very poor performance that may result in wet conditions where rubber brake blocks are used on chromed rims. This is in agreement with a previous study(140). The youngest child would have traveled over 20m in braking to a halt from the modest speed of 16km/h. This level of performance may result in an inexperienced rider failing to give way at a road junction and emerging dangerously into the major road. On hill descents, much longer stopping distances may result. Under controlled tests, braking distances were about 4-½ times those measured under dry conditions. Neither hardness nor patterning of the rubber blocks nor the use of dimpled and grooved rims significantly affected stopping distances. By contrast, leather blocks on chromed rims produced a statistically significant improvement, and adequate braking was achieved in the wet. With wet alloy rims, adequate levels of braking performance were achieved with the synthetic blocks. The leather and rubber blocks (e) and (g) (see Table 36) were slightly less effective and the other rubber blocks were less effective still.

In the dry, braking efficiencies with any of the combinations of block and rim were good; however, very high levels of braking were found with synthetic blocks on the plain chromed rims. This is potentially dangerous since the longitudinal stability of the bicycle is poor compared with other road vehicles. Calculations for the rider and bicycle employed showed that the rear wheel would be expected to lift at a deceleration of 0.56g. This is in reasonable accord with the observation that consistent rear wheel lift occurred where average decelerations were significantly greater than this value.

The reduction of accident risk in both wet and dry is likely if the correct combination of brake lock and rim is selected. Even if a collision is unavoidable, the relative velocity at impact may be reduced with better brakes. This can lead to less severe injury.

Leather blocks are now available in Great Britain, and one major manufacturer fits them to all its bicycles equipped with chromed rims. British Standard BS 6102 part 1 specifies a maximum wet braking distance of 7.5m from 16km/h, which would exclude the fitment of the worst combinations of brake block and rim. (This is a significant improvement on the ISO standard (ISO 4210) on which it is based, which specifies a braking distance twice as long (15m).) As mentioned above, the British Government is considering making the standard mandatory for all bicycles sold.

Defects and Maintenance

The two-wheeler rider will have less chance of avoiding an accident if his machine is not maintained in good condition. Defects in brakes, transmission, and tires, for example, may delay or otherwise reduce the effectiveness of accident avoidance maneuvers. Obviously, direct failure of frame or parts can be the prime cause of accidents; for example, failure of pedal crank or forks can easily lead to loss of control. Lighting that flickers, dims, or goes out completely can lead to virtual invisibility in poorly lit areas.

Table 36. Mean decelerations and expected braking distances from 16km/h

			Plain Chrome		Light Alloy		Dimpled Chrome		Grooved Chrome	
Block	Type	Condition	Deceleration (g)	Braking Distance (m)	Deceleration	Braking Distance	Deceleration	Braking Distance	Deceleration	Braking Distance

Accident Studies

TRRL carried out on-the-spot investigation of 183 accidents involving two-wheelers from 1970 to 1972(141). They considered that 14.5 percent of the bicycles and 4.7 percent of the motorcycles involved had defects that contributed to the accident. A Finnish study on 74 bicycle fatalities(142) indicated that defects were a contributory factor in 4 percent of the cases.

Maintenance Survey

To get an estimate of the size and nature of the problem, a survey was carried out by TRRL into the state of maintenance of bicycles ridden to primary and middle schools(143). It was found that, of the 439 bicycles examined, over one-third (151) were categorized as in a dangerous condition and only 36 percent were regarded by the examiners as being in good condition. A fault was categorized as dangerous if it was possible for it to be a contributory factor in an accident. The component showing the largest number of dangerous faults was the rear brake. Twelve percent were in a dangerous condition, and 9 percent of front brakes were similarly categorized.

No firm conclusion can be drawn from the existing data on the direct contribution of defects to accidents, but they do indicate the need for remedial action. This could take the form of vehicle inspection schemes and instruction on regular maintenance, especially for younger riders. The standard BS 6102 referred to above has minimum requirements for the strength of essential parts such as brake system, frame and fork assembly, wheels, pedals, and chain. It also includes requirements on sizes of protrusions and sharp edges that may come into contact with the rider during normal use. In addition, it contains a requirement that instructions be provided with each bicycle. These include, among many items, instructions on brake adjustment and recommendations for replacement of brake blocks, correct chain tension, lubrication, and recommended tightening of fasteners related to handlebar, saddle and pillar, and wheels. Also it contains recommendations for safe riding, e.g., regular checks on brakes, tires, steering, and lighting.

The design of the bicycle to aid adjustment or eliminate it would be advantageous. For example, it is often difficult to adjust brakes; yet self-adjusting brakes are already on the market(144).

Stability and Maneuverability

A certain degree of skill is required to ride any two-wheeler. To become proficient, there is a learning process, and the rider must acquire sufficient experience in a range of traffic and road conditions. To reduce accident risks,

the two-wheeler must be easy to maneuver so obstacles can be avoided quickly and must also be stable so it follows the intended course when, for example, the cyclist is signaling or is caught in a crosswind. The extent to which bicycle design affects rider performance has been examined in a number of experimental situations.

Studies of Stability and Maneuverability

In an early study at TRRL(145), an attempt was made to assess maneuverability of cycles and motor-assisted cycles by the number of faults committed on an obstacle course and on a slow-riding test. Similar tests were carried out using schoolchildren(140) on a number of bicycles, both on smooth and bumpy surfaces. These tests showed that there were large differences between the performances of riders and small differences between different cycles. A Swedish study(113) tested cyclists attempting to hold a straight course while looking behind, which was intended to simulate a common turning maneuver involving crossing the traffic stream. With three types of bicycle investigated (small-wheeled, standard touring, and rodeo type), the probability of making errors in following the course and assessing the situation behind ranged from 10 to 50 percent.

A Dutch study(130) also found differences between different machines. In one of several tests, the riders had to follow a track consisting of a sloping road section immediately followed by a sharp left turn. The riders attempted to stay within two lines 0.15m apart. The percentage of time spent outside the prescribed course was used as a measure of performance. When riding down the slope, speed increased, which made the bend more difficult to negotiate, and so both good stability and maneuverability were important for course holding. Figure 36 shows the average percentage of time outside the prescribed course when negotiating the curve with one and two hands. It can be seen that differences between the bicycles and mopeds are comparatively slight. However, the performance of the racing bicycle and standard model with high handlebars differs significantly from that of the other two bicycles. With these other models, path deviation (averaged over conditions) occurred for about 25 percent of the time. For the racing bicycle, this was nearly 50 percent; for the bicycle with high handlebars, it was 40 percent.

It appears from these studies that bicycle design has an influence on stability and maneuverability although it is not yet possible to quantify the contribution of a particular design feature to the accident risk.

Recommendations Concerning Accident Prevention Measures

When compared with motor vehicles, bicycles generally have inferior lighting and braking systems and are poorly maintained.

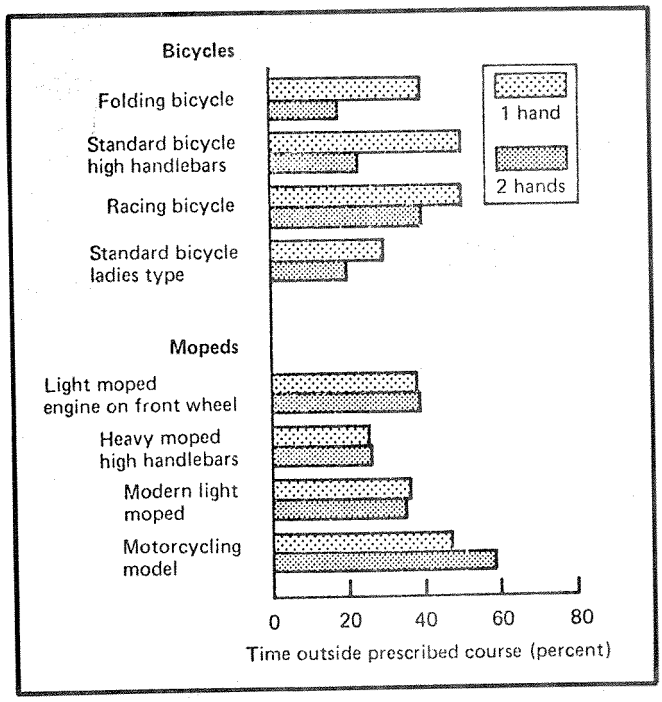

Figure 36. Time (percent) outside prescribed path in test 2, "course holding in a curve"(768 runs)

In the case of bicycle lighting, surveys and observations have demonstrated that a large problem exists. Better lighting systems are required not only to provide more reliable lighting in order that the cyclist may be easily seen at all times but also to provide an adequate beam to illuminate the road ahead. Further work in this area should be beneficial. Improvements to the nighttime visibility problem can be made by requiring that bicycles be equipped with a range of high-performance reflectors that will be readily visible in most situations and will also aid recognition. Of particular importance is an effective rear reflector and pedal reflectors. The cost of providing such reflectors is small, especially if it is carried out during manufacture. Better legal requirements for lights and reflectors are indicated.

The increasing popularity of lightweight bicycles indicates that rim brakes are now more widely fitted. It has been demonstrated that dangerously long stopping distances occur in wet conditions if rubber brake blocks are used with the chromed-steel rims. Since this is a common combination of block and rim, a legal braking requirement based on wet and dry braking standards should improve the situation. Such a requirement could apply to all new bicycles offered for sale.

Regular bicycle maintenance checks may reduce the number of poorly maintained bicycles. This could be carried out at schools or by the police. At the present time, it seems unlikely that an annual inspection similar to that required for motor vehicles would be feasible. Steps could be taken to persuade manufacturers to improve bicycle design so that maintenance is reduced to

a minimum, for example, the fitting of brakes that are automatically adjusted. Consideration should be given to a requirement that there be no sharp edges and dangerous protrusions on bicycles and mopeds, and chain guards should be fitted. In addition, there may be a case for a minimum requirement for the strength of essential parts such as brake system, frame and fork assembly, wheels, pedals, and chain. A measure that could be taken to reduce the risk of accidents to both bicycle and moped riders is the promotion of the wearing of conspicuous clothing, particularly during daytime and twilight. It would be helpful to have a standard for conspicuous clothing so that only high-visibility clothing of an adequate standard would be promoted in publicity and training courses. Consideration should also be given to encouraging the use of cycle spacers. Since they have been shown to decrease the number of vehicles passing very close, they should reduce the risks in the overtaking situation. They have the advantage of being very cheap to fit.

If a safety requirement is introduced on a large scale, it is recommended that relevant accident statistics be compared both before and after the change so the effectiveness of the measure in reducing the accident risk can be established.

Trends and Priorities in Vehicle Development in Relation to Road Safety

M.R. Dunn, Chairman, United Kingdom

Trends and Priorities in Vehicle Development in Relation to Road Safety

A. Chenevez
France

As in the first nine ESV conferences, the discussions of this Tenth Conference have largely shown that the manufacturers' research activity is not slowing down toward road safety improvements.

Such research is conducted in close cooperation with the public authorities and independent organizations. Numerous regulations have been developed from the results of that activity; they have had deep consequences on vehicle construction and have played an important role in the continuing reduction of the number of road accident victims in all countries, related to the number of kilometers driven and even in absolute figures.

Further safety progress requires new imaginative efforts. In this field, as in many others, the benefit/cost ratio is decreasing. In the 1970's, we took benefit of the most obvious and profitable measures, such as seatbelt improvements, energy absorption in front and rear ends of cars, etc. But to still improve safety through car design, we need to create much more sophisticated and expensive devices, the efficiency of which will necessarily be lower than for those invented before.

Without slowing down their efforts toward the specific safety of the vehicles, many manufacturers are wondering if the international scientific community should now concentrate on usage problems rather than just on vehicle construction.

To take just one example, I would like to mention how much the manufacturers have taken part in the seatbelt use campaigns throughout the world. Why should we provide customers with better and better restraining devices if they remain unused or can be disconnected in the case of passive restraints?

You know that in many countries more than 40 percent of the fatal accidents are caused by alcoholic drivers, so you will certainly understand why the manufacturers are in favor of more severe and more frequent controls of drunk drivers.

Similar examples could be cited in which the role of the police appears to be as important as that of the engineers. If public authorities accept that way of thinking, this will not mean the manufacturers' task would be reduced but their cooperation with public authorities will be rendered more efficient.

Prof. H.J. Kraft
Federal Republic of Germany

The round number 10 suggests the idea of a retrospect. Therefore, when treating at this Tenth ESV conference the topic of the panel discussion, "Trends and Priorities in Vehicle Development in Relation to Road Safety," the beginnings should be considered also.

The development of experimental safety vehicles originated from specifications that disproportionately emphasized occupant protection. Thus, overheavy tank-like vehicles were designed and built in which the passengers could be better protected indeed, but that

constituted a considerably higher danger for the safety of other road users. In this context, the impairment of other vehicle properties as, for instance, vehicle-handling or low-fuel consumption is mentioned only incidentally.

After construction and testing of a series of such vehicles, it was also realized by the involved governments that this was the wrong way. But before this knowledge had become generally accepted, diverse governmental delegates blamed the industry for having no interest in insuring the safety of its customers in the best possible way. However, just the opposite is the case for two reasons:

- Humanitarian reason: A sense of responsibility stimulates the automobile engineers to continuously do their very best to protect the customers against all avoidable dangers.
- Economical reason: For quite a long time, the industry has recognized that the life and health of its customers must be protected to insure also the existence of the enterprises. Vehicles can be replaced, but not lives.

Because of frank discussions between industry and government, the actual situation has improved considerably. Together we are on the right track. It is only by virtue of a well-balanced concept and special consideration of the compatibility of different vehicles that overall safety can be further improved. In this context, also, the importance of harmonization of regulations must be mentioned. Above all, legal regulations that are expected in the future (e.g., side impact) from the very beginning should specify only internationally valid requirements, and legal activities on a national basis should be avoided.

The most important tendencies toward an improvement of traffic safety can unquestionably be observed in the use of modern electronics for control systems with respect to steering, brakes, and drive. The resulting gain in safety lies in ease for the driver and an even better control of the vehicle in critical situations. We are confident we will make further gains toward our common goal, namely, the increase in safety on our roads.

Dr. E. Landsberg
Italy

The automotive industry will continue to cooperate in the promotion of improvements for road safety. In fact, cars have been greatly improved in this respect during the past 30 years. The industry has been particularly concerned to promote active or accident-avoidance features on cars. They include the many improvements to brakes, steering systems and suspensions, and lighting, quite apart from better instruments and warning signals. These advances have been achieved by the automotive industry largely without the introduction of regulations requiring them. Protective devices and features have also been introduced, and the overall safety of cars has been improved almost beyond recognition.

The latest accident-avoidance features to be proposed are the supplementary rear stoplights, which are being required in the United States, but it may be worth noting that no advantage was found for such a system when evaluated in trials in the Federal Republic of Germany.

Despite these problems, it is probably true that mechanical safety features on cars do need regulations to enforce their uniform introduction.

Sadao Takeda
Japan

I would like to present a brief summary of recent Japanese research and development in safety-related technology and also to introduce the recent development of internationalization of the Japanese road safety standards and certification system.

In general, there are four factors that influence the level of technical innovation in automobiles. First, the emergence of fundamental technologies, such as new materials and electronics, that will lead to the development of many associated technologies; second, consumer demand and the marketplace; third, social or public demands, as seen in the antipollution movement; and fourth, the desire of automakers to strengthen their competitive powers.

Regarding social or public requirements, safety-related technology has been regarded as an important aspect in this field since the 1960's. Today, safety is not only a social requirement but is necessary for the individual consumer, besides helping to differentiate one automobile product from another.

As a result, many attempts have been made to develop viable safety-related technology. Safety measures concerning vehicles are broadly divided into two categories. One is the provision of adequate protection once a

collision occurs, and another is the prevention of such collisions. Particularly in the field of accident prevention, we believe technological development has been and will be made in many areas as a result of the increasing progress being made in electronics.

The necessity of providing adequate protection for people involved in automobile accidents, including pedestrians, is a well-established fact. In Japan, studies are being carried out on seatbelts, on child-restraining chairs, and on how drivers and passengers can be afforded adequate protection from double-end collisions and side collisions. However, since this conference has focused on these issues at various sessions, I would like to concentrate on the recent technological developments in the field of accident prevention, reflecting the overall improvements made in the electronics field.

Amazing progress has been made in the electronics field in recent years. These achievements point to the possibilities of adding intelligence to machines and of applying more sophisticated control methods to driving. As a result, car electronics technology is spreading from engine control to power train, body control, and other aspects of the overall car structure. Today, many car models incorporate more than 10 chips. Safety-related technology has continually moved forward by using electronics as a major starting point.

The antiskid brake, a widely used safety feature, has been upgraded with the aid of electronics. Also, as already introduced in this ESV conference, an electronic warning system capable of sensing the driver's drowsiness and other fatigue conditions is now in practical use. Electronics technology is also applied for the brake power-maintaining system to make starting on an inclined road smoother as well as to eliminate the creep phenomena encountered in automatic transmission vehicles.

Attempts are underway to use electronics in improving running performance, such as the four-wheel steering system to achieve greater turning stability and improved response speed. Further, research on the use of supersonic waves, laser beams, and millimeter waves for detecting any obstructions located near the automobile has made important strides for future realization.

Further progress will be made in electronics, insuring a more sophisticated control system for automobiles. We anticipate development of a wide variety of systems for traffic safety, especially in the area of accident prevention.

I would like to explain three important points concerning the trouble-free development and diffusion of new technology. First is the importance of an interface between humans and machines. For example, a car provided with an antilock system is still not entirely safe if the driver is overconfident in the system's ability to prevent an accident. Drivers are all too human, and their continuing education and growing awareness in this field are important for increasing safety.

Second is the importance of developing more economical technology. This is indispensable for popularization. For example, more and more people in Japan are beginning to recognize the positive effects of antilock brakes, but their use has been limited to only 2 percent of new cars because each antilock brake system costs more than $500.

Third is the importance of exchanging information about safety technology. Although joint research and development among automakers is difficult to carry out, due to the incorporated safety measures contributing significantly to the competitiveness of each automobile product, as mentioned earlier, it is important nevertheless that information be exchanged to further the development of safety technology. Therefore, I hope the ESV conference will serve as a forum for the exchange of information concerning safety-related technology.

I would like to mention also the recent progress made in Japan concerning certification formalities as part of the overall move toward internationalization. Automobiles are so-called international merchandise, and it is of considerable importance that, as far as is possible, existing nontariff barriers be transformed into more harmonized formalities. Considerable efforts have been undertaken by Japan in this area.

As far as certification formalities are concerned, wide-ranging simplification of the Automobile Type Designation System was introduced in August 1983 with a view to increased internationalization so the system could be more accessible as far as the import of foreign automobiles is concerned. Based on the new system, the type designation was approved in 1984 for seven models and eight types of imported automobiles.

Much effort has been made to coordinate fundamental safety requirements in Europe and the United States. In October 1983, 12 items in the safety standards were amended to conform with those in Europe and the United States. Regarding 14 items of safety-related requirements, the safety standards in Europe and the United States have been treated as being at the same technological level as those in Japan. As in the past, we still feel we would like to participate wholeheartedly in ECE WP29 as one of our activities for setting up the International Uniform Safety Standard for Automobiles, which will contribute to the harmonization of standards between countries.

I had mentioned the recent developments in safety-related technology, especially the progress in electronics technology and internationalization of the safety standards and certification formalities in Japan.

I.D. Neilson
United Kingdom

Starting on a general point as a contribution to this discussion, it may be worth drawing a distinction between safety developments that are highly desirable on grounds of safety effectiveness and those that are possible. The need is to make progress, and this must clearly be done where it is readily possible. On a longer time scale, things that are highly desirable may have to wait until they can be engineered satisfactorily, but this should not delay the possible items being done first.

To balance these introductions, I have been asked to refer to trends and priorities for the improved safety of trucks, buses, and motorcycles.

For trucks, it is known that about 9 out of every 10 fatal injuries in accidents involving trucks are to road users outside the trucks—car occupants, pedestrians, and riders of two-wheelers. Only 1 in 10 are drivers and occupants of the trucks. There is a clear trend toward antilock braking systems to maintain braking stability, and these systems become even more highly desirable as the number of axles increases. There is scope for improved protection for other road users. Side guards can be designed to stop pedestrians and cyclists from being dragged under the rear wheels of trailers. There is a clear need for front underrun bumpers for trucks as a means of protecting car occupants from being killed in the many accidents where this can be avoided.

Improvements in the structural design of coaches may be anticipated, and it is to be hoped that regulations for improving structural resistance to collapse in overturning accidents will be universally adopted. Seatbelts can be fitted in coaches but, apart from some consumer resistance to using them, there are technical difficulties in designing satisfactory installations and so they may be fitted only to seats "at risk."

The largest scope for improvements in safety is in the field of motorcycle design. In particular, antilock braking should become essential equipment in the near future and in years to come even on small machines. Leg protection for riders of motorcycles is at an interesting stage of development. Progress appears to be at the point of a breakthrough in providing this much-needed item. Doubts should be resolved quickly. It seems protective wear can now be designed that gives some useful protection for the enthusiast who may choose to wear such clothing.

Ralph J. Hitchcock
United States

Several months ago, I attended a conference in the United States of various experts involved in different aspects of highway safety. Included were experts in vehicle design, human factors, driver licensing, enforcement, emergency medical services, highway design, and highway operations and maintenance. The reason I mention this conference is that a couple of suggestions were made by the emergency medical services experts on vehicle improvements that rather surprised me. The emergency medical services people are on the scene of the accident after it occurs. They said the big problem they see every day is head lacerations and head injuries caused by inside rear view mirrors and by sun visors and their mounting systems. I think it is clear to everyone at this conference that those items—the rear view mirror and sun visor—can clearly be designed so they don't cause head injury and lacerations. The fact that they do cause these kinds of injuries should tell us we need to do more in the component design areas of the car.

There were many things discussed at this conference that involved major changes and additional cost items on the car to improve safety. Such things as airbags, truck underride guards, truck side guards, antilock braking systems for motorcycles, center high-mounted stop lamps, daytime running lights, and Securi-flex windshields have been discussed and will continue to be discussed at other conferences such as this for many years. Various countries and car manufacturers will employ them as major changes in coming models to improve the safety of the vehicles. Other major potential safety improvements discussed at this conference included side impact and pedestrian impact protection. Again, these are major vehicle safety areas that will be discussed for many years. Performance criteria will be developed, and safety benefits will be weighed against costs. There is little I can add to the debate on these major safety projects. Rather, what I would like to stress are the smaller improvements that can be made, many at no additional cost, when incorporated into the basic vehicle design.

The General Motors presentation on built-in safety systems that were linked to detailed accident data and several of the papers by the British and others on smaller safety improvements in the car are notable. For example, the hood or bonnet of the car should be designed with an overlap at the fenders to provide 50 to 100mm of crush space for mitigation of pedestrian impact in injuries. As I

walked back from lunch today, I noticed that many of the European cars parked outside had hoods that overlapped while others did not. Clearly, some of them—the ones that overlapped—are probably going to be much better for pedestrian impact than the ones that do not. While it may be many years before we have a complete pedestrian impact protection requirement, new vehicle designs should have this hood overlap as a part of their basic design.

Similarly, in the United States, recessed windshield wipers were quite popular as a styling feature for several years. Again, these offer major benefits when impacted by a pedestrian. Our current stylists should try again to incorporate recessed windshield wipers into new designs.

In the interior of the car, some of the presentations at this conference have shown that steering wheel vertical displacement in a crash can be dangerous. While our national and international regulations limit the rearward displacement of the steering wheel, manufacturers certainly have the capability to limit vertical displacement as well. Similarly, padded steering wheels and steering wheel hubs are well within current technology and can prevent many serious head and facial injuries to drivers, particularly those who are wearing their safety belts. Last, soft plastic urethane bumpers have been put on many cars as a style feature. If they were designed with a foam support structure, with pedestrian protection in mind, they would do a lot to prevent pedestrian knee and leg injuries.

To summarize, I would like to encourage everyone at this conference, particularly the vehicle manufacturers, to take back to their companies or to their jobs the message that accidents result in many injuries by parts of the car that could be redesigned with little or no additional cost. I would encourage manufacturers and others at this conference to talk to the emergency medical services personnel and accident investigators in their countries to find out which little things might be done to make cars safer for people involved in accidents. If each of us does one or two small things to make cars safer, we can rest assured that many people involved in accidents will suffer fewer injuries and perhaps be alive after an accident because of our work.

Section 6
Conference Summary

C. Ashley, Motor Industry Research Association, United Kingdom

Conference Summary

Dr. C. Ashley
Motor Industry Research Association, United Kingdom

In reviewing this conference, it soon became apparent that the wealth of information cannot be summarised in any detail in 30 minutes. My comments will attempt to pick out the highlights and assess the principal trends. First, we know the conference as a whole is a considerable success. With 475 delegates and 127 papers, it has exceeded all expectations. It must now be regarded as the centre of excellence for communicating knowledge on experimental safety research in relation to vehicles.

Let us look at the value of the conference in simple monetary terms. If each paper represents $100,000 of work, then the total value of the conference is $12.7 million as a minimum. I would estimate that safety research worldwide by government and industry exceeds $100 million. That figure could be compared with the broad-band vehicle development costs of an annual $6 billion per annum, based on 40 million vehicles, $5,000 per vehicle, and 3 percent R&D costs.

Even the $6 billion on R&D is dwarfed by the $120+ billion cost of car fuel and the $12 billion cost per year if pollution measures increase fuel consumption by 10 percent. Perhaps road safety could be given a little more financial priority than less than 1 percent of the final annual cost of emission control.

Now let us return to the conference and the status reports. These are not a formality but represent a most important statement on "where we are" for each individual government agency. The United States shows a situation with a significant fall in fatalities of 11 percent 3 years ago, and this situation has been broadly maintained. There are signs of car occupant fatalities increasing, and it is to be hoped the courage of the first 13 States in bringing in mandatory seatbelt laws will be rewarded by the appropriate reduction in fatalities and injury and hence encourage the others. It would appear essential that research is carried out to show how Britain's and Germany's success in getting better than 90 percent seatbelt usage can be carried over to the United States where usage can be as low as 30 percent in mandated States. The United States gives major support of over $30 million to research and data collection. Their whole comprehensive programme in airbag development and demonstrations, crash avoidance, lighting, handling heavy vehicles, alcohol, and crashworthiness is commendable. Need I add the importance of harmonisation in this work?

The initiative of the European Experimental Vehicle Committee is well demonstrated by the work presented at the conference on the side impact dummy Eurosid, the mobile barrier, and studies on cycles and pedestrians. This work is, of course, supported by a number of countries including Germany, Italy, the United Kingdom, Holland, and Sweden.

Japan has a remarkable safety record, showing significantly lower accident rates, however measured, than other major countries. They have a slight negative trend, due to an increasing vehicle population, and it is reflected by increased motorcycle casualties. They hope to control this by increased application of existing legislation.

The accident situation in Italy, France, The Netherlands, and Germany still leaves room for improvement compared with the United States and Japan. Not that matters are static: in France, fatalities are down to the level of 20 years ago, in spite of the traffic increase. Their programme of assessment of accident Reagir, in which 10,000 injury accidents per year will be analysed, should play a major part in directing their efforts. The incentive scheme linking general subsidies of local authorities to accident reduction is novel, and we look forward to hearing of their experience in 2 years time. Like many countries, France is directing particular attention to motorcycles, heavy goods vehicles, and coaches. They are also, somewhat belatedly, introducing a road-worthiness fitness test for second-hand cars. Another logical step is the introduction of lower speed limits for wet conditions, and, again, we look forward to hearing of their experience.

An interesting proposal from Italy is for an international accident data bank. Perhaps this can be pursued in Europe as part of 1986 Road Safety Year. Italy also raised the contentious question of replacement part quality in safety-related matters and how this could be controlled—a very big question, which we expect will be looked at in many countries.

Germany outlined many interesting trends in driver education and training. We note that seatbelt usage in the rear has been made mandatory, but with no fines for the time being. This initiative will give useful evidence for other countries. Another interesting initiative will be the new Canadian legislation on running lights; this will be a valuable experience for comparison with Sweden.

Now let us turn to the conference proper, with the plenary technical session on progress with safety developments for road vehicles chaired by Mike Finkelstein. I mention the chairman because he has the important responsibility of inviting the papers and structuring his session. This particular session opened with two presentations by TRRL on modified safety vehicles. Hobbs discussed a series of modifications to an Austin Metro, making it more pedestrian-friendly through a more compliant front and bonnet or hood. Theirs was an interesting solution to the problem of reconciling standard bumper heights with reduced leg injuries. Watson's paper described the latest advances in motorcycle safety with antilock braking, leg guards, nonspill fuel tank, and an airbag. This is important because many observers are feeling that antilock braking should be available on motorcycles, perhaps starting on the big bikes of over 500cc.

The airbag panel of Breed, Maugh, Reidelbach, and Romeo discussed optimisation of airbag design for performance and cost. The experience of Ford and Daimler-Benz unit production systems will be invaluable, and the low-cost approach of Breed is exciting. I feel the use of mandatory 3-point belts, with an optional auxiliary airbag system for additional protection, is the logical route to take.

Finally, the panel of Detloff, Johanssen, Haenchen, and Sano described the wide range of automatic seatbelt designs available. The panel was convinced of the necessity to evaluate carefully automatic belt performance over a wide range of conditions. The usage rate of 98 percent in the Toyota Cressida was commendable but explicable in that people bought the car to use that feature. Perhaps increasing application of seatbelt usage laws will reduce the emphasis on automatic operation but place increased pressure on comfort, fit, and convenience.

The technical session on biomechanics and dummy development was chaired by M. Leroy. Ten papers were presented, of commendable quality. The work from the University of Pennsylvania on brain injury will be a great help in this field, as will the three papers on thorax tolerance and injury mechanism by Eppinger, Lan, and Vernir. Hoffner dealt with pelvic tolerance in side impact, and this was both a synthesis of available data and a proposed criterion based on energy. The paper by Langdon on modelling lateral impact of the thorax leads naturally to the important session on dummy development and, in particular, to the Eurosid side impact dummy, which is the result of collaboration between TRRL, ONSER, TNO, and PSA. One might expect a dummy that combines the best attributes of four groups to need careful development to produce an effective device. With the major emphasis on side impact, Eurosid is clearly designed for a need, and we will look forward with close interest to major participation in the next phase.

John Melvin described a major analytical study leading to new concepts in anthropomorphic test devices with a bold approach to a realistic dummy capable of coping with a range of impact directions. Finally, Aldman described the Chalmers/ONSER approach to an omnidirectional one-legged rationised dummy, intended to give human-like and repeatable impact response in pedestrian tests. We look forward to further reports on all three projects at the next ESV meeting.

Session three was chaired by R.M. Nicholson from the United States and was concerned with crash avoidance. It was notable for papers on three electronic devices originating from Japan: laser radar for obstacle distance measurements, a drowsiness warning device, and a tyre pressure warning system. Microwave radar devices have been demonstrated for some time but have been unable to meet size and cost targets. The lower cost 100m-range laser diode is encouraging, and I expect it to be available as an optional warning device within this decade. Quantifying fatigue or drowsiness is an almost insoluble biomedical problem, but indirect detection through steering behaviour does appear to have possibilities.

Handling was covered by aerodynamic stability computer modelling, a run fairly flat tyre bead design, practical and theoretical optimisation of four-wheel-drive vehicle handling, and further development of the Honda four-wheel steering system. The handling papers deserve close study by vehicle designers. There is still room to increase safety margins in this area, particularly under slippery conditions.

Other papers dealt with visibility, considering beam pattern and windshield condition. There were two major survey papers on statistical analysis of vehicle size involved in accidents, and on car controls for physically handicapped people.

As an incidental on accident avoidance, I asked K. Digges to reconcile the difference between the United States and German experience on high-mounted brake lights where the United States found improvement but Germany did not. He said the improvement in the United States was linked to centre-positioned high brake lights, and their experience with paired high lights mirrored that of Germany.

Although not specifically mentioned, antilock must be the most important development in crash avoidance. It is now available on a range of cars, the latest application being standard fitment to the Ford Scorpio-Granada. We look forward to lower cost mechanical systems for application to smaller cars, as promised by Lucas-Girling.

Session four on occupant protection for frontal impact was chaired by K. Digges. The key element of the presentations was growth in the use of modelling for both structures and occupants. Associated with growth was the reported accuracy and the cost-effectiveness of these techniques. Indicative of this growth is the decision of Ford Europe to invest $6 million in a Cray computer, which will give them an expanded scope in nonlinear modelling by finite elements. The exchange of information in this area between different countries was of particular value.

The principal problem addressed is that of mitigating the effect of head contact on the steering wheel for belted drivers. A test method for evaluating the severity of this impact was proposed by TRRL. Two solutions to prevent the contact were the use of airbags by Mercedes-Benz and steering wheels developed to meet the new TRRL test procedure.

The question of global, compared with subsystem, test was not addressed specifically, but it is clear that each plays its part in developing and signing off the vehicle. The actual angle and speed of a frontal impact test is still an outstanding question.

The Wilson paper, which calculates the benefits of individual treatments of parts of the vehicle, opens new perspectives in design tradeoff. His paper touches upon the friendly interior concept, which has raised so much interest.

The fifth session was organised by R. Stamm and covered accident investigation and its relevance to legislation. A significant paper by Dr. Mackay looked in detail at the effects of mandatory seatbelt use in the United Kingdom. They found a 25 percent reduction in serious injuries and deaths for car and light van occupants. They also concluded that the increase in pedestrian and pedal-cycle injuries and fatalities were statistically insignificant and did not support the hypothesis of risk compensation. They also found gross intrusion in the majority of accidents in which restrained occupants are killed and suggest that seatbelt design improvement is not a major priority. They do point out the significant reduction in fatalities and injuries that would follow fitment and use of rear seatbelts, which were also the subject of the Dutch study on seatbelts. This latter also supports the general United Kingdom experience.

Other investigation papers included the Japanese experience with a 50 percent fatality reduction from 1970 to 1980. The well-known car size effect was well detailed from the invaluable NHTSA Fatal Accident Reporting System (FARS). I have already mentioned the Italian proposals for a European data bank. Such data banks need major investment if the information is to be sufficient for valid correlations to be derived.

Finally, in the detailed trauma area, a German paper suggests a method of dealing with high scatter and uncertain limit values for crashworthiness criteria, such as HIC. This matter is important to resolve, if realistic targets are to be set for the so-called global test.

The side impact session was chaired by Ian Neilson of TRRL. This was a most significant area with nearly 20 papers, the largest section of the conference. The essential outcome of the work presented must be a harmonised side impact test procedure. Standardisation will be needed for dummy, injury criteria, barrier characteristics, and test speed, angle, and position.

Standardisation of the moving barrier is a first priority, and I feel that sufficient information and will is available to make decisions on this as soon as possible. May I suggest that the stiffness of the final model should tend to be in line with good design practice for minimising pedestrian injury and side impact aggressivity, rather than represent the current average vehicle norm, which will be a moving target. This harmonisation could be a most important consequence of the conference. It should be followed by dummy harmonisation.

There remains the discussion about whether legislative subsystem tests can be devised, instead of a full-scale test with a dummy. Conflicting ideas are still being put forward but, finally, a combination of both may be appropriate. The time for decision has arrived.

The other papers in the session significantly moved forward our modelling techniques and the study of the impact of vehicles into pedestrians.

The seventh session on safety development of goods vehicles and buses was chaired by L. Strandberg from Sweden.

A major programme on development of the tractor semitrailer unit for the future was given by M. Soret of Renault. In the VIRAGES concept vehicle, they showed development in ride, handling, stability, antilock braking, visibility, conspicuity, spray reduction, and side underrun and shielding. Spray reduction was also featured in the MVMA work (where the laser method of measurement they developed has advanced), as well as techniques for making objective comparisons.

Other papers dealt in detail with commercial vehicle-handling quantification, obstacle avoidance, front underrun, and conspicuity. A paper from my own organisation dealt with load restraint in light vans where a recommended practice has benefited both manufacturer and user.

There has been increased emphasis on PSV and coach safety, and this was reflected by papers concerned with accident analysis and the soon-to-be-legislated rollover test procedure. The discussion showed concern with the need for belts in coaches. The minimum must be belts in

the front and safety seats to absorb impact and retain the other passengers.

Much is known and agreed on how to improve safety in these vehicles, and has been clearly shown by the known concept trucks by Renault and TRRL/MIRA. Let us hope that at the next ESV conference there will be more representation by truck and coach manufacturers.

The study of severe coach accidents in France has emphasised the important hazard of fire and the need to provide easy evacuation of the vehicle. One must always remember that a significant proportion of the passengers are elderly, and experimental work must be realistically based.

Signor Rossi from Italy chaired the session on pedestrian safety and protection, a subject designated as a target area for improvement by several of the national position papers.

Thirteen papers were presented, covering a range of approaches. The problem is a complex one, with interactions between many different design aspects including frontal dimensions. This makes it difficult to specify component tests, but there are difficulties with a whole vehicle approach also in the wide range of speeds and points of impact possible.

For cars, three principal areas are important—the bumper, the bonnet leading edge, and the bonnet top. Secondary areas are the wing and windscreen. Many of the papers were concerned with optimisation, whether by experiment or analysis of these areas.

Progress on defining standards for the car-pedestrian interface must move forward with the work on side intrusion to insure engineering compatibility.

One of the techniques used by Maestripieri and others is a mobile barrier with adjustable characteristic simulating a range of vehicle front end possibilities. This enables the interaction between the frontal dimensions to be explored and quantified. The computer-based study of Harris and Grew opens up new approaches to defining these interactions.

The chairman for the final parallel session was Nakamura, and this session dealt with motorcycle safety.

Clearly five aspects are important:

1. Antilock braking
2. Leg protection for rider and passenger
3. Airbag use to control side movement in frontal impact
4. Conspicuity
5. Protective clothing and helmets

The importance of rider training has also been stressed in this status report.

All these aspects were brought out and demonstrated in the exhibition, particularly in the TRRL safety motorcycle.

The time now seems ready to move forward, and I would particularly like to encourage application of antilock braking and leg guards to motorcycles, perhaps starting with the larger machines where cost is not such a major factor.

Conclusion

I will conclude by making general comments on the conference. Some people have asked whether the scope should be enlarged to include driver behaviour and road design. Even emissions and noise have been mentioned. This will be reviewed by the committee, but I believe the tendency must be resisted so we can concentrate on the key area of safety and the vehicle.

I would like to congratulate Diane Steed on her dramatic statement that she is establishing an office of international harmonisation, reporting directly to herself. Even more encouraging is her specific reference to braking standards and side impact test methods and standards.

The final message is to ask each one of you to do your utmost within your area of professional responsibility to take advantage of the wealth of information given at this conference. When this is done, there will be a significant positive effect on vehicle safety and accidents worldwide.

Section 7
Closing Remarks

Michael M. Finkelstein, United States
John W. Furness, United Kingdom

Closing Remarks

Michael M. Finkelstein
National Highway Traffic Safety Administration

As the Tenth International Technical Conference on Experimental Safety Vehicles comes to a close, we in the auto safety community again have tangible evidence of the benefit gained from our effort to seek solutions to our common problems. As we progress beyond the development of experimental safety vehicles to the examination of the full range of vehicle safety problems facing us all, it is clear that our success to date in the ESV program must serve as a model for future cooperation.

Here in Oxford, we have had 4 days of wide-ranging discussions of vehicle safety. We have heard and discussed papers of the highest quality, papers whose importance will grow as we have time to study them and incorporate these new findings into our own future research.

We would be remiss if we did not take this opportunity on behalf of Administrator Steed and the entire U.S. delegation—I am sure I can say without fear of contradiction, on behalf of all of the conference participants—to express our gratitude for the generosity, hospitality, and remarkable efficiency of our British hosts: Her Majesty's Government and the Institution of Mechanical Engineers. Thank you all.

John W. Furness
United Kingdom

Ladies and gentlemen, it is now my task as your conference chairman to formally close this Tenth ESV Conference. In doing so, I would like to make some comments on the proceedings. First, I am sure you will agree that the conference itself and the associated social events have been both interesting and enjoyable. We have had a considerable number of reports and papers presented on a variety of topics concerning the safety design of road vehicles. Many were of high quality and have shown us some new and promising aspects of vehicle safety design to exploit. In addition, we were able to see the practical application of several of these ideas on vehicles and components exhibited here this week. The result seems to me to have fully justified the decision of the organisers to extend the scope of the conference to include motorcycles, trucks, and buses, as well as passenger cars.

On behalf of my co-chairman Michael Finkelstein and myself, I would like to thank everyone for their contribution to the success of the conference: to the U.K. Department of Transport for hosting the conference, the Planning Panel and staff of the Institution of Mechanical Engineers, and the U.S. National Highway Traffic Safety Administration for organising the event; to all who contributed papers, took part in panel discussions, chaired technical sessions, presented status reports, or made exhibits available; for the cooperation of the Society of Motor Manufacturers and Traders, the University and Colleges of Oxford, our interpreters, the catering staff, projectionists, and the secretarial and other workers behind the scenes. Even the weather was unusually kind to us, which helped the outdoor events!

I would also like to make special reference to James

Shively of NHTSA who has acted as U.S. coordinator for all ten ESV conferences and is, I understand, due to retire shortly; to Ian Neilson of the Transport and Road Research Laboratory for helping to organise the exhibition and acting as the focal point for the receipt of all the European papers, and to Dr. Cedric Ashley for his able summary of the technical highlights of the conference papers and exhibits.

In conclusion, I am most grateful to Sir Peter Lazarus, Permanent Secretary, U.K. Department of Transport, for opening the Conference, and to Miss Diane Steed, Administrator, NHTSA, U.S. Department of Transportation, for her stimulating keynote address, for presenting the NHTSA awards, and for giving us so much of her valuable time.

It only remains for me to thank you once again, to wish you all a safe journey home, and to declare the Tenth ESV Conference closed.

*U.S. GOVERNMENT PRINTING OFFICE: 1986-499-027

DOT HS 806 916
February 1986
